This great reduction in the amount of water introduced, plus the fact that the joints are subjected to heat in the core press, prevents the later development of sunken joints. At the same time, the stick-piling and kiln-drying operations are eliminated, as the slight amount of excess moisture introduced is quickly distributed through the stock. Also, the heating of the wood vaporizes a considerable portion of this moisture.

A further fact to be considered is that lumber-core joints, glued with animal or vegetable glues, often deteriorate greatly in strength when the cores are thereafter veneered in a hot-plate plywood press. The resin-bonded cores are in no way affected by this subsequent reheating.

Some Operating Details of New Lumber-Core Press

The boards to be glued together can be brought directly from the ripsaw or glue jointer to the lumber-core press, without matching to width. The edges are then spread with urea-resin glue (one edge only of each board). This spreading is done by a power-feed core-edge glue spreader, which may be either hand-fed or hopper-fed, Figs. 1 and 2.

The operator feeding the lumber-core press takes the boards as they come out of the glue spreader and places them on the feed table of the core machine, Figs. 3 and 4. A reciprocating pusher plate feeds these boards or strips into and through the machine continuously.

A continuous ribbon of lumber core, chair seats, solid tops, etc., thus passes through the core press. In the machine, the boards are subjected to powerful edge pressure. This pressure establishes and maintains firm edge-to-edge contact and squeezes out surplus glue. As the boards then continue to move forward through the machine, they are subjected to heat from above and below, transmitted by top and bottom steam-heated hot plates. The glue is set in this hot zone to a sufficient depth from each surface to permit safe handling of the freshly glued cores. Due to the use of a cold-setting hardener in the resin, the cure of the glue continues after the cores are discharged from the machine. Generally, the resin will have set up all the way through the joint within 10 to 15 min after the core emerges from the core press, because of the effect of continued heating as the stock slowly cools.

The boards, as glued together, emerge from the lumber-core press in the form of an endless ribbon of stock. At the outfeed end of the machine, this endless ribbon of lumber is divided into

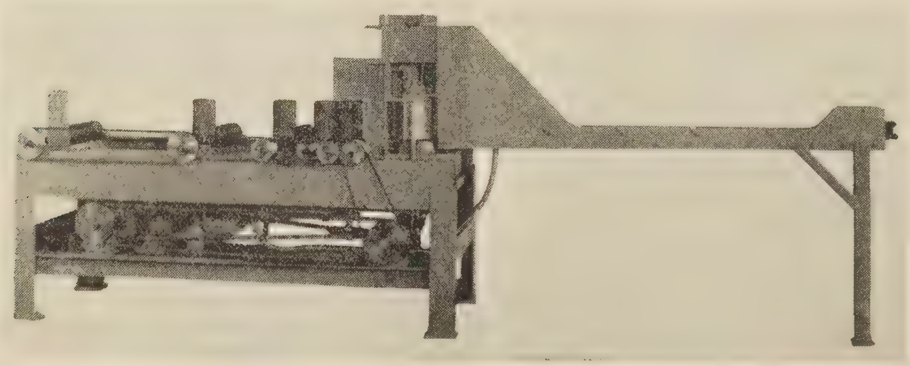

Fig. 2 Hopper-Fed Core-Edge Glue Spreader

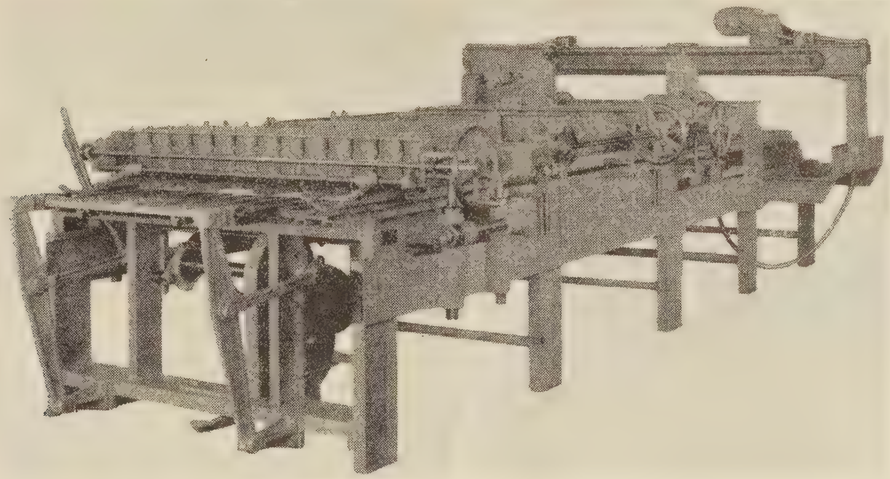

FIG. 4 LUMBER-CORE PRESS

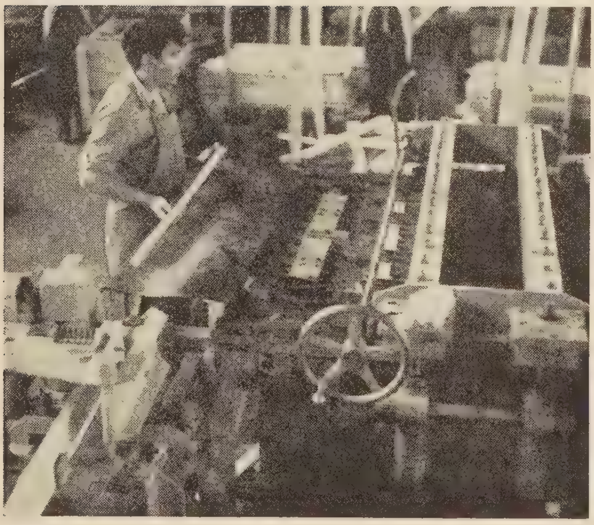

FIG. 3 OPERATOR FEEDING BOARDS AS THEY COME FROM THE GLUE SPREADER ONTO TABLE OF LUMBER-CORE PRESS

any desired width by an automatic cross-traveling ripsaw. The operation of this saw is started when the end of the core trips an adjustable trigger in the outfeed table of the machine.

The cores can also be divided to width periodically by leaving a dry joint in the assembly at the feed end. When this latter method is employed, it is generally necessary to match the cores or tops to width beforehand.

The core machine can also be equipped with one, two, or more end-trim saws. The purpose of these is to trim the cores to desired length, to square them up, or to divide them into shorter lengths if this latter is desired. Thus, it is seen that this new lumber-core continuous-feed press not only glues up the stock, but also dimensions the cores on all four sides; it even divides the stock into shorter lengths.

The lumber-core machines are generally built to handle any lumber from $^1/_2$ to $1^1/_2$ in. thick. Stock as thin as $^1/_4$ in. and thicker than $1^1/_2$ in. can also be handled in special machines. The greatest length of stock which can be handled in any given machine depends, of course, upon the size of the machine in question. These machines are built in a number of standard sizes. Naturally, there is no limit to the width of the cores which can be produced in any machine.

The machines can also be equipped to handle two or more rows of short stock. In that case, the stock is fed in two or more rows, side by side. This feature is of value not only for short lumber-core stock, but also for such products as solid chair seats, etc., which are relatively short in length. When feeding multiple lines of core, dividing to width is generally done by means of dry joints, unless the core strips in both lines are all of identical width.

The lumber-core presses will handle tapered stock, i.e., the two edges of each board do not have to be parallel. However, both edges must be straight. Joints suitable for this process can be made on a glue-joint ripsaw or on a glue jointer. Joints can be flat, or they can be tongue and groove. However, the core press eliminates one of the chief needs of tongue-and-groove joints, namely, holding the boards in alignment. The core press exerts such great flattening pressure that the need for tongue-and-groove joints is eliminated.

After the dimensioned cores are discharged from the lumber-core press, they are dead-piled (or stick-piled for faster cooling), and are then ready for surfacing in the planer. Cooling can be forced for yet quicker processing. If the factory layout permits, movement of the cores from the core press to the planers can be effected by means of conveyer, with cooling taking place en route.

The production of a lumber-core machine depends not so much upon the thickness of the core as it does upon the proficiency of the operator and upon the correct catalyst being used in the resin glue. Experience has shown that cores up to 1 in. thick can be fed through the machines at speeds averaging 4 to 5 linear ft per min. The actual feeding speed is higher, but the progression of the stock through the machine is "stop-start." These speeds can be exceeded under favorable conditions, and may also be less under unfavorable conditions.

Assuming cores 60 in. in length are being made, approximately 9600 to 12,000 sq ft of core or other glued stock can be produced in 8 hr, if the average feeding speeds of 4 to 5 linear ft per min are maintained. This is an enormous production when compared with the conventional lumber-edge-gluing methods.

Operation of one lumber-core machine requires from 2 to 3 men depending upon the type of glue spreader employed.

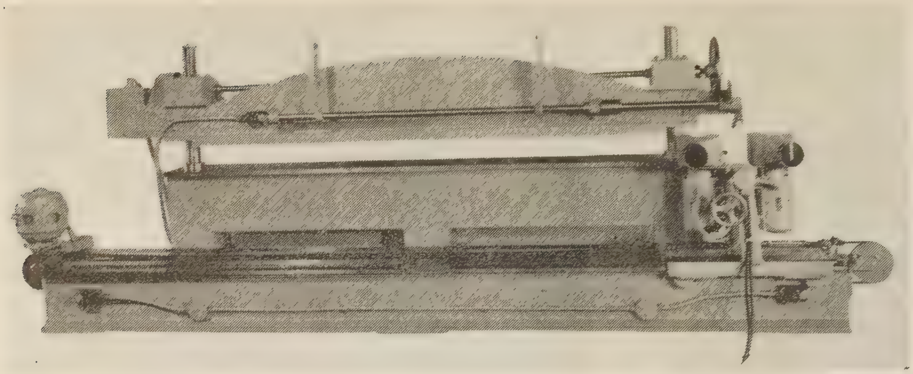

Fig. 5 Veneer Jointer With Glue-Spreading Attachment

Edge-Gluing of Veneer With Resin Adhesives

Prior to 1934, the standard method of joining veneers together in the United States was by means of paper tape. When veneers were to be edge-glued, the standard practice was to fold back the veneers after taping, spread the exposed joints with glue, unfold the veneers again, and then place them in a concave cradle until the glue had set. Taping of veneers is still the most widely used veneer-joining method.

In 1934, the first tapeless veneer-edge-gluing machines were introduced into this country. These first machines were of foreign manufacture. Several years ago, however, the manufacture of these machines was undertaken in this country. At first progress was slow with these tapeless veneer edge gluers, but today they are coming into more and more widespread use due to great improvements made in current models.

Until very recently, the conventional adhesive used with tapeless veneer edge gluers has been hide (animal) glue. The method of operation is as follows:

After the veneers are jointed, the veneer edges are spread with a light-colored hide glue. This glue application is done either manually with a brush or by mechanical means in the veneer jointer. Fig. 5 shows a veneer jointer with glue-spreading attachment. After being spread with glue, the pack of veneers is "fanned" apart and laid aside until the glue has dried.

Following this, the veneers with dried glue on their edges are fed into the tapeless veneer-edge-gluing machine. Driven rolls automatically draw the veneers into the machine, while the glue-spread edges are moistened automatically with a dilute formaldehyde solution. As the veneers pass through the machine, they are firmly pressed together, edge to edge, and simultaneously subjected to controlled electric heat transferred from top and bottom heating elements. This heat sets the animal glue almost instantly.

One make of tapeless veneer-edge gluer has a single wide bottom transport chain with toed-in pressure rolls on top. These rolls press the veneers tightly together. Another type of tapeless edge gluer has two converging transport chains with straight pressure rolls on top. In this machine, the chains pull the veneers firmly together. A modification of this latter machine has two parallel chains on top in place of the rolls.

The main drawback to the method of tapeless edge-gluing of veneer, as described, is the necessity for applying the glue in an operation separate from the edge-gluing operation itself. The piles of veneer, with prespread glue on the edges, have a tendency to stick together, sheet to sheet, due to the inherent "stick" of animal glue. This causes some loss of time and damage to the veneers as the operator separates the individual sheets of veneer. A secondary drawback is that the glue used does not have that degree of water resistance found in resin adhesives, although it must be pointed out that the application of the formaldehyde to the animal glue does render it water-resistant to some extent.

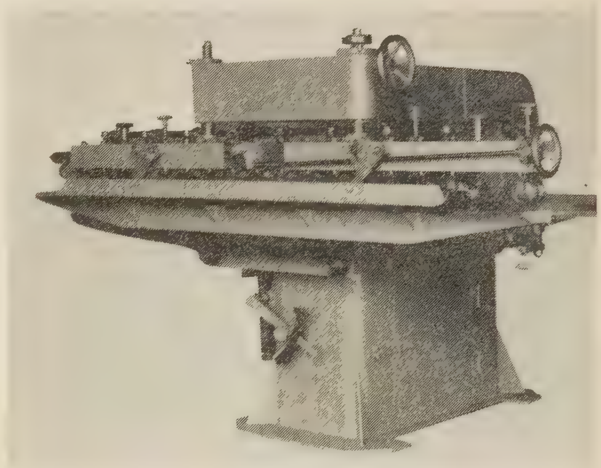

Fig. 6 Tapeless Veneer-Edge-Gluing Machine With Automatic Glue-Spreading Device

The ideal tapeless veneer-edge-gluing machine is one in which the glue is spread on the veneer edges as the stock is fed into the edge gluer. Attempts to produce such a machine have been made by several sources in the past. Only recently has the problem been solved successfully, to an extent where the method can now be employed on a regular production scale.

A tapeless veneer-edge-gluing machine with an automatic glue-spreading device is shown in Figs. 6 and 7. A urea-resin glue is placed in a glue tank which is located directly beneath the first pair of pressure rolls. A grooved thin glue wheel, operating between these pressure rolls, spreads the resin adhesive to the veneer edges as the veneers are fed into the machine. The veneers then progress onto the heated transport chain, while toed-in top-pressure rolls force the veneer edges tightly together. Heat is also applied from above through a pressure shoe located between the pairs of pressure rolls. This shoe also irons the veneer joint against the moving transport chain, thereby preventing overlapping. Special means are provided in this machine to keep the machine parts clean of squeezed-out glue. The resin is cured almost instantly under the heat, and the veneer sheets emerge from the discharge end of the machine ready for subsequent processing.

When edge-gluing relatively thick veneers, the glue-applying wheel is often removed so that the veneers will not be held apart

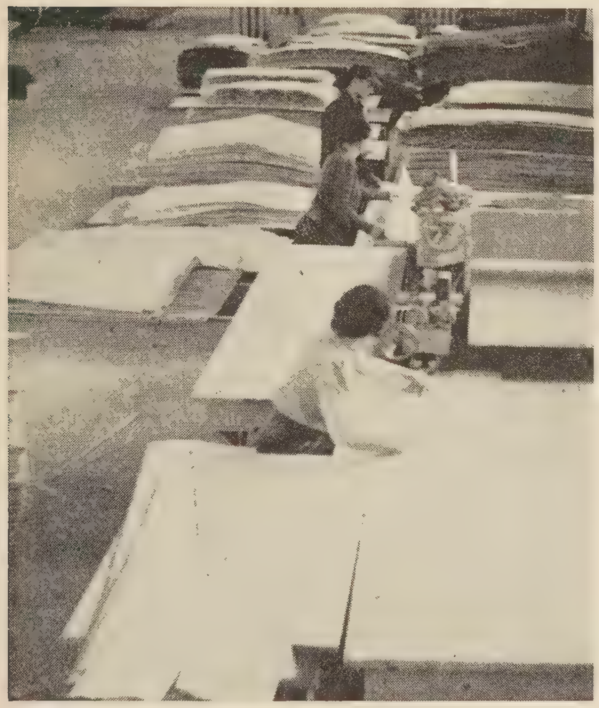

FIG. 7 OPERATORS FEEDING TAPELESS VENEER-EDGE-GLUING MACHINE

by this wheel. In such instances, the glue is applied to the veneer edges just before the veneers are fed into the machine. This can be done mechanically by a special spreader. Boards as thick as $^1/_2$ in. are being edge-glued in this way on a production scale, using the method herein described.

Another type of veneer-edge-gluing machine is still under development as far as this country is concerned. This machine is known as a cross-feed tapeless veneer edge gluer. It is patterned generally after similar machines which have been widely used in Europe for over 20 years. The European machines all operate with prespread animal glue, whereas the American machine will employ urea resin, spread at the machine.

In general, the cross-feed edge gluer will be quite similar to the lumber-core continuous-feed press previously described. The main difference will be the method of feeding. Whereas, the lumber-core presses have pusher-bar feed, the cross-feed edge gluers will have roller feed. The veneers will emerge from this machine in a continuous ribbon, in a manner very similar to the way veneer comes from a rotary veneer lathe. An automatic veneer clipper at the outfeed end of the cross-feed edge gluer will clip the edge-glued veneers to desired width.

This cross-feed edge gluer is suitable chiefly for thicker veneers. It is not suitable for face veneers. Its purpose is to fill the gap between the edge-gluing machines first described, which are intended chiefly for thinner veneers, and the lumber-core presses which are for heavier board stock.

ADVANTAGES OF TAPELESS VENEER-EDGE-GLUING

Tapeless edge-gluing of veneer saves the cost of the tape. The cost of the glue used is very minor.

Sanding costs are greatly reduced, since there are no tape particles to clog the sandpaper. In many instances, the drum-sander operation, used to remove tape, is eliminated. The plywood is taken from the trim saws direct to the belt sander.

Edge-gluing also makes practical the utilization of narrow veneer strips for cores and crossbands, without having closely spaced lines of paper tape in the interior of the plywood to detract from quality of surface appearance or strength of the glue bond between the plies. Edge-glued crossbands are superior to one-piece crossbands in minimizing warpage of plywood.

The growing use of plywood in military and naval aircraft and boats makes tape-free joining of veneers of vital importance. The presence of tape on veneer cores or crossbands would destroy the waterproof glue bond at the points where the tape occurs, because paper separates under the action of moisture.

A further advantage of tapeless edge-gluing is the elimination of pressed-in tape in the case of plywood glued in a hot-plate plywood press. Such tape is often difficult to remove.

GLUES

To date urea-formaldehyde resins have had the most widespread use in the machines for edge-gluing lumber and veneer, as described in this paper. However, work is being done toward adapting other heat-setting adhesives for these purposes. Not only phenol-formaldehyde resins, but also such adhesives as blood albumen, casein, animal, and soybean glues can be set under heat and pressure, and many or all of them may well find important application in this field.

CONCLUSION

The development of fast heat-setting glues has made possible great forward strides not only in the machinery for gluing plywood (such as hot-plate plywood presses), but has also been a prime factor in instigating the development of new methods and machines for the edge-gluing of lumber and veneer. The mechanization of the wood industries is thereby increased, with the goal of true straight-line production ever nearer in sight.

Discussion

HENRY GRINSFELDER.[4] We have investigated the Plycor core machine from the "resin" angle and feel that three of our findings are worth disclosing at this time. We have made a study of the surface temperature of the exit wood and find that there is a variation from about 125 F to 190 F, depending upon the speed of the machine, the temperature of the steam-chest surface, and the degree of contact between the lumber cores and the steam chest. The depth to which the resin cures before leaving the machine is dependent upon the heat penetration. As the author has pointed out, it is desirable to have a resin bond at least $^1/_8$ in. in depth from the top and bottom surfaces of the lumber cores before the cores are to be handled and subject to fracturing. If the bond is less than $^1/_8$ in. in depth, the cores are liable to break apart when first handled. In a reasonable time, of course, these resin adhesives will set throughout the entire thickness of the core, so that the critical point of judging the quality of the bond is when the core stock is first moved from the Plycor core machine.

In our work, we have also investigated the quality of bond produced by various resins and catalysts, and our findings have been that, whereas a great many catalyst and resin mixtures will give a depth of cure of $^1/_8$ in., the quality of the bond is not the same, depending upon the resin and catalyst. Some of the resins produce a very poor bond, others a very good bond, as evidenced by the strength necessary to break the joint open and the amount of wood failure.

H. S. JONES.[5] The development of the edge-gluing process

[4] The Resinous Products & Chemical Company, Inc., Philadelphia, Pa.

[5] Factory Manager, The Globe-Wernicke Company, Cincinnati, Ohio.

both for lumber and veneer is another step in the advancement of the woodworking industry. It not only makes a superior product but reduces the process time very materially. It is not uncommon for those who have edge-gluing equipment and a hot-plate press to make delivery of certain special runs in 24 hours. As these methods become more universally used, the writer sees the possibility of making deliveries of plywood in 48 hours a common practice. In other words, the plywood industry is rapidly approaching straight-line production when the veneers will be taken directly from the lathes into the driers, directly from the driers to the edge gluers, to the hot-plate presses, through the saws and sanders, and out. It certainly should reduce the amount of inventory required under the old methods.

Author's Closure

The depth to which the resin cures in the Plycor lumber-core press depends not entirely upon the heat penetration but also upon the type of catalyst or hardener used in the resin adhesive. Since writing this paper, further progress has been made in the development of special resin hardeners. As of December, 1941, it is possible to secure solid bonds all the way through a 1-in-thick lumber joint even at high feeding speeds.

Results of Laboratory Embrittlement Testing of Boiler Waters

By F. G. Straub,[1] Urbana, Ill.

This paper reports the results of laboratory embrittlement testing of boiler waters as part of an investigation conducted under a cooperative agreement between the Utilities Research Commission, Inc., Chicago, Ill., and the Engineering Experiment Station, University of Illinois. The data presented have been released by permission of both institutions. The author briefly describes the testing apparatus and procedure. He then presents, in the form of curves, results of 1300 laboratory tests on power-plant boiler waters, completing the paper with a general discussion of the results.

In 1938, the author reported the results of tests which had been conducted at the University of Illinois in the embrittlement-testing units. The development of these units has been described in detail.[2] However, in order to facilitate the presentation of data in this paper, a brief description of the apparatus will be given.

Testing Equipment and Procedure

Fig. 1 shows a section of the testing unit. The test specimen is normally made of 1-in. round hot-rolled S.A.E. 1020 steel with the center bored out, but for special tests can be made of any desired steel. Inserted into the specimen is a small steel plunger or partial filler, the diameter of which at the top is several thousandths of an inch less than the inside diameter of the specimen, and is still further reduced below this top portion. The specimen is partially filled with the boiler water to be tested, the filler inserted, and the specimen, with a thin solid iron gasket on top, is screwed into the holder at the top. Iron and constantan thermocouples are peened into the side of the test specimen. Another holder, fitting into a sleeve around the specimen, is screwed on the bottom of the specimen, which is thus held so that, when the spring is compressed by screwing down on the top nut, a definite load is applied to the reduced section of the specimen. A small electric furnace, in which the test unit is placed, enables the specimen to be heated to any desired temperature. Fig. 2 shows two batteries of 48 test units with heating furnaces and temperature-control equipment.

In testing a sample of boiler water, 7 cc is put in a new specimen, a new oxidized filler inserted, and the unit assembled. The filler is oxidized prior to use in order to retard action of the boiler water on the unstressed filler, and thus concentrate the attack on the stressed walls of the test specimen. Without the filler no cracking will occur due to lack of capillary space where the boiler water might concentrate.

The assembled unit, without any stress being applied to the specimen, is then placed in the heating furnace and heated to the desired temperature for about 4 or 5 hr. At the end of that time, the spring is compressed, by using the equipment shown in Fig. 3, until the desired stress is applied. In standard tests, this is 40,000 psi on the area at the reduced section of the specimen, although some tests have been run at higher stresses. The temperature is held at the desired value.

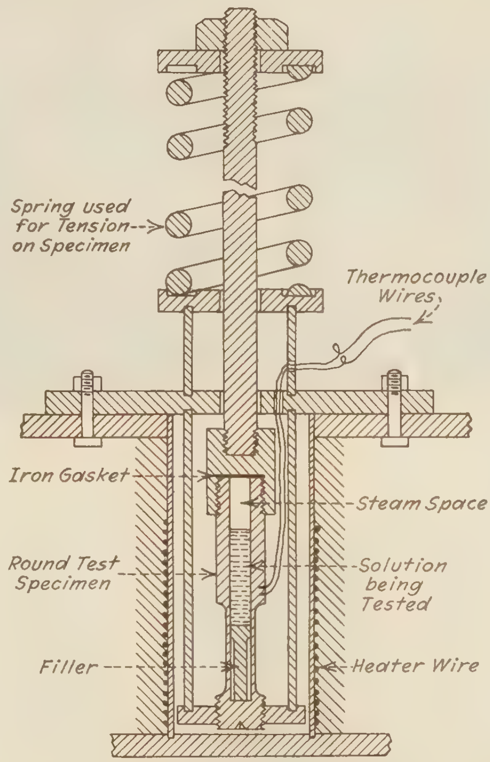

Fig. 1 Section of Embrittlement-Testing Unit

If the water is embrittling in nature, the specimen will break. The time in which a break occurs depends upon the type of water being tested. However, the fracture usually takes place within 24 hr. If no failure occurs, the test is continued for about 30 days, after which the specimen is removed, sectioned, and examined for any cracks. A water not causing failure or cracks in 30 days is classed as a nonembrittling type. Since, in each test, a new test specimen and filler are used, cracking or lack of cracking can be directly attributed to the water being tested. If a water is tested and found to cause failure, additional tests can be made after various chemicals have been added to the water to see what types of treatment would prevent failure.

Boiler-water samples from power-plant boilers have been submitted for testing by engineers interested in determining the condition of water being used. To date, we have tested 900 boiler waters, involving the running of 1300 tests in the laboratory test units. The results of these tests are plotted in Figs.

4 to 10. Since many of the results fall close to other results, it has not been possible to plot all the results in these curves. However, since these results fall in the crowded area of the curves, their absence does not detract from the conclusions to be drawn.

The curves have been plotted several ways so as to allow comparison with those previously published, as well as with those to be presented by others.

In the tests conducted at 400 and 425 F, the ratios of the NaCl to the alkalinity and NaCl to NaOH are plotted against the A.S.M.E. ratio (Na_2SO_4 to alkalinity) and the Na_2SO_4 to NaOH.

At 470 and 570 F the ratios[3] of the R_2O_3/SiO_2 are plotted against the A.S.M.E. ratio and against the NaCl to NaOH.

Results of Tests

The results of tests conducted at 400 F, shown in Figs. 4 and 5, indicate that with low NaCl content the sulphates do not appear to be effective in preventing failure of the test specimen. When the NaCl is greater than about 0.6 of the alkalinity or 1.0 of the sodium-hydroxide content, the combination of sulphate and chloride appears to be effective in preventing failure. There are many tests in which the chloride is low, but failure does not take place. Many of these waters have been treated with organic extracts, and no analyses have been made for the organic matter, nitrates, etc. In many waters having low chloride content and which produced failure in the laboratory tests, chlorides have been added, with the result that failure has been prevented.

At 425 F, in Fig. 6, there does not appear to be the correlation of high chlorides preventing failure, although in many cases the addition of chloride has stopped failure.

At 470 and 570 F, in Figs. 7 to 10, there appears to be a definite influence exerted by the R_2O_3 content in respect to that of the SiO_2. It has been noted that, when the chlorides are rather low, the failure occurs even when the R_2O_3 content is comparatively high. However, when the chloride is increased, the failures are prevented. This is shown in Figs. 8 and 9, where the ratios of the R_2O_3/SiO_3 are plotted against the NaCl/NaOH.

Discussion of Results

It should be remembered that these results represent laboratory tests and are not the results of actual cracking in power-plant boilers. In order that a laboratory test may be of any real service to industrial operation, the test must be correlated with actual plant experience. The tests which have been conducted have been controlled so that conditions existing in the

[3] R_2O_3 means the iron and aluminum presence expressed as their oxides.

tests are similar to those existing in the stationary power boiler. The stress has been held around 40,000 psi on a steel of about 36,000 psi yield strength. This stress might be encountered as localized stresses around rivets, etc. It has been found that, if the stress is increased to around 50,000 to 55,000 psi, no reasonable combination of salts, either inorganic or organic, would prevent failure. Consequently, this lower stress has been set as the standard.

If the results of the laboratory tests do not agree with those obtained in actual operation, it is not logical to discard the operating data in favor of the laboratory tests. In such an instance, it appears to be necessary to modify the laboratory control tests so that the results will agree with actual operating results.

The power-plant data which have been submitted to the author indicate that sodium sulphate has been effective in preventing embrittlement in the stationary power boiler. We have made no study of the locomotive boiler, and very meager data have been published in respect to embrittlement in this type of boiler, consequently this statement is limited to the stationary boiler. Our tests indicate that sulphate is effective in preventing failure in the laboratory at the pressures where the greatest percentage of embrittlement failures has occurred in steam boilers. This appears to indicate definite correlation between the laboratory tests and actual operation.

Embrittlement of Boiler Steel—Experiences With the Schroeder Detector

By T. E. PURCELL[1] and S. F. WHIRL,[2] PITTSBURGH, PA.

In 1928 the authors were faced with the discovery that boilers of the authors' company were being attacked by so-called caustic embrittlement, and steps were taken to combat the evil. Experiences with this metal disease, since that time, are described. More specifically, however, the paper treats with results of 26 tests in which the Schroeder embrittlement detector was used on boilers, operating under varying conditions of water treatment, pressure, time, and specimen composition.

The type of boiler-metal cracking, identified as caustic embrittlement, was first encountered on our system in 1928 at the Brunot Island Power Station (1).[3] Both intercrystalline and transcrystalline cracks were found in the flange of a mud-drum blowoff pad of a 195-psi Stirling-type boiler installed in 1919. In 1931, cracked and broken rivets were noted in a similar boiler placed in service at the same time. Examination revealed drum-metal failure at both the head and longitudinal seams. Detailed inspection of the other boilers disclosed cracks in the drum metal in all of the twenty-six Stirling-type boilers, twenty of which were damaged to the point that they were not considered fit for service. These units had been installed between 1914 and 1919. Typical failures, in which some of the cracks extended across the ligaments between the rivet holes, and representative examples of misalignment of rivets and poorly fitted butt straps are shown in Figs. 1, 2, and 3. Up to this time the boilers were not treated internally, and the ratio of sodium sulphate to total alkalinity as sodium carbonate, as recommended by this Society (2), was not maintained. The approximately 10 per cent make-up was Ohio River water, softened by the cold, intermittent, lime-soda-ash process, using ferrous sulphate as a coagulant.

At the Colfax Power Station, built in four stages between 1920 and 1927, no failures due to embrittlement have been experienced. It was intended that this station should be operated with evaporated make-up and without chemical treatment, but corrosion and scale early became major problems. In spite of pronounced efforts to reduce the oxygen content of the boiler feedwater by mechanical means, corrosion persisted until caustic-soda and oxygen scavengers were added to the boiler water. Trisodium phosphate, the first chemical used for internal treatment, eliminated scale but did not correct the corrosion difficulties. A detailed account of these experiences has been reported by Partridge and Hall (3).

Chemical treatment of the boiler water has been practiced at the James H. Reed Power Station since its initial operation in 1930. The make-up is provided by the evaporation of zeolite-softened Ohio River water. It is noteworthy that a scaling machine has never been used on these boilers and that corrosion has not been encountered.

Since 1931, the boilers at all stations have been treated with sodium sulphate, in keeping with the recommendations of this Society (2) for the protection of boilers against embrittlement. In view of the doubtful efficacy of this form of treatment, an extensive program was begun in 1938 to determine to what extent the boiler waters might be embrittling. The embrittlement detector, developed by Schroeder and his associates (4), has been used for this investigation.

Embrittlement-Detector Tests

The data relative to 26 tests made on boilers at three different stations are presented in Table 1 and shown graphically in Fig. 4. From the results of these tests, it is apparent that the maintenance of the A.S.M.E. ratio (2) does not afford protection against embrittlement of the specimens. Of particular interest are the tests at the Reed station, where a sodium chloride to total alkalinity ratio of 1.6, as well as the A.S.M.E. ratio (tests Nos. 102 to 104, inclusive), also failed to prevent embrittlement. The specimens did not fail, however, during three tests (Nos. 106 107A, and 107B), in which the alkalinity was maintained by the use of trisodium phosphate, there being no caustic alkalinity. It is particularly noteworthy that the last two of these tests, which were simultaneous, were concurrent with two tests (Nos. 201A and 201B) on an adjacent boiler using the same feedwater, in which specimen failures were experienced while maintaining the A.S.M.E. ratio.

In contrast, the four tests conducted at the Stanwix plant of the Allegheny County Steam Heating Company produced no specimen failures in spite of the fact that the last of these was 195 days in duration, approximately one heating season, and that internal treatment of the boilers was similar to that practiced at the two power stations. The reason for this seeming anomaly was not evident at the time; but it was found that a sample of water taken during the last test contained 22 ppm of sodium nitrate.[4] Subsequent analyses have shown that approximately 20 ppm of sodium nitrate are normally present in this boiler water. In view of present knowledge relative to the possible inhibiting effect of sodium nitrate, it is believed that its presence may be responsible for the noncracking of the specimens. Analyses at the Reed and Colfax stations have shown only negligible amounts of this salt.

Data obtained at the Colfax station, while comparable with those obtained at Reed, have not been as consistent. The time element is noted to be very important. It was found in a number of tests that, where no failure was evident at the end of 30 days, 60-day tests showed marked etching and checking of the specimens, and complete failure was experienced at the end of 90 days. Typical specimens as they appeared at the end of three different tests of 30, 60, and 90 days duration under similar conditions are shown in Fig. 5.

Operation of Detectors

The boilers selected for test purposes were chosen as being

representative of conditions at the several stations with respect to pressure, make-up conditions, and internal treatment. Installation of the detectors was such that the boiler water was supplied from lines connected directly to the drums. In all cases the piping between the boiler and the detector inlet was lagged and the flow of water so controlled that the specimen temperature approximated that of saturation conditions within the boiler. The detectors were inspected daily, except Saturdays and Sundays, to assure the proper amount of steam leakage. Such tests were made by observing the amount of condensation occurring on a watch glass held in close proximity to the exposed end of the specimen. In most cases, adjustment was necessary approxi-

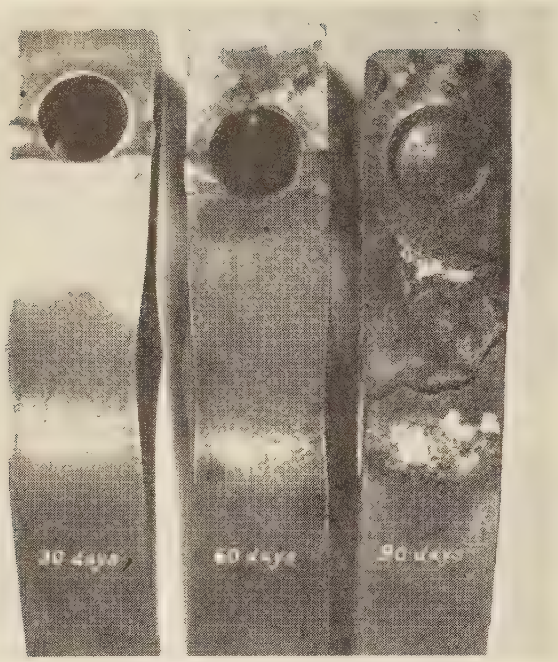

Fig. 5 Embrittlement Specimens at End of Three Different Tests Made Under Similar Conditions

mately once every 7 to 10 days. This was usually accomplished by adjusting the specimen setscrew approximately $^1/_6$ turn. When this was not effective, the top bolts in the test block were loosened slightly.

It is interesting to note the change of shape of the specimen during the course of testing. Fig. 6 (*A*) shows the straight specimen before being placed in the detector; (*B*) indicates the shape of the specimen when in place at the start of the test; and (*C*) and (*D*) are, respectively, a failed specimen, and one which at the end of the test showed only slight checking on the test surface and was subsequently bent to determine whether or not cracking occurred.

A typical example of the type of specimen cracking encountered is shown in the photomicrographs in Fig. 7. It is to be noted that the cracks are principally intercrystalline. In general, it is difficult to obtain a good photomicrograph in the region of the principal crack due to distortion at the time of failure or while bending during subsequent study.

For those tests, where internal treatment of the boiler water was a departure from standard practice, the special treatment was initiated sufficiently in advance of placing the detector in service in order to permit the establishment of the desired conditions.

Specimen Composition

In the initial tests of this investigation, cold-rolled S.A.E. 1020 or 1112 steel specimens were used. When repeated failures were experienced, hot-rolled specimens of boiler-flange quality were tried. With ten detectors now in service, six at Colfax and four at Reed, it is standard practice to make simultaneous tests on the same boiler using both materials. The detectors are installed in parallel with separate drain lines. The cold- and hot-rolled specimens are identified in the data, presented in Table 1, by the letters C.R. and H.R., respectively; the suffixes A and B following the test number indicate the simultaneous tests.

Boiler-Water Analysis

Except for the silica and organic contents, the boiler-water data, given in Table 1, are the average results of analyses made three times each week. The silica and organic contents were determined biweekly.

The analyses for silica were made in accordance with the A.P.H.A. gravimetric procedure (5). The method proposed by Hecht and Whirl (6) was used in the determination of organic matter. In the alkalinity titrations, the standard Winkler test (7) was followed, except in tests Nos. 106, 107A, and 107B, when the strontium-chloride modification (7) proposed by Schroeder and Partridge was employed. Other constituents were determined by accepted procedures for routine control work; these were checked periodically by referee methods.

Discussion

When internal treatment of boiler water was initiated at the several stations, it was made to conform with the recommendations of this Society (2) for protection against embrittlement. From the data obtained with the Schroeder detectors, it has become apparent that boiler waters treated in this manner may produce embrittlement under certain conditions.

While the Schroeder detector simulates conditions existing in a leaking boiler seam, it must undoubtedly accelerate the action; otherwise, it would be difficult to understand how the specimens crack in such a short time. Experience has shown that boilers which leak may operate for many years without failure. The severity of the test is not believed to be a cause for undue criticism, however, since the development of a method of treatment which completely inhibits specimen cracking would offer increased assurance against failure of the drum metal itself.

In the operation of the embrittlement detector, evaporation of the boiler water to the atmosphere permits the solids to accumulate on and adjacent to the highly stressed specimen. A concentrated solution of the boiler water is thus obtained, which, if aggressive, will attack the specimen. Since caustic soda is the active chemical, there are two logical methods of affording protection against its action, namely (a) the control of alkalinity with chemicals, which on evaporation do not deposit caustic soda, and (b) the use of inhibitors. The tests made in this investigation include experiences with both methods. The use of trisodium phosphate alone in tests Nos. 106, 107A, and 107B is an example of the first; the presence of nitrates in the boiler water in tests Nos. 601 to 604, inclusive, illustrates the latter.

The fundamental principle in the use of trisodium phosphate as the only treating chemical in tests Nos. 106, 107A, and 107B was to produce a boiler water which on evaporation would yield a deposit containing no caustic soda and yet provide sufficient alkalinity for protection against corrosion. Due to variable feedwater quality, in some stations, the use of trisodium phosphate alone may not be feasible. An acid feedwater would require excessive amounts of this chemical for neutralization of the acid, resulting in high boiler-water salines; an alkaline feedwater would tend to defeat the purpose of the treatment by developing caustic alkalinity. In addition the use of oxygen scavengers may be absolutely essential in some cases.

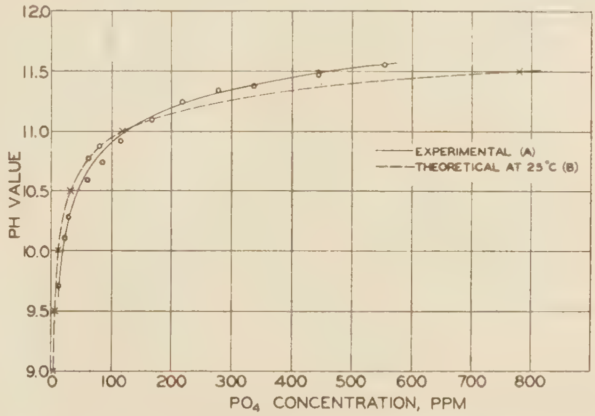

Fig. 8 Relation of pH to Trisodium-Phosphate Concentration Expressed as PO_4 Ion
(A Determined by measurement at room temperature of the pH of known concentrations of C.P. trisodium phosphate with a hydrogen electrode pH meter. B Calculated according to method proposed by McKinney, ref. 8.)

It is possible, however, to adhere to the principle of the method of treatment by controlling the pH of the boiler water with the requisite amounts of either alkaline or acid chemicals, depending upon conditions. The relationship of pH and trisodium-phosphate concentration in pure water is shown in Fig. 8. As long as the pH and phosphate concentration conform with this curve, trisodium-phosphate salt will be obtained on evaporation; no caustic soda will be present. Should the pH be above that corresponding to the phosphate concentration, a mixture of trisodium phosphate and caustic soda would result. Therefore, to assure complete protection against embrittlement in accordance with the theory, the measured pH should never be above the curve. Should the pH of the boiler water fall below the curve value, acid-phosphate salts, which are not conducive to embrittlement, would be obtained. The optimum condition, therefore, with respect to embrittlement, corrosion protection, and boiler-water

salines is the maintenance of the pH value slightly below that on the curve corresponding to the desired phosphate concentration.

The testing program at Colfax and Reed has been expanded considerably. Tests are now under way at both stations to determine the effect of sodium nitrate. At Colfax, the influence of quebracho in one boiler and phosphate alkalinity control in another, in accordance with the curve in Fig. 8, is also being studied.

In experimenting with these new methods of treatment, the practice has been to make careful internal inspections of the boilers following each test. In addition to data on embrittlement, valuable information will be obtained concerning the influence of these types of treatment on other boiler conditions, such as boiler deposits, corrosion, and carry-over. It is noteworthy that no ill effects have been observed at Reed following the use of trisodium phosphate alone.

Conclusions

From the data obtained to date with the Schroeder detector, it is concluded that

1 Maintenance of the A.S.M.E. ratio of sodium sulphate to total alkalinity as sodium carbonate does not prevent embrittlement of the specimens.

2 A sodium-chloride to total-alkalinity ratio of 1.6 in conjunction with the A.S.M.E. ratio does not protect the specimens against failure at 420 psi.

3 Specimen cracking is not encountered in boiler waters in which the alkalinity is controlled on the basis of the pH value corresponding to the phosphate concentration, as shown in Fig. 8.

4 Sodium nitrate appears to offer possibilities as an inhibitor against embrittlement.

5 Under some conditions the duration of the test period is an important item.

Experience With Intercrystalline Cracking on Railroads

By R. C. Bardwell,[1] Richmond, Va., and H. M. Laudemann,[2] Huntington, W. Va.

With 60 per cent of the steam-boiler horsepower of the United States in locomotives, which operate under widely diverse conditions and with waters of many compositions, this field offers extensive opportunity for the study of embrittlement cracking. The authors present a record of the experience of The Chesapeake & Ohio Railway with intercrystalline cracking as representative of the more recent work being done by the railroads to combat this form of metal deterioration. The paper deals with the investigation of various inhibitors, covering a period from 1933 to the present time, based on extensive testing with the embrittlement detector applied to locomotives in service. It was found that sodium sulphate does not prevent or even delay embrittlement cracking; that waste sulphite liquor will prevent cracking of detector specimens on many boiler waters, failing in but few cases; and that sodium nitrate has essentially eliminated cracking of detector specimens on the entire system of The Chesapeake & Ohio Railway.

In the report of the National Resources Committee, 1937, which was reviewed by Orrok (1)[3] before the American Society of Civil Engineers, Dean Potter scheduled 56,684,000 hp in steam plants at stationary power plants in the United States, as compared with 88,000,000 hp in steam locomotives. With 60 per cent of the steam-boiler horsepower in America embodied in approximately 42,000 locomotives normally in service on American railroads, consuming water of varying quality under widely diverse conditions, it would appear that this affords an excellent opportunity to observe and consider cases of intercrystalline-cracking, both from the standpoint of the number of boilers in service, as well as from the number that have been reported as cracked. A single large railroad may have several thousand locomotives under its jurisdiction operating over a large territory, which should permit consideration of this subject from a broader viewpoint than could be the case with isolated central power stations using one definite supply.

The history of intercrystalline cracking or "embrittlement" on the railroads is ordinarily dated from the "epidemic" of cracking on the Chicago & Northwestern lasting from 1912 through 1926. During and subsequent to this period, other railroads have had similar difficulties of a more or less acute nature. Study of such cases has yielded very interesting information, but the cracking on The Chesapeake & Ohio Railway is unique in several respects. It occurred during a period when the art of water conditioning was in an advanced state and when rapid, accurate, and complete methods of water analysis were available. It was paralleled by extensive investigation, especially by the U. S. Bureau of Mines, concerning the chemical and mechanical factors involved in intercrystalline cracking, the development of test equipment for determining the embrittlement characteristics of boiler water, and methods of treatment for preventing embrittlement. This situation led to rapid field application of laboratory findings to see if they would stand the test of practical operation. This study has been made as systematic and complete as is possible in railroad operation, and an enormous amount of data has been accumulated.

It might be well to review briefly the development of water treatment on railroads as affecting embrittlement cracking. Early in this century, it was found that, if waters were treated with soda ash or an equivalent chemical in amount to maintain the sodium alkalinity at least at 15 per cent of the dissolved solids in the boiler (2), the scaling matter would not adhere to the tubes and sheets and could be blown out readily as soft sludge, which fact was later developed more fully by Hall (3) at the Bureau of Mines and Carnegie Institute. Pitting and corrosion in locomotive boilers caused losses estimated to exceed $12,000,000 per annum, and, as limited clearances on locomotives prevent use of deaerating feedwater heaters to remove the oxygen, it was found necessary to increase the excess sodium alkalinity from 15 per cent of the total dissolved solids as recommended by McDonnell (4) to as high as 30 per cent in some cases, as found necessary by Seniff (5). Silica is usually present in railroad water supplies and, with this excess alkalinity which is required to offset scale, pitting, and corrosion, conditions resulted which were favorable to starting intercrystalline cracking where small apparently insignificant leaks caused a saturated solution of caustic soda to form in the capillary spaces against the stressed metal in riveted seams. Where the water is of an embrittling nature, cracking results.

In view of the interest which is still active in some quarters concerning the effect of sodium sulphate on cracking, the first section of this paper will be devoted to a brief discussion of experience with this salt. Extensive testing has been carried out with the embrittlement detector (6) to determine the usefulness and protective action of waste sulphite liquor, and of sodium nitrate in locomotive boilers. The results of this work will be presented in detail. Throughout the investigation, close contact has been maintained with the U. S. Bureau of Mines laboratory. Reports made to Subcommittee 6 of the Joint Research Committee on Boiler Feedwater studies have been made the basis of large-scale plant tests in the field.

Railroad Experience With Sodium Sulphate

In the early experience of the Chicago & Northwestern Railroad with embrittlement, it was noted that embrittlement cracking predominated on the divisions in which the sulphate was high. Strangely enough, certain western territories were free from this trouble, in spite of the fact that alkalinities were extremely high with comparatively small amounts of other inorganic salts in solution. It was later found that this was not necessarily due to the absence of the inorganic salts, but more probably to the use in these waters of an antifoam compound which contained waste sulphite liquor.

1941	J	No cracks reported.

[a] Lignin treatment started February 12, 1938.
Sodium-nitrate treatment started January 14, 1941.

The experience of The Chesapeake & Ohio Railway with sodium sulphate parallels that of the Chicago & Northwestern. Through and east of the Allegheny Mountains, the waters contain but little sulphate, and the ratio of sodium sulphate to total alkalinity in the boilers rarely exceeded 1 to 1. In the Ohio River district and through Ohio and Indiana, the sulphates are higher and the sulphate-alkalinity ratio will average 1.5 to 1 or much higher. Out of 203 cases of intercrystalline cracking reported, 134 or 66 per cent were in the territory of the high sulphate ratios, while 69 or 34 per cent were in the territory of the low ratio. The number and types of power units involved were similar. This would indicate that, if this salt had any value in preventing embrittlement, the reverse of this situation should have existed.

More specific evidence concerning the action of sodium sulphate is available for 11 switch engines, operating at 180 psi gage. They were assigned to one city terminal, and took water from other sources only on infrequent trips to the shops for heavy repairs. Even then they were in territory in which the sulphate content of the water was quite high.

The average sulphate ratios for these engines for the years 1933 through 1939 are shown in Table 1. Since these locomotives used only treated well water and untreated city water throughout their life, the values shown should represent normal conditions. Table 2 shows that, in spite of the sulphate present, 8 of the 11 boilers had suffered embrittlement by 1938. This was all rivet-hole cracking in circumferential seams, or cracks in butt straps or drum metal of longitudinal seams.

The history of engine I is especially interesting, as the second course was renewed at the end of 1936, and again in the early part of 1938. During this interval the analysis showed fairly high sulphate values. These data offer no support for the idea that sodium sulphate will prevent embrittlement cracking in locomotive boilers.

The development of the embrittlement detector made available yet another means for testing the effect of sodium sulphate on cracking. In this equipment, the stress application and the arrangement of test surfaces are very similar and directly comparable with those existing in the riveted seams of a locomotive boiler. Concentrated boiler water is produced by slow leakage of water into the crevice under the stressed specimen, and diffusion of steam toward the atmosphere. Since it is well known that it is difficult to keep riveted seams in locomotive boilers tight against such minute leaks, this condition is one which may readily exist.

None of the tests with the embrittlement detector attached to the locomotive has shown that sodium sulphate has any influence on cracking of the specimens. This confirms laboratory work (6) and testing in stationary plants (7) with this equipment which have been reported already.

Use of Waste Sulphite Liquor to Prevent Embrittlement

Tests reported by the U. S. Bureau of Mines Laboratory in 1936 (8), and published in 1938, indicated that waste sulphite liquor[4] would inhibit embrittlement. Its use was started on The Chesapeake & Ohio Railway early in 1938. It was first noted that it caused and stabilized foam in the chemical vats, and it was suspected that it would engender similar difficulties in locomotive boilers. This did not prove to be the case, however, and no difficulties were reported. No extended search has been made for an explanation of this fact, but it seems logical to believe that the foam-stabilizing characteristics are destroyed by the elevated temperature in the boiler.

One of the most unsatisfactory factors, involved in the treatment with waste sulphite liquor during this early period, was the lack of a method for determining its concentration in the boiler water. It was simply added to the feedwater with the hope that it would reach the boiler and exist in the right concentration. This situation was greatly improved by the development in the U. S. Bureau of Mines Laboratory during 1938, of an approximate method of analysis (9), and the boiler waters showed concentrations much lower than had been anticipated. The losses apparently occurred through adsorption and coprecipitation with calcium-carbonate sludge in both the feedwater-treating tanks and in the boiler. The effect of the sludge in the water treatment was especially bad. Destruction by dissolved oxygen in the boiler was a second source of loss. The magnitude of this latter effect is unknown, although laboratory results would indicate that it might be large.

Loss of waste sulphite liquor in the feedwater could be prevented by introducing it after all softening operations had been completed. This procedure was followed, although it introduced some complications in the treatment. The loss in the boiler was taken care of simply by adding a sufficient excess to the feedwater.

The analysis afforded assurance regarding one point of the treatment, namely, that the inhibiting agent was actually in the boiler water. However, the vital point as to whether it would stop cracking in the riveted seams was still wide open to question. During the early part of 1939, the embrittlement detector was made available, which offered means of securing an immediate answer to this question.

[4] Waste product containing large amounts of lignin, obtained from the sulphite process of paper manufacturing. The material used in this investigation was furnished by the West Virginia Pulp and Paper Company in the form of a viscous liquid, containing about 50 per cent dissolved solids. An analysis shows approximately the following properties and constituents:

Specific gravity	1.32
Baumé	35.0
Ash	15.65
Fe	0.062
CaO	0.13
MgO	0.07
Na_2O	9.67
Sulphur	3.71
Total solids	54.6
Nontannin	40.1
Tannin	14.5
pH	10.6
Carbohydrate	6 3

Detector installations were made on switch engines, which normally take their feedwater from one source, in order that the effect of the treatment could be most accurately ascertained. The tests were started on six engines and the number was later increased to fifteen. Ordinarily, one detector was attached to the engine, although in two cases three units were used to permit simultaneous testing of three different steels. Fig. 1 shows three detectors attached to a boiler. These were bolted to a bracket which was in turn fastened to the side sheet, below and just forward of the cab. Water connections were tapped into the side sheets as shown; the bottom connection was high enough so that it did not clog with sludge. Both lines to the detectors were, of course, provided with valves so that the specimens could be removed and new ones put in at any time. The cooling of the solution as it passed through the detector blocks caused rapid circulation of the boiler water.

The detectors were examined and leakage adjusted once daily by shopmen at the various points on the road. The reason for the tests was explained to these men, and they were shown exactly how to install the specimens and adjust the steam flow. During

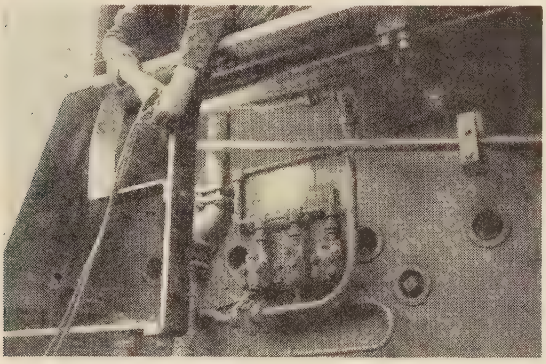

Fig. 1 Battery of Three Embrittlement Detectors Installed on a Locomotive

the first few tests on each engine, officials of the railroad were present during the removal of specimens and installation of new ones to insure continued interest and to eliminate any possible carelessness. The shopmen were very cooperative and took an active part in the study.

In general, it was necessary to adjust the steam leakage three or four times during the early part of the test, but it would then continue for long intervals without further adjustment. It appeared that the units needed less attention than is normally the case where they are used on stationary boilers. This is probably due to the effect of vibration and motion of the locomotive in preventing plugging of the leakage.

The results for the detector tests during the time waste sulphite liquor was in use are shown at the left in Fig. 2. The boiler water in each engine was usually analyzed from five to ten times during each experiment, the long-time tests requiring the greater number of analyses. The averages are plotted in Fig. 2. Alkalinity was determined by titration with phenolphthalein and methyl orange. The value for total alkalinity as NaOH was calculated from the methyl-orange end point. This normally runs from 300 to 600 ppm. Chloride was determined by titration with silver nitrate. Total solids were estimated by a calibrated conductivity measurement. Waste sulphite liquor was determined as previously indicated (9).

None of the specimens, tested at Peach Creek or Huntington, W. Va., Stevens or Russell, Ky., or Gladstone, Va., has cracked. These waters may have been nonembrittling, due to the presence of some naturally occurring inhibiting agent, or the maintenance of concentrations of waste sulphite liquor or sodium nitrate. The testing was not carried far enough to identify the inhibiting agent.

At Walbridge, Ohio, the first four specimens did not crack in periods up to 90 days, but when a substitute material, Glutrin,[5] which laboratory tests had shown to be inferior, was used in place of the West Virginia waste sulphite liquor, the last specimen cracked in 60 days.

At Parsons Yard, Ohio, the first specimen cracked with concentrations of waste sulphite liquor below 20 per cent,[6] but all of the remaining specimens were uncracked, even in periods up to 90 days, when the concentration was about 25 per cent, except the last two specimens when Glutrin was used.

At Peru, Ind., one specimen cracked, but an increase in waste sulphite liquor eliminated the cracking for periods up to 90 days.

At Newport News, Va., cracking was produced in the first specimen, which was eliminated by an increase in concentration of the waste sulphite liquor. In test No. 6, the waste sulphite liquor was purposely reduced and essentially eliminated from the feedwater, and cracking occurred. An increase in concentration of a protective agent again stopped the cracking. These tests seemed to demonstrate quite clearly the marked protective action of the treatment at Newport News.

At Fulton, Va., the first specimen cracked, but subsequent specimens, with much higher concentrations of waste sulphite liquor did not crack.

At Clifton Forge, Va., the first four specimens cracked, and it was necessary to reach concentrations of waste sulphite liquor near 70 per cent to secure any marked protective action. Even then, some slight cracking was encountered.

At Ashland, Ky., and Handley and Hinton, West Va., the cracking has little direct relation to the concentration of the inhibitor. It is possible that results at Hinton may be taken to indicate that a comparatively high concentration is effective, but this is not clearly demonstrated.

The results of the treatment at Charlottesville, Va., were quite unsatisfactory, and cracking of the specimens continued even though the concentration of waste sulphite liquor was raised nearly to 70 per cent.

These tests would indicate that waste sulphite liquor is satisfactory on many waters, but its protective action can fail in some cases. This result seems to be in qualitative agreement with the most recent laboratory studies, although the reasons for the differences are still obscure (6). In spite of these facts, however, the use of this inhibitor did bring a noticeable reduction in engine cracking over the 2-year period in which it was in use, and no cracked engines have been reported at the Parsons, Fulton, or Newport News terminals since this treatment was started in February, 1938, whereas, a number had occurred previously.

Use of Sodium Nitrate to Prevent Embrittlement

During the latter part of 1940, the West Virginia Pulp and Paper Company changed its manufacturing process and waste sulphite liquor was no longer available from this source. Other supplies were investigated, but laboratory tests showed that the concentrations necessary to produce protection were somewhat higher, and some of the materials gave sticky sludges when they were used in conjunction with metaphosphate.

About this time, investigation[7] had indicated that the protective action of sodium nitrate was superior to that of waste sulphite liquor and less subject to interference from the presence of other

substances in the boiler water. Sodium nitrate had other advantages, as follows:

1 It could be added at any point in the feedwater treatment without being lost.

2 It is not adsorbed or coprecipitated in the boiler.

3 It is not subject to oxidization. Our experience also shows that it does not decompose in a locomotive boiler.

4 It is an inorganic chemical of definite known composition which can be purchased from numerous sources.

5 Its concentration in the boiler water can be determined by accurate and precise analytical methods.[8]

The effect of sodium nitrate on the embrittlement-detector tests is shown at the right in Fig. 2. The operation of the detectors and the chemical analysis of the boiler waters were made in the same manner as described for waste sulphite liquor. The determination of waste sulphite liquor was omitted,[9] of course, and the nitrate determination made instead.

The use of sodium nitrate was first introduced at Charlottesville, and Fulton, Va. At Fulton, cracking was prevented for 90 days without difficulty. Results at Charlottesville were especially gratifying, and cracking was completely stopped for periods up to 120 days. If these results are compared with those shown at the left in Fig. 2, for waste sulphite liquor at this same location, it will be seen that the nitrate is by far the more effective inhibitor.

After the nitrate treatment had been in use about 3 months at these two locations, a thorough internal inspection was made of the engines for evidences of pitting and corrosion. The engine boilers were found to be in excellent condition and, so far as could be determined, the nitrate treatment had no undesirable effects.

Sodium-nitrate treatment was then introduced on the entire system and, as shown at the right in Fig. 2, cracking was eliminated in all tests with the exception of two specimens at Ashland, which were slightly cracked in 90 and 37 days. These results may have been due to an interval not picked up in the analysis, during which the nitrate concentration was low, or may indicate the requirement of constituents other than nitrate. No boilers have been reported cracked as yet at this terminal. The test is now being repeated with an increase in nitrate concentration, as well as more frequent analyses.

During the tests shown at the right in Fig. 2, it was desired to maintain a concentration of sodium nitrate equivalent to 40 per cent of the total alkalinity as sodium hydroxide. This was done with reasonable accuracy in most cases. At Clifton Forge, Handley, and Peru, however, higher concentrations have been held in order to protect road engines that subsequently take some feedwater which is not nitrate-treated.

[8] For the work reported in this paper, nitrogen was determined by distillation with Devarda's alloy essentially in accord with the Vamari-Mitscherlich-Devarda method for determination of nitric nitrogen in soil extracts, Wilfred W. Scott, "Standard Methods of Chemical Analysis," 1917 edition, pp. 304–305. A more rapid colorimetric method is now under investigation.

[9] In all cases the addition of waste sulphite liquor was discontinued when the nitrate treatment was started.

In view of the fact that most of the tests, shown at the right in Fig. 2, are for periods of 60 or 90 days, or even longer, the almost complete elimination of cracking is deemed quite satisfactory. The nitrate treatment has been very easy to use and does not have the objectionable features encountered with waste sulphite liquor.

Conclusions

Embrittlement-detector tests and railroad operating experience have shown that sodium sulphate does not prevent or even delay embrittlement cracking.

Waste sulphite liquor will prevent cracking of detector specimens on many boiler waters, but in a few cases its protective action fails.

Sodium nitrate has essentially eliminated cracking of detector specimens on the entire system of The Chesapeake & Ohio Railway. This treatment has been easy to apply and its use has not created any difficulty in the operation of the locomotive boiler. This chemical seems to be the most efficient treatment yet developed for counteracting intercrystalline cracking, but more information concerning its action is desirable.

Treatment with waste sulphite liquor and subsequent treatment with sodium nitrate have made a material reduction in the repairs required because of cracking in locomotive boilers. Repairs, which are still necessary where these materials are being used, appear to be due to cracks started before the treatment to prevent embrittlement was undertaken. Once these old cases have been eliminated, it is believed that further improvement will be noted.

Studies on the Cracking of Boiler Plate

By P. G. Bird[1] and E. G. Johnson,[1] Chicago, Ill.

This paper reports a series of tests on the cracking of boiler steel, based upon the use of the Schroeder embrittlement detector. Two types of waters were employed, one consisting of synthetic solutions and the other of boiler waters. The results are reported in comprehensive tables which show the amount and kind of inhibitor added, the water analysis, the amount of organic matter as indicated by the Tyrosin test, and other pertinent data. The tests show that, of the inorganic substances used to inhibit cracking, sodium nitrate is one of the best when combined with organic matter. With a given feedwater, it was found that ever-increasing amounts of inhibitors are required as the number of concentrations increases. This unit should be used only by skilled operators.

THE cracking of steel in locomotive and stationary boilers has been a subject of interest for many years. Most investigators are in agreement as to the factors involved in the cracking of boiler plate. The essential conditions appear to be the presence of a high concentration of caustic with some silica in contact with steel under high tensile stress.

An example of how such stresses can be brought about is illustrated in Fig. 1. This shows an etched cross section of a locomotive-boiler seam which cracked close to a rivet. In this case calking was severe enough to separate the plates on both sides of the rivet. This put the section of the steel under the rivet head in high tension. Microscopic examination revealed both transcrystalline and intercrystalline cracks.

In order to reproduce in the laboratory conditions similar to those which are necessary to crack steel, the embrittlement detector, as developed by W. C. Schroeder, of the United States Bureau of Mines, was adopted, and the results embodied in this report were obtained by employing this device.

Fig. 2 is a general view of the laboratory used for this work. Each of the units has an insulated cover to minimize the loss of heat. These covers also help in obtaining more consistent results by maintaining constant conditions. There are thirty-four units, including two obtained from the Bureau of Mines, one of which is shown at the right in Fig. 2. A close-up view of an assembled unit is shown in Fig. 3. The unassembled test blocks, the clamping blocks, and specimens are shown in Fig. 4. These units were built to accommodate two test specimens instead of one. In all other respects, the units are like those designed by Dr. Schroeder.

Principle of Concentrating Boiler Waters

The principle employed in concentrating boiler waters is quite simple, although the adjustment required to maintain proper conditions must be expertly done. The connecting pipes from the test block to the autoclaves extend down nearly to the bottom inside of the autoclaves, so that, when the unit is heated up to boiler operating pressure, the water in the autoclave is forced upward and is circulated through the test block. The test specimens are laid in the grooved portions of the test block, and when clamped down in place, assume the curvature of the grooves. There is a small opening connecting the water space and the bottom of the groove. This opening is tight when the test specimen is clamped in place. A very small amount of boiler water is allowed to escape from this hole under the test specimen. Tightening or loosening the clamping blocks, together with proper setting of the adjusting screw, regulates the amount of boiler water escaping from this small hole. As the temperature of the head block is above 212 F, the escaping solution flashes into steam and leaves a deposit of the solids contained in the boiler water. This results in a highly concentrated solution in contact with the stressed metal specimens. These conditions provide for the physical and mechanical requirements to produce cracking.

The usual time of testing is 30 days. Fig. 5 shows the depth of cracking of one specimen after it had been removed from the block at the completion of the test. This specimen had been broken by placing it in a vise and tapping it with a hammer. The freshly broken portions, resulting from the hammer blow, are the light patches in the broken section. The dark patches show the penetration of corrosion through the metal.

When test specimens are subjected to an embrittling solution without inhibitors being present, they will generally crack in a period of 2 weeks; always in less than 3 weeks, but when distilled water only is in the bomb, no cracking is obtained on repeated 30-day tests. Thus, it is apparent that the chemicals in the solution are necessary for producing cracking in this device.

In operating this equipment the fundamentals required for cracking must be constantly observed. The operator must bear in mind that the solution under test must be concentrated to a high degree on the surface of the steel at a point where the steel is under high tensile stress. Obviously, if a concentrate is not obtained, or if the concentration takes place on metal not under high tensile stress, cracking cannot be expected, even with a highly embrittling boiler water.

Great care must be taken when making water-leakage adjustments on the embrittlement detector. Failure to do this may result in erroneous conclusions.

Test Procedure Followed

The following procedure has been found to yield reasonably good check results. This procedure was adopted because it seemed to insure a high tensile stress and would also maintain a high concentration of solution on this stressed surface.

Tension is first applied to the specimen when the unit is assembled for testing. The specimen, which has previously been polished to insure a smooth surface, is placed in the groove of the detector and the adjustment screw is turned into the specimen to a point where the end of the screw is flush with the bottom surface of the specimen, as shown in Fig. 6. After placing the specimen in the groove, it is clamped tightly in place. This puts the under surface of the test piece under tension, due to the curvature of the bottom of the groove.

Tension is also maintained on the under surface of the specimen during the water-leakage adjustments, which are made daily for the duration of the test. The initial adjustment is made in the following manner:

The adjustment screw is tightened by a fraction of a turn. Then the clamp is loosened just sufficiently to produce a small leak, after which the clamp is again tightened until the leak is just

Fig. 2 General View of Testing Laboratory

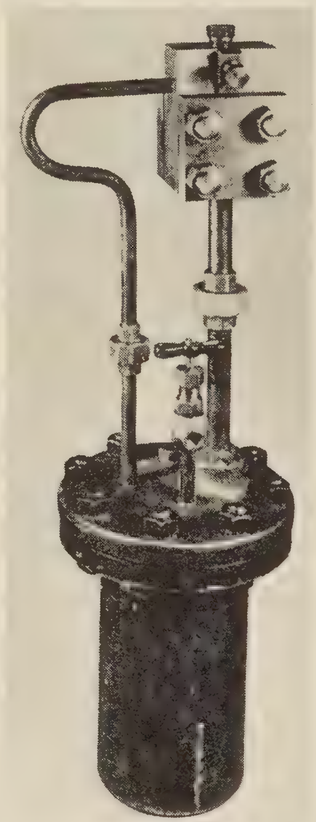

Fig. 3 Assembled Detector Unit

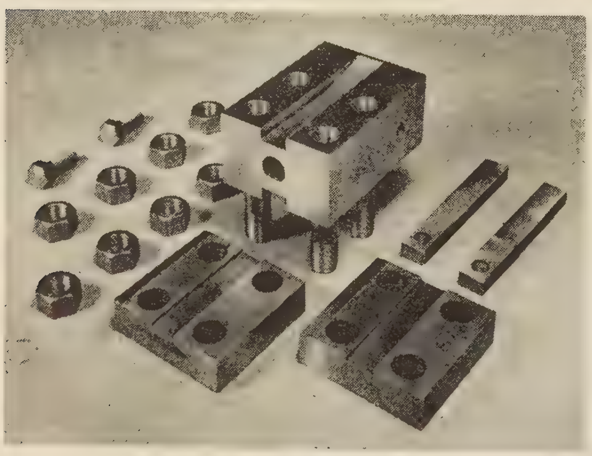

Fig. 4 Disassembled Test Block

stopped. The water leak is then regulated the desired amount by turning in the adjustment screw a fraction of a turn. Subsequent daily adjustments are made by releasing the clamping block slightly until a small leak is obtained, and then closing or nearly closing the leak by tightening the clamp. This is then followed by a sufficient turn on the adjusting screw to give the desired leakage. Care is taken while making adjustments to prevent excessive loss of water, which would wash away accumulated deposits.

When the specimen is originally clamped in place the under surface is put under tension. However, when the clamp is re-

leased ever so slightly, the under surface of the specimen is no longer under tension, and may even be in compression. As it is necessary to have this surface under tension, the clamp is again tightened to a point of little or no leakage, which may or may not put the under surface in tension. The desired leakage is obtained by turning in the adjustment screw which insures the under surface of the specimen being under high tension. Failure to have the under surface under tension will result in no cracking, even though a highly embrittling solution is employed.

Because of the careful adjustment required in the use of the detector, it is believed that results obtained by other than

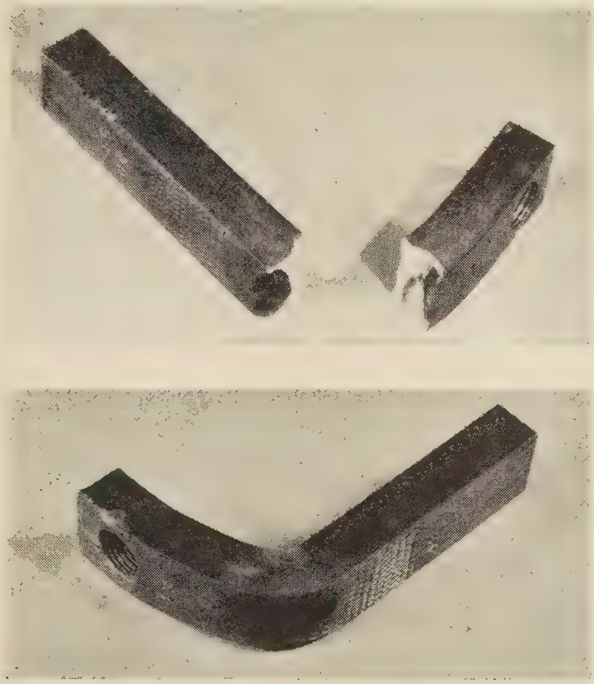

Fig. 5 Cracked and Uncracked Detector Specimens

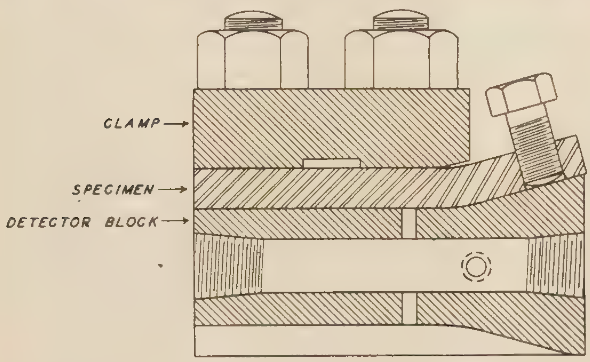

Fig. 6 Cross Section of Detector Assembly

highly skilled operators are likely to be misleading. For example, if the specimen should crack, it may not mean that the boiler is in danger. Likewise, if the specimen does not crack, it does not necessarily mean that the boiler is not in danger. This does not mean, however, that the detector is not a valuable tool when operated by, and the results interpreted by, competent personnel. Indiscriminate usage of this instrument should be avoided.

Because of the fine adjustments required, all tests conducted

Note: The solutions used contained 500 ppm caustic soda; 50 ppm sodium silicate; 500 ppm sodium chloride; and 1500 ppm sodium sulphate.
All results are averages of two or more tests, except where indicated.
The No. 9 steel showed only a small amount of cracking. This is a very soft steel.

in the laboratory are carried out with utmost care and comparable tests are conducted as nearly alike as is humanly possible. By refining the technique of testing, it was found that the results obtained agreed fairly well on check tests. This led to a method of recording the results which may be referred to as being a semi-quantitative method. In this method all results are recorded in terms of per cent cracking. This term refers to the depth to which cracking penetrated through the metal. If the cracking penetrated $^1/_2$ the thickness, the result is recorded as being cracked 50 per cent.

This method of recording the results is not to be interpreted quantitatively, that is, a record of 50 per cent cracking does not mean that the inhibitor was 50 per cent effective, or that 50 per cent of the total number of specimens cracked. Such records may be used in a qualitative manner to indicate in a general way the relative effectiveness of various inhibitors when all conditions of such tests are the same.

Types of Waters Tested

In general, two types of waters were employed in this work. One type consisted of synthetic solutions, while the other type consisted of boiler waters. Included in the latter type were a number of experimental boiler waters which were tested to com-

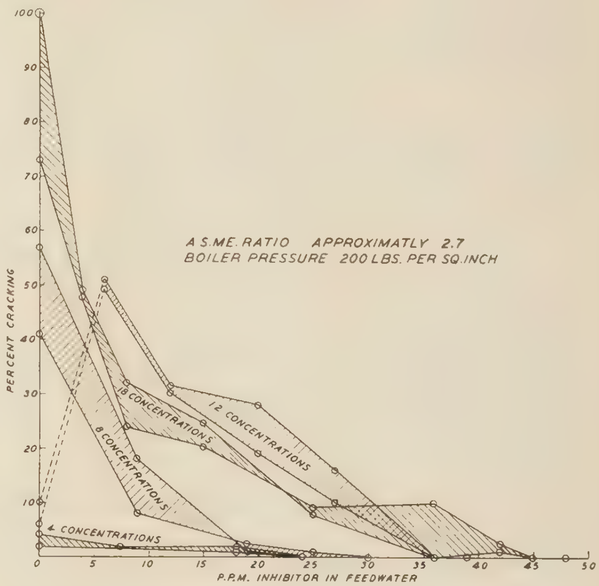

Fig. 10 Effect of Concentration of Inhibitor

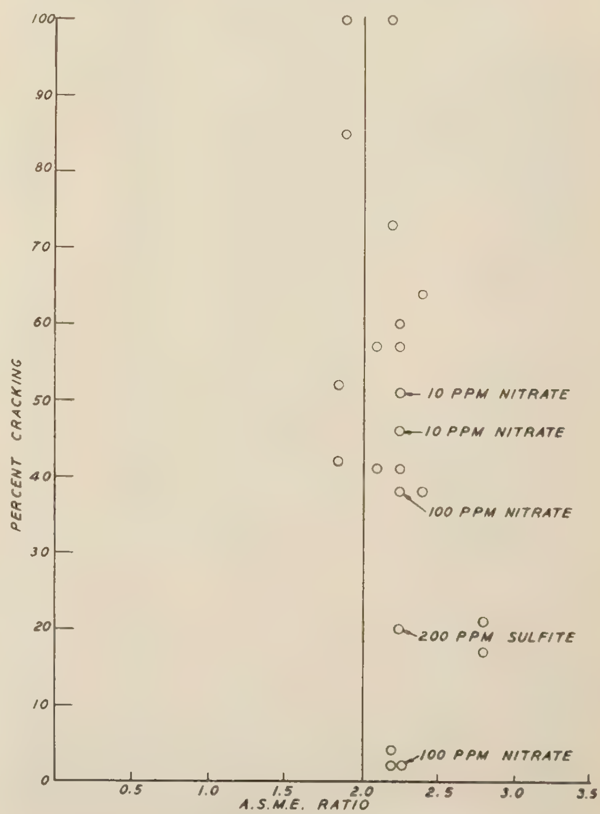

Fig. 11 Per Cent Cracking Versus A.S.M.E. Ratio
(Pressure 200 psi; no inhibitors present.)

pare the effectiveness of inhibitors added to the feedwater against the addition to synthetic solutions.

The feedwater for all experimental boiler waters had an analysis of hardness as $CaCO_3$ of 120 ppm, alkalinity of 166 ppm, sulphates as Na_2SO_4 of 132 ppm, NaCl of 43 ppm, and SiO_2 of 4.5 ppm. The pressure was 200 psi gage, and no condensate was returned to the boiler.

The accompanying tables show the amount and kind of inhibitor added to the feedwater, the boiler-water analysis, and the results of the cracking tests. The amount of organic present as indicated by the Tyrosin test, and the amount of inhibitor calculated to be present from the amount known to be in the feedwater are also indicated.

It is much easier to protect steel against the action of synthetic solutions than against boiler waters. For example, 22.5 ppm of lignin, which had been pretreated, plus 2.5 ppm of sodium nitrate

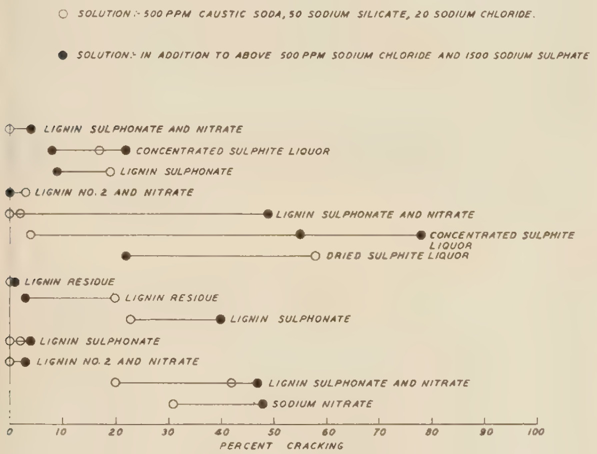

Fig. 12 Effect of Salts on Cracking

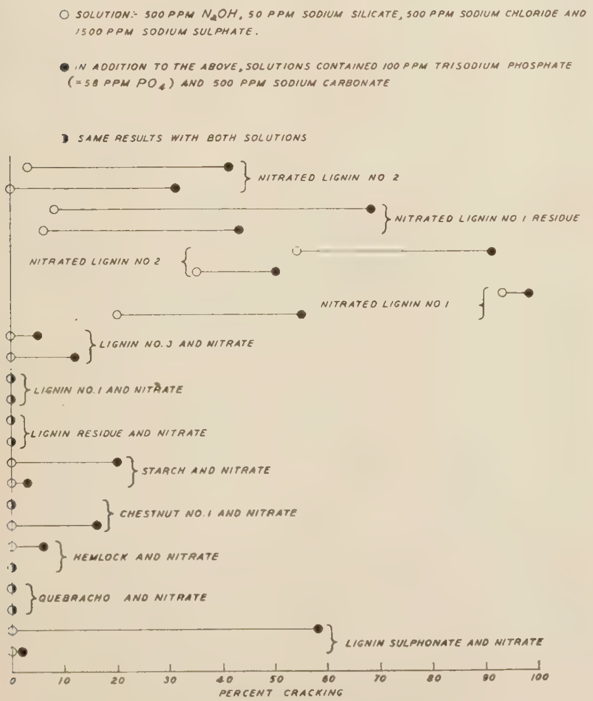

Fig. 13 Effect of Carbonates and Phosphate on Cracking

gave good protection on synthetic solutions containing a high salt content (Table 10), but much higher quantities failed to protect steel when this treatment was added to the feedwater, and the resulting boiler water tested (Table 1). This is also true of other inhibitors tested.

The explanation of this may be the fact that when synthetic solutions are used, it is customary to withdraw the excess air from the bomb before bringing it up to pressure, as most organic inhibitors have slight effect unless this is done. While this same procedure is followed with boiler waters, the feedwater in these tests was not deaerated, as such is not the common railroad practice. It would be interesting to see what effect predeaeration would have on the results with boiler waters.

The amounts of inhibitor indicated as being required by these boiler-water tests seem excessive, being calculated at about 240 ppm in the boiler when carrying only 8 concentrations of feedwater. This value is higher than is probably necessary, as the test is admittedly very severe. It would be an exceptional condition where boiler plate had undergone distortion as great as these steel specimens, and at the same time such ideal conditions for leakage were maintained.

These tests with boiler water show that in general, as the number of concentrations increases, increased organic matter is required for complete protection. As boiler waters are increased in concentration, the quantity of alkalinity often increases also. Figs. 7 and 8 indicate the amount of alkalinity present and the number of concentrations with respect to the amount of inhibitor required in the feedwater for complete protection in these tests.

Effect of Inorganic Salts

The effect of the various inorganic salts commonly present in boiler waters is not great when these salts are tested in synthetic solutions. The addition of 500 ppm of sodium chloride and 1500 ppm of sodium sulphate has, in some instances, resulted in more cracking, and in others less.

The addition of trisodium phosphate and sodium carbonate has resulted in several cases of cracking where cracking was not obtained in their absence. However, there is no conclusive evidence that these salts are undesirable, as in some cases no cracking resulted when these salts were present.

The great discrepancy, therefore, between results obtained with synthetic solutions and boiler waters is due to factors other than the inorganic salts which are present.

Of the inorganic substances tested, sodium nitrate is one of the best. It is not nearly as effective alone as when combined with organic matter, as shown by the tests on synthetic waters.

Sodium nitrate in such tests is very effective in small amounts and greatly improves the inhibiting effect of all organics with which it was tested. These results are shown in Table 10.

Because of the uniformly better results with a mixture of nitrate and organic matter, some organic substances were nitrated and tested. The nitrated materials in general were not effective.

A number of the inhibitors listed in the accompanying tables should be described in some detail.

In some cases organic substances were secured from more than one source. Such materials are labeled, for example, myrobalans No. 1 and No. 2. The numbering of such samples is consistent throughout.

The substance, lignin sulphonate, is a purified product, and differs from sulphite liquors in that the solid content of the latter is approximately one half lignin sulphonate, the remainder being sugars and other substances. The lignin sulphonate used was a solid. The concentrated sulphite liquor used contained approximately 50 per cent solids.

Lignin residue is the product remaining after the cellulosic portion of wood has been converted and removed. The exact

nature of this substance is unknown, but is believed to be a partially oxidized form of lignin, which has the property of forming alkali-soluble salts.

Powders obtained by evaporating sulphite liquors from spruce wood were found to be unstable. Two samples of such powders were found to be very effective when fresh, but they were not effective after aging for a period of several weeks. Table 12 and Fig. 9 give the results. The age as indicated is the time at which the tests were started after the materials were manufactured. Further tests are under way to determine whether or not similar substances show a decrease in inhibiting properties with age.

There has been considerable discussion regarding more resistant steels than some which have been in use. Accordingly, a number of steels were tested without inhibitors present. A few of these steels were of $^1/_4$ in. thickness and are listed separately. The value of these data on various steels lies in the fact that steels are known which have greater resistance to cracking than some steels now in use for boiler shells. Whether or not any of these chemical crack-resistant steels would be suitable from the standpoint of other properties is outside the scope of this paper. Likewise, those steels which show low resistance in these tests should not be condemned for use in boiler parts not normally subject to caustic embrittlement, nor rejected solely on the basis of chemical analyses for use in boiler plate, as variations in rolling conditions, heat-treatment, etc., may so alter the physical properties of such steels that they would show high resistance to cracking. This, of course, is a subject for further investigation.

Conclusions

On the basis of tests on synthetic solutions and boiler waters there is no indication that inorganic salts ordinarily found in boiler waters exert a pronounced protective action. This is also true of sodium sulphate while operating well within the A.S.M.E. code recommendations. Some tests indicate that a high sulphate content may interfere with the protective action of organics, but this effect is not pronounced nor consistent enough to be used as a basis for drawing the conclusion that sulphates are harmful.

With a given feedwater, it was found that increasingly large amounts of inhibitors are required in the feedwater, as the number of concentrations increased. Whether this is due to a corresponding increase in the concentration of neutral salts or caustic soda, or whether it indicates deterioration of the inhibitor in the boiler water, has not been determined.

Highly effective inhibitors are known as indicated by tests on synthetic solutions.

The embrittlement detector is believed to be a valuable instrument in the study of cracking of boiler plate, but great care must be exercised in its use.

Field Data From the Embrittlement Detector

By E. P. PARTRIDGE,[1] C. E. KAUFMAN,[2] and R. E. HALL[3]

This paper constitutes a progress report based on test data from 100 embrittlement detectors installed on operating boilers to ascertain the embrittling tendency of the respective boiler waters. Not until more than 10 years after the well-known sulphate-alkalinity ratios were formulated and published in the A.S.M.E. Boiler Code of 1926 were means devised whereby the tendency of an actual boiler water to cause cracking could be tested. Mention is made of the apparatus designed for laboratory use, developed by Straub and Bradbury, and the embrittlement detector of Schroeder and his associates for installation on an operating boiler. The tests reported by the authors were carried out by means of the latter. The procedure followed and the effects of various inhibitors used are given in some detail and the results are presented in the form of a series of graphs. The authors in conclusion suggest that boiler operators, faced with the problem of embrittlement cracking, take advantage of the testing methods now available, and determine the conditions which they can economically and effectively maintain in their boilers to minimize the difficulty.

INTERGRANULAR failure along riveted seams in steam boilers has now been a matter of concern for more than 30 years. Attempts during the first half of this period to correlate the incidence of cracking with various factors led, in Europe, to major emphasis upon methods of fabrication; in the United States, concurrently with efforts to improve boiler manufacture, attention was directed particularly toward control of boiler-water composition. The well-known ratios of sodium sulphate to total alkalinity as sodium carbonate, which first appeared in the A.S.M.E. Boiler Code in 1926, were the expression of the hope shared in common by the manufacturers and the operators of boilers that chemical control might obviate cracking.

When the sulphate-alkalinity ratios were formulated, no simple direct test of their efficacy was possible. The suggested values were based largely upon the limited information available concerning the composition of the water in low-pressure boilers which had cracked or had not cracked in service over a period of years. The data, which have never been made public, must necessarily have been rather sketchy, for few analyses of boiler waters were made prior to 1926. The sulphate-alkalinity ratios received some support from tests with highly concentrated synthetic solutions in the laboratory equipment of Parr and Straub (1),[4] but not for more than 10 years after 1926 were means devised whereby the tendency of an actual boiler water to cause cracking could be tested.

How thoroughly the sulphate-alkalinity ratios had been accepted in the meantime is attested by the initial program of a co-operative investigation undertaken in 1933, by the Joint Research Committee on Boiler Feedwater Studies and the Bureau of Mines. This program, initiated by one and directed for the first $2^1/_2$ years by another of the authors of the present paper, had as its first objective the determination of the solubility of sodium sulphate in the saline solutions which would result from the excessive concentration of a boiler water in a riveted seam. The question at that time was not whether sodium sulphate would inhibit cracking but, instead, how much would be necessary under various conditions.

The rest of the story of the renaissance of research concerning cracking in riveted seams has been told in the technical papers published during the last few years (2–13). Much has been learned about the mechanism of intergranular cracking. In the opinion of the authors, however, the great achievement has been the development of devices, on the one hand by Straub and Bradbury (6, 7), and on the other by Schroeder, Berk, and O'Brien (11, 12, 13) for direct testing of the ability of a boiler water to cause cracking when the necessary mechanical conditions are provided.

While the apparatus of Straub and Bradbury was particularly intended for use in a central laboratory, the "embrittlement detector" of Schroeder and his associates was developed for installation on an operating boiler. The relative advantages of these two methods of approach to the problem of testing might be argued without end. Admittedly uniform procedure during the actual test is more probable if samples of boiler water from many plants are brought to the laboratory and run by specially trained personnel. On the other hand, the samples so tested may not properly represent the average compositions of the respective boiler waters over a period of time, and may be significantly altered in composition and behavior during sampling and transfer to the laboratory.

The alternative procedure of installing an embrittlement detector on an operating boiler automatically integrates the effect of fluctuations in the composition of the boiler water during any desired test period, but unavoidably introduces variation in the personal factor. That the latter is not serious has been demonstrated by the experience of the authors with approximately 100 plants which had carried out tests with the detector by August 1, 1941.

This field experience, over a period of approximately two years, constitutes the basis for the present progress report. In common with the other papers on this general subject, correlation—or lack of correlation—of cracking with boiler-water composition has been presented graphically in a series of figures based upon the tabulated data.[5] The results are offered, not as a basis for codification of recommendations for preventing intergranular cracking, but instead as an argument that each plant should determine by direct test what boiler-water conditions will most effectively and most economically safeguard it against this type of damage.

Significance of Data From Embrittlement Detector

Viewed against the background of knowledge accumulated since Stromeyer's first simple but suggestive experiment (14),

[1] Director of Research, Hall Laboratories, Inc., Pittsburgh, Pa.

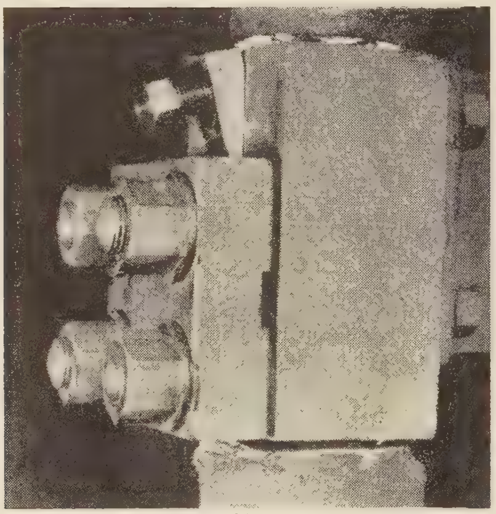
[4] Numbers in parentheses refer to the Bibliography at the end of the paper.

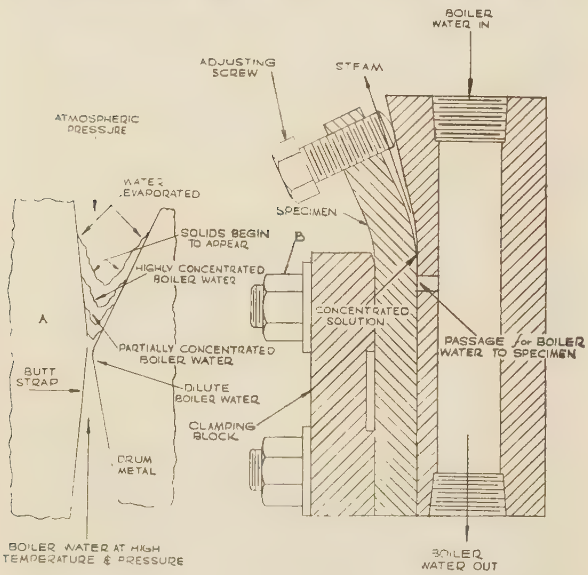
Contributed by the Joint Research Committee on Boiler Feedwater Studies and presented at the Annual Meeting, New York, N. Y., December 1–5, 1941, of The American Society of Mechanical Egineers.

[5] Space did not permit publication of tabulated data which resulted from the tests, but a complete set of these tables is on file at the Engineering Societies Library, 29 West 39th Street, New York, N. Y., for reference.

intergranular cracking of a riveted seam in a boiler is evidence of the co-operation of certain essential mechanical and chemical factors: Boiler water must have concentrated greatly, a hundred or a thousandfold; the concentrated solution must have been in contact with steel under high applied or residual stress; and the chemical composition of the concentrated solution must have been such as to lead to localized corrosion at grain boundaries, rather than general attack (15).



(*A*)



(*B*)

Fig. 1 Embrittlement Detector

(*A*, Photograph of detector installed on vertical blowdown line. *B*, Cross section of detector and schematic representation of concentration of boiler water by flashing through a capillary leak.)

The absence of cracking in a riveted seam might be due to the absence of any one of these factors. The seam might have been so tight as to obviate concentration of dissolved substances by flashing of vapor to the outside through a slow leak; concentration might have occurred, but not in contact with metal under sufficiently high stress; or some inhibitor of intergranular corrosion might have been present naturally in the water or have been added as a conditioning chemical. Uncracked seams in operating boilers can only then be adduced as evidence of the chemical protective effect of an inhibitor, if the basic assumption is made that every riveted seam is so constructed that it would crack in the absence of such an inhibitor.

Perhaps this is true; however, instead of wondering year after year whether it is true and whether his water really is safe because his boiler has not failed, the operator may now set up the mechanical factors for himself in the embrittlement detector. Then, if the specimen fails to crack, he will feel reassured; on the other hand, if it cracks, he can determine in successive tests the effect of various inhibitive treatments.

The operator must, of course, consider the question of adjustment of leakage in the detector. If no leakage occurs between the test specimen and the block of the detector, illustrated in Fig. 1, no concentration of boiler water can occur; on the other hand, if water leaks too freely through this space, little concentration may take place until the water has passed the region of high residual stress at the bend in the specimen. Emphasis is therefore placed upon adjustment of the detector until only the slightest haze of condensed moisture can be discerned on a cold

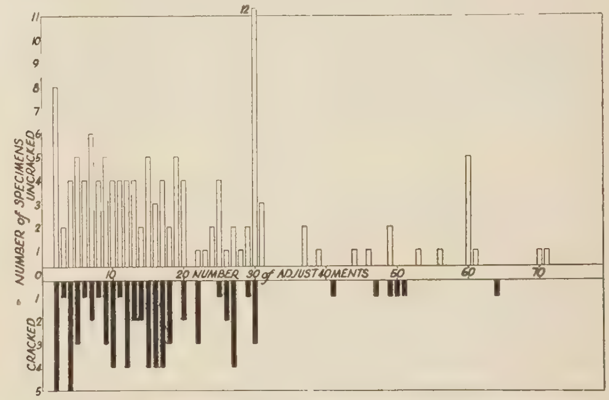


Fig. 2 Lack of Significant Relation Between Number of Adjustments and Cracking of Specimens

(Repetition of stress on specimen as a result of adjustment apparently does not promote cracking.)

surface of glass or polished metal held directly over the end of the specimen.

Frequent adjustment is undesirable, because it increases the likelihood that a concentrated solution will be washed out by too wide an opening of the capillary space, and because it subjects the specimen to repeated changes in stress. That the number of adjustments is not, however, particularly significant is indicated by the lack of any consistent trend in Fig. 2, representing the experience with the nearly 250 specimens discussed in the present paper. The rather even distribution between cracked and uncracked specimens continues from the lowest to the highest number of adjustments.

From the viewpoint of the authors, cracking of a specimen during a properly conducted detector test means that the boiler water during that test would have been capable of promoting cracking at any point in a riveted seam where mechanical conditions of stress and concentration equivalent to those artificially created in the detector happened to exist. Since the opportunity for boiler water to concentrate to a high degree in contact with steel stressed as severely as the cold-rolled specimen may not actually exist in the boiler, cracking of the specimen does not necessarily mean that cracks have already developed or will develop in the boiler seams, but it is a warning signal that some corrective treatment might well be initiated. More severe chemical conditions are required in the laboratory to induce failure in

a hot-rolled than in a cold-rolled specimen; hence cracking of a hot-rolled specimen in a detector test is considered as a more emphatic warning of the embrittling character of the boiler water.

Correlation of Cracking of Detector Specimens With Boiler-Water Composition

Many substances have been mentioned as affecting intergranular failure. Of these, sodium hydroxide is regarded as the fundamental corroding agent, and silica as the agent which tends to accelerate failure by localizing the chemical attack at the grain boundaries. Of the various substances suggested as inhibitors, the greatest attention has been paid in recent years to sodium sulphate, chloride, phosphate, and nitrate, to alumina, and to organic products such as tannin and lignin. The relation between these chemical factors and the incidence of cracking is shown in Figs. 3 to 14. In most of the figures, a chemical factor such, for example, as the concentration of NaOH in Fig. 3,

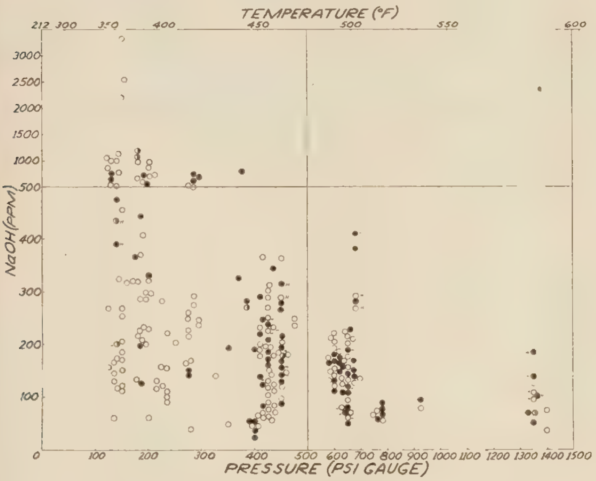

Fig. 3 Incidence of Cracking Related to Concentration of Sodium Hydroxide

(Cracking may occur with as little as 50 ppm, or may not occur with as much as 3000 ppm of NaOH.)

(Specimens cracked when A.S.M.E. ratio values were above as well as below the recommended levels indicated for the various pressure ranges by the broken line.)

or the $SiO_2/NaOH$ ratio in Fig. 4, is plotted against boiler pressure. Two ratios may also be plotted against each other to investigate interdependence or relative significance, as in Figs. 7, 12, and 13.

The values of the various chemical factors are based upon one or more samples of boiler water analyzed for this particular purpose during each test. The collection of composite samples over periods of 30, 60, or 90 days being impractical, it was necessary to rely on spot samples selected to reflect, as well as possible, the average conditions during a test. Comparison of many of the analyses with the daily plant-control records indicates that few of the points in the figures are likely to be significantly out of their proper places.

Each solid circle in a figure indicates that the detector specimen showed obvious cracks when removed from the detector, or contained cracks not visible to the eye, which opened up when the specimen was bent in a hydraulic press after removal. An open circle signifies the absence of such cracking even after bending, while a few borderline cases, in which only the slightest indica-

(Values for nitrate have been determined only in most recent tests. No conclusion can be drawn from these few data.)

tion of checking of the surface was seen after bending, are represented by half-solid circles. Specimens of hot-rolled steel are indicated by the letter H adjacent to the circle.

By considering as a group the tests from each detector, one might characterize the boiler water in each plant as inherently capable or incapable of producing cracking. The character of the boiler water may, however, change from test to test as a result of natural variation in the water supply, as well as intentional modification of treatment. It has seemed best, therefore, to plot each test independently, even though this may throw disproportionate emphasis upon those boiler waters with which more tests have been run. Any real correlation should not be obscured, however, by this treatment of the data.

Concentration of Sodium Hydroxide. From Fig. 3, it appears that a high concentration of sodium hydroxide in the boiler water is not a prerequisite for cracking; a number of specimens failed with waters containing only from 50 to 100 ppm of NaOH. This is understandable, however, since, in the detector, as in the riveted seam it simulates, boiler water may be concentrated thousands of times, producing a film of strong caustic from the flashing of a boiler water with a normal low content of this constituent.

The number of cases in which abnormally high concentrations of sodium hydroxide failed to produce cracking may seem strange until it is remembered that naturally occurring or intentionally added inhibitors may have been present.

The tentative conclusions may be drawn from Fig. 3, that as little as 50 ppm of sodium hydroxide may be sufficient to cause cracking in the absence of an inhibitor, but that as much as 3000 ppm may not produce failure in the presence of sufficient inhibitor.

Ratio of Silica to Sodium Hydroxide. The profound effect of small amounts of silica in promoting the intergranular corrosion of steel by concentrated caustic solutions was reported simultaneously in 1936 by Straub and Bradbury (3) and by Schroeder and Berk (2). In the tests of the latter investigators, as little as 0.08 per cent of silica on the weight of the sodium hydroxide showed a definite effect. That no cracking is evident in Fig. 4 at a value lower than this for the SiO_2/NaOH ratio is perhaps

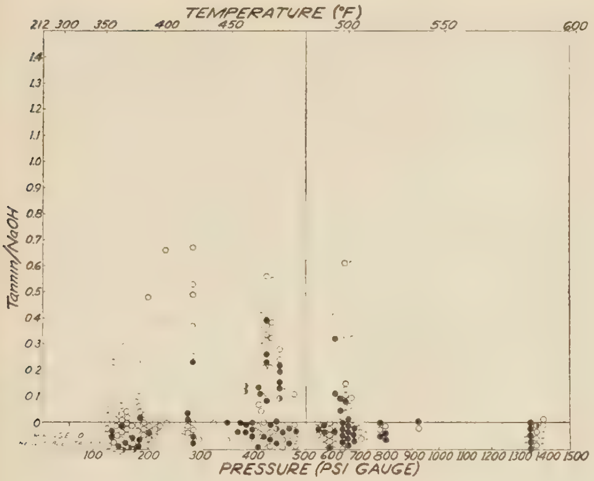

FIG. 11 INCIDENCE OF CRACKING RELATED TO RATIO OF TANNIN TO SODIUM HYDROXIDE

(Three quarters of cracked specimens came from boiler waters with negligible tannin content, while no cracking occurred when ratio value was above 0.4.)

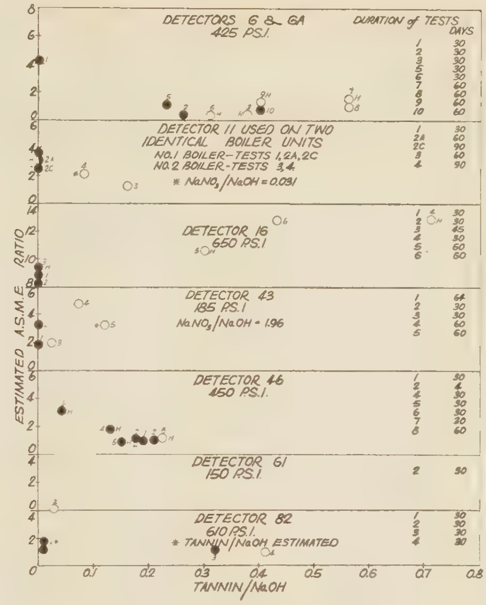

FIG. 12 COMPARATIVE INFLUENCE OF SULPHATE AND OF TANNIN UPON CRACKING IN SEVEN PLANTS

(In various plants, values of tannin to NaOH ranging from less than 0.1 to nearly 0.6 have been found to inhibit cracking more effectively than maintenance of the A.S.M.E. ratios.)

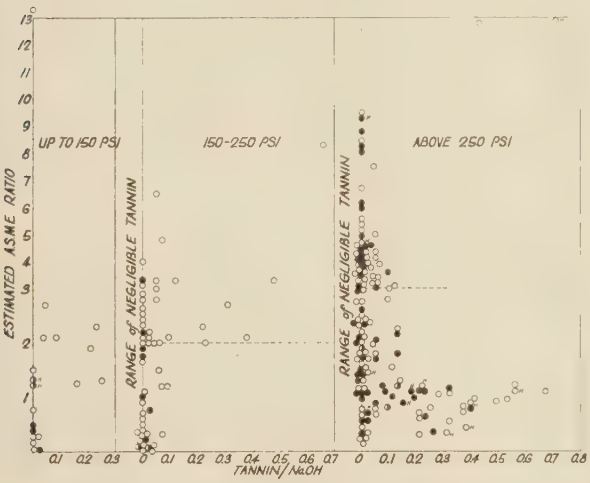

FIG. 13 COMPARATIVE INFLUENCE OF SULPHATE AND OF TANNIN UPON CRACKING IN ALL TESTS

(Cracking has occurred when the sulphate to alkalinity ratio exceeded 9, but not when the tannin to NaOH ratio exceeded 0.4.)

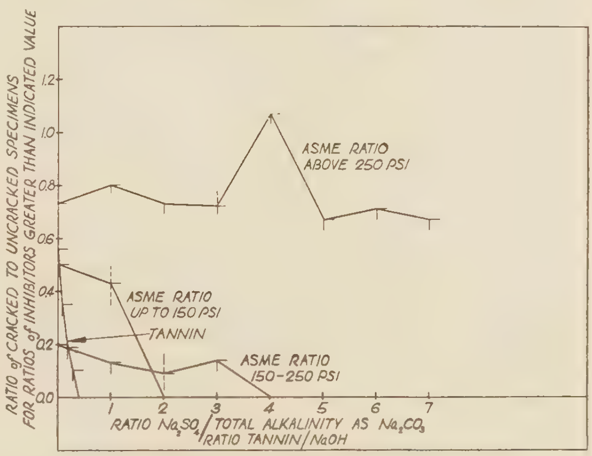

FIG. 14 TENTATIVE EXPRESSION OF CHANCE OF CRACKING A SPECIMEN WHEN A.S.M.E. RATIO OR TANNIN-TO-NaOH RATIO IS MAINTAINED ABOVE ANY SPECIFIED VALUE

(Maintenance of A.S.M.E. ratio recommended for each pressure range does not appreciably reduce chance of cracking over that in absence of sulphate; relatively low values of tannin to NaOH ratio seem to exert a protective effect.)

fortuitous, but nevertheless interesting. Most of the cracking seems to have been produced in the range from 0.1 to 1; still higher ratio values apparently tend to inhibit failure, although not enough data are available to justify a definite conclusion to this effect.

Ratio of Sodium Sulphate to Total Alkalinity Expressed as Sodium Carbonate. In boiler water containing carbonate, silicate, and phosphate, as well as hydroxide, "total alkalinity" has so little significance that it is not customarily measured by the authors' organization. In the past it has been observed that "total alkalinity as sodium carbonate" averaged approximately 5/3 times the sodium-hydroxide content of the boiler water. If the use of this factor in Fig. 5 seems arbitrary, it may be recalled that, since all evidence points to sodium hydroxide rather than to the alkaline buffer salts as the corroding agent, "total alkalinity," as the denominator of the A.S.M.E. ratios, rests actually upon no less arbitrary a basis.

While any individual point in Fig. 5 might lie at a somewhat higher or somewhat lower value if the total alkalinity had been measured directly by titration rather than approximated from the value for sodium hydroxide, the general conclusion could scarcely be changed. This conclusion is obvious: Poor correlation is shown between the incidence of cracking and the sulphate-alkalinity ratio.

The right-hand vertical scale of Fig. 5 expresses the data directly in terms of the ratio of sodium sulphate to sodium hydroxide.

Ratio of Sodium Chloride to Sodium Hydroxide. Sodium chloride has been regarded both as an accelerator of intergranular attack (16, 5), and as a promoter of the reputed protective action of sodium sulphate (6, 7). From Fig. 6, it would appear that any

influence of sodium chloride is overshadowed by other factors, since cracking occurs in a random manner over a wide range of ratio values.

Combined Ratios for Pressures Up to 250 Psi. Straub has concluded from laboratory tests that, in the pressure range up to 250 psi, maintenance of ratios of Na_2SO_4 to total alkalinity, and NaCl to total alkalinity greater, respectively, than 1 and 0.6 will inhibit cracking (7).

While a plot of the Na_2SO_4/NaOH ratio against the NaCl /NaOH ratio is admittedly not identical with one in which values for total alkalinity are employed, considerable similarity would be expected. Fig. 7, however, shows a random occurrence of cracking, in no way dependent upon the relative concentrations of sodium sulphate, sodium chloride, and sodium hydroxide, for specimens tested in the pressure range up to 250 psi.

Ratios of R_2O_3 to Silica. It has been suggested by Straub (7), that the tendency of boiler water to cause cracking may be offset in the range of pressure above 500 psi by maintaining a value of 0.6 or above for the ratio of R_2O_3 to SiO_2. In a normal alkaline boiler water, the iron in solution will be so low that R_2O_3 virtually means aluminum oxide.

As a matter of general interest, values for the ratio of R_2O_3 to SiO_2 have been plotted in Fig. 8, for all tests for which data were available. In the range above 500 psi, it will be noted that four specimens cracked in spite of ratio values well above that recommended.

Ratio of Phosphate to Sodium Hydroxide. Although phosphate has been included among the possible inhibitors of cracking (17), there is little indication from Fig. 9 that maintenance of any particular ratio of phosphate to sodium hydroxide might prevent cracking. On the other hand, as suggested by Schroeder (13), phosphate conditioning may be so controlled as to yield a water which is moderately alkaline in the boiler, yet will not produce a concentrated caustic solution by flashing through a slow leak.

Control of the boiler water in the manner just noted would correspond to maintenance of a substantially infinite value for the ratio of phosphate to hydroxide in Fig. 9.

Ratio of Sodium Nitrate to Sodium Hydroxide. Although Parr and Straub reported eleven years ago[6] that sodium nitrate inhibited cracking in their tests with concentrated solutions, no attempt was made to employ this substance in boiler-water conditioning until very recently. Since nitrate was not considered as a factor in the prevention of cracking when the tests described in this paper were started, only the relatively few data plotted in Fig. 10 are available. Three specimens cracked, but the $NaNO_3$ /NaOH ratios in these cases, as well as in six of the seven cases of uncracked specimens, were considerably below the value of 0.4 suggested by Schroeder, Berk, and Stoddard (13). No conclusions could safely be drawn from this small number of tests.

Ratio of Tannin to Sodium Hydroxide. Lignin-containing materials, derived from sulphite-waste liquor, and various tannins have long been used in compounds for treating boiler water. While tannic acid was reported by Straub (17) to act as an inhibitor of cracking, lignin derivatives and tannins have only come into general intentional use for this purpose in the field since the further experimental work of Schroeder and his associates (5). Waters to which no lignin or tannin has been added during treatment may, however, carry significant amounts of these types of organic materials, derived either from the dumping of industrial wastes into streams or the natural decay of vegetation.

Fig. 11 must be regarded as an encouraging progress report concerning the efficacy of tannin, rather than as proof of universal ability to inhibit cracking. Approximately 75 per cent of the cracked specimens came from boilers in which the content of tannin was negligible, while no cracking was observed when the ratio of tannin, as determined by the tyrosin test (18),[7] to sodium hydroxide was more than 0.4. In only a few stubborn cases was it necessary to attain as high a value as this. Some of these individual cases are discussed in the following section.

Cases Illustrating the Effectiveness of Tannin as an Inhibitor

Since individual discussion of every series of tests is not possible within the limitations of this paper, data from seven plants have been selected to represent the experiences with tannin as an inhibitor. The individual plots of Fig. 12 show the values of the A.S.M.E. sulphate-alkalinity ratio and of the ratio of tannin to sodium hydroxide for each test.

Tannin Used Primarily for Sludge Control. At the plant in which detectors 6 and 6A are installed on a welded-drum 425-psi boiler, quebracho tannin is used primarily as a dispersing agent in sludge control. Initially only one detector was installed; later two were connected in series so tests could be run simultaneously on specimens of both cold- and hot-rolled steel. The first test without feed of tannin, but with the A.S.M.E. ratio maintained, resulted in cracking. In subsequent runs, no attempt was made to hold the recommended value of 3 for this ratio. During tests in which the tannin content varied, cold-rolled specimens failed, with the exception of one trial in which a tannin-to-NaOH ratio of about 0.56 was reached. Hot-rolled specimens did not crack in tests where the tannin-to-NaOH value varied from about 0.31 to 0.56. The evidence indicates that this boiler water is mildly embrittling when the tannin concentration is low; cold-rolled specimens crack while hot-rolled bars do not. By maintaining a minimum value of tannin, which may vary with the season and the total boiler-water concentration, it seems possible to prevent all specimen cracking.

Comparative Tests on Low-Pressure Boilers. Detector No. 11 has been installed successively on two identical boiler units operating at about 140 psi. No tannin was added to No. 1 boiler; the results indicate a highly embrittling water, since even hot-rolled specimens cracked. On the other hand, on a comparison boiler running under substantially the same conditions except that tannin was added, two cold-rolled specimens failed to crack. At this low pressure, a relatively small tannin-to-NaOH ratio appears to be adequate. In all these runs, the A.S.M.E. ratio of 1 was maintained. A small quantity of nitrate was found in a sample drawn during test No. 4; this may have had some protective influence, although it is likely that nitrate was present to a similarly slight extent during the other tests.

Tannin Effective as Inhibitor at 650 Psi. Runs with detector No. 16, installed on a 650-psi boiler in a utility plant with evaporated make-up, provided a test of the efficacy of quebracho treatment at a higher pressure. Three initial runs were made with no tannin added. In each case, severe cracking resulted, even though one specimen was hot-rolled. During these and subsequent runs, the estimated sulphate-alkalinity ratio was very high, between 8.3 and 12.9, as a result of the conversion to sodium sulphate of sodium sulphite, added as an oxygen scavenger. After tannin feed was instituted, three specimens were tested; none cracked. Two of the unaffected bars were hot-rolled while the last was cold-rolled steel.

Nitrate Present With Tannin. The plant in which detector No. 43 is mounted on a 185-psi boiler draws its water from an impounded section of a river contaminated with sewage. Two specimens were cracked when no organic inhibitor was added. When quebracho was fed, even in amounts to yield a tannin-to-NaOH value of less than 0.1, three specimens remained uncracked. The sulphate-alkalinity ratio was met during prac-

[6] Bibliography (16), p. 80.

[7] Refer to Appendix, section on "Tannin."

tically all of the testing program. However, there should be no hasty conclusion that tannin was the effective inhibitor in this case. Determinations made during the last run showed the presence of over 500 ppm of sodium nitrate in the boiler water. It is possible that this constituent, rather than the tannin, may account for the nonembrittling character of the boiler water during the later tests. If this is the case, the nitrate content during the first two runs presumably was considerably less.

Natural Organic Inhibitor Present. The water in the 150-psi boiler on which detector No. 61 is installed might be considered on the basis of its content of ordinarily determined constituents to be quite embrittling. Alkalinity is very high while sulphate is vanishingly small, hence the sulphate-alkalinity ratio is negligible; yet four specimens tested at this plant for periods up to 120 days did not crack. The inhibiting effect appears to be due to the naturally occurring organic material in the feed, which concentrates to an appreciable extent in the boiler water. A determination of this organic material made during test No. 2 (the only specimen plotted) yielded a value of 97 ppm on the basis of a quebracho standard. It is possible that the actual amount of organic substance present is greater, since it may react to a different extent than does tannin in the colorimetric test employed.

Higher Tannin-to-NaOH Ratio Required. Detector No. 46 takes water from a 450-psi boiler to which quebracho has been added from the beginning of the test program. During practically all this period the A.S.M.E. ratio was not met. Cracking of both hot- and cold-rolled specimens occurred despite the addition of tannin, until the last run made with a hot-rolled specimen, when the average concentration of quebracho was slightly higher than in previous tests. Further work will be required to define protective conditions more fully.

Detector No. 82 is attached to a closely controlled boiler operating at 610 psi, in which the A.S.M.E. ratio is not maintained. Two initial tests in the essential absence of tannin (a very small amount of naturally occurring material was present) resulted in pronounced cracking. Tannin was fed, but a third specimen failed, although less severely than the first two. During a fourth run, the quebracho content was increased somewhat. The result was no cracking. All four of these tests were for 30-day periods. It remains to be seen whether present conditions will inhibit failure over longer intervals.

Relative Effectiveness of Sulphate and of Tannin in Preventing Cracking

That tannin is more effective as an inhibitor of cracking than sulphate is indicated by the selected series of tests in Fig. 12. When all of the data are plotted similarly for the three pressure ranges of the A.S.M.E. ratio, as in Fig. 13, the same conclusion is reached. It is true that, in the range above 250 psi, a number of specimens cracked when the ratio of tannin to NaOH was above 0.2, ranging up to 0.4; comparison of Figs. 12 and 13 shows, however, that most of these specimens came from detectors Nos. 6, 46, and 82, with each of which an increase in the tannin-to-NaOH ratio apparently has lessened the tendency to crack. In contrast, among the waters containing negligible or low amounts of tannin, cracking has occurred with values of the sulphate-alkalinity ratio far above the suggested limits of 1, 2, and 3.

Even in the pressure range above 250 psi, the number of observations is scarcely large enough to justify statistical treatment; in either of the two lower ranges of pressure, the cracking of a single future specimen in a water with a high sulphate-alkalinity ratio would materially alter any conclusions which might now be attempted from a statistical viewpoint. Nevertheless, Fig. 14 is ventured as a tentative picture, subject to modification as data accumulate, of the relative effectiveness of sulphate and of tannin in preventing cracking.

In Fig. 14, the chance of cracking is represented by the vertical scale, expressing the ratio of cracked to uncracked specimens. This ratio has been determined for the group of specimens whose sulphate-to-alkalinity or tannin-to-NaOH ratios exceed each of various values on the horizontal scale. Looking first at the line representing the A.S.M.E. ratio for boilers operating at 250 psi or above, it is apparent that the chance of cracking was about the same whether the ratio value was 1 or 7, or any intermediate value; on the average, three specimens cracked for each four which did not.

In the pressure range from 150 to 250 psi, no specimen had cracked by August 1, 1941, when the A.S.M.E. ratio equaled or exceeded 4. The chance of cracking, therefore, is represented as zero at this value of the ratio, although at 3 or below one specimen cracked on the average for each seven which remained undamaged.

In a similar manner, the limited number of tests in the pressure range up to 150 psi might be interpreted to mean no chance of cracking when the A.S.M.E. ratio was 2 or above, although at lower values one specimen cracked for each two which did not. Test results on a 130-psi boiler have already been published by others (13), however, which, if included in Fig. 14, would greatly increase the indicated chance of cracking for any A.S.M.E. ratio value up to more than 8. The suspicion cannot be avoided that, as data accumulate from detectors on boilers in the two lower pressure ranges, the line representing the chance of cracking will tend to flatten out like the one now shown for the range above 250 psi. If this should happen, it would remove such slight evidence, as Fig. 14 now indicates that sulphate inhibits cracking.

Although the effectiveness of tannin can only be proved beyond doubt by many more tests, the manner in which the curve for tannin, in Fig. 14, plummets consistently downward until the chance of cracking becomes zero at a tannin-to-NaOH ratio exceeding 0.4 suggests it to be a real inhibitor.

A Practical Program to Obviate Cracking in Riveted Seams

It would be easy to find contradictions in the data presented in the preceding sections or to stress the uncertainties inherent in field testing conducted by many individuals. An enthusiast for any particular method of controlling cracking could at least cast doubt upon the efficacy of other methods, even if he could find little support for his own. Certain conclusions, however, seem justified to the authors:

1 Neither sulphate nor chloride, nor sulphate and chloride in combination show evidence of an inhibiting effect over the range of pressures above 250 psi. At pressures up to this level, some effect is indicated by the limited data of the authors, but contradicted by the published results of other detector tests.

2 R_2O_3 (alumina) has not proved effective as an inhibitor of cracking either in the suggested range above 500 psi, or at lower pressures.

3 Phosphate appears to be without effect as an inhibitor, even at a PO_4/NaOH ratio as high as 2. This does not deny, however, the possible utility of eliminating sodium hydroxide substantially from a boiler water containing phosphate by controlling the pH in the range below 11.

4 The experience of the authors with nitrate is not yet sufficiently extended to justify any conclusion concerning its effectiveness.

5 Tannin, as determined by the tyrosin test, seems effective as an inhibitor over the range up to 650 psi in which it has been used to date.

Starting with these conclusions, it would seem logical neither

to accept with blind faith the semiofficial sulphate-alkalinity ratios, nor with blind zeal to replace them with some other system of ratios based upon the effect of tannin or any other proposed inhibitor. Instead of the formulation of rules, the authors suggest instead that full advantage be taken of the testing methods now available, and that each operator determine, with the assistance of whatever coordinating agency he may choose, the conditions which he can most economically and effectively maintain in his own boilers to minimize the likelihood of cracking.

If he has no boilers with riveted seams, the operator may feel justified in ignoring the problem. He may still, however, wish to take precautions to avoid the admittedly rare possibility of intergranular cracking in tube ends. Along with the operator more directly concerned because of riveted construction, he can, by means of the embrittlement detector, first test his boiler water under existing operating conditions. If specimens crack in repeated tests, he can then explore, in a consistent manner, the effect of any changes in treatment. Experience to date indicates that he will be likely to find practical conditions under which the steel of the detector specimen will remain uncracked.

Having once achieved favorable conditions, there is then much to be said for using the detector as a continuous or semicontinuous indicator to be sure that some apparently unimportant change may not make the boiler water again capable of cracking steel. Once established, the routine of adjusting leakage is simple, requiring not more than five minutes attention per day, while the cost of the detector and of specimens is nominal. Altogether, the use of the embrittlement detector in this manner may prove as desirable as the measurement of carbon dioxide in the flue gas or of dissolved salts in the steam condensate.

Perhaps the answer in any particular case will lie in the use of tannin; on the other hand, nitrate may demonstrate its superiority, or the reduction of the sodium-hydroxide content of the boiler water substantially to zero by maintaining alkalinity with phosphate may prove satisfactory and desirable. The emphasis does not rightly belong upon any particular chemical means of inhibiting cracking; instead, the important fact to be realized is that the reinvestigation of boiler-metal cracking in recent years now has produced a means of measuring the elusive chemical factor in this type of failure. Even though the measurement be rough, the way has been opened to approach the problem of cracking, not by arguing as an advocate, but by testing as an engineer.

Acknowledgments

To the many men in the various plants who have cooperated wholeheartedly in the testing program; to Dr. Schroeder, Mr. Berk, and their assistants at the Eastern Experiment Station of the Bureau of Mines, who have examined all specimens and given helpful advice; to the field engineers of Hall Laboratories, Inc., who have assisted in checking test conditions in the detector units; and to their associates who have supplied the analytical data and otherwise assisted in the preparation of this paper, the authors express their sincere appreciation.

Appendix

Methods of Analysis

The following methods were employed in the analysis of the samples of boiler water taken during the various tests:

Silica. Gravimetric determinations were made on all samples.

R_2O_3. This was determined gravimetrically as aluminum (and iron) phosphates.

Hydroxide. After the addition of barium chloride in excess of the amount required to precipitate buffer salts such as carbonate and phosphate, the sample was titrated with standard acid to the end point of phenolphthalein.

Sulphate. Both the turbidimetric method devised by Hall (19) and the gravimetric method were utilized.

Phosphate. The method developed by Hall (20), in which the amount of the yellow precipitate of ammonium phosphomolybdate is estimated visually, was verified on a number of the samples by separation and titration of the yellow precipitate with standard alkali and acid, using phenolphthalein as an indicator.

Chloride. A sample was titrated with silver nitrate, using potassium chromate as an indicator.

Tannin. The analytical method suggested by Berk and Schroeder (21) depending upon the reducing or oxygen-absorbing power of tannins and lignins was employed. The tyrosin reagent of Folin and Denis (18) is reduced to give a blue solution of a color density which varies with the concentration of the tannin or lignin. The reagent is sensitive to small amounts and is, therefore, particularly suitable for boiler and feedwater analyses.

Solutions needed include the following:

1 Sodium tungstate-phosphomolybdic acid: 100 g of sodium tungstate, 20 g of phosphomolybdic acid, and 50 ml of 85 per cent phosphoric acid are dissolved in 750 ml of water. The liquid is boiled under reflux for 2 hr, cooled, and made up to 1 l.

2 Saturated sodium carbonate: Add enough sodium carbonate to 1 l of water to supersaturate the solution with respect to $Na_2CO_3 \cdot 10H_2O$ and allow excess to crystallize.

3 Comparison solution: This solution represents the "standard" for the method and should be made up with exactly the same organic material that is fed to the boiler. Weigh out a 10-g sample of the solid and dissolve in 1 l of water. Let this be solution *A*. Pipette out 10 ml of solution *A* and dilute to 1 l to form solution *B*. Tannin solutions are slightly acid. They should be especially guarded against alkaline contamination, since, in the presence of alkalinity, oxidation of the tannin will take place and poor results will be obtained. If after a period of use the purity of the solutions is in doubt, make up fresh reagents.

The procedure is as follows:

1 A 50-ml filtered, clear, and cooled sample of boiler or feedwater, containing less than 20 ppm of tannin or lignin, is put in a Nessler tube. If the water contains more than 20 ppm, a smaller sample should be taken and diluted to 50 ml.

2 Make up 2 or 3 similar samples from the comparison solution *B* to contain lower and higher concentration of tannin or lignin than the unknown sample. A definite amount of solution *B* is diluted to 50 ml with distilled water to form each standard, according to the following table

Preparation of tannin or lignin standards

Tannin or lignin, ppm	Solution B, ml
0	0
2	1
4	2
6	3
8	4
10	5
12	6
14	7
16	8
18	9
20	10

3 Treat each known and unknown with 2 ml of the sodium tungstate-phosphomolybdic acid solution. Stir and allow to stand 5 min. Add 10 ml of saturated sodium carbonate to each sample, stir it, and allow to stand 10 min.

4 Match the blue color of the unknown with the knowns to estimate the amount of tannin or lignin.

This method of analysis is free from interference by sulphate, silicate, chloride, phosphate, hydroxide, and sulphite, as well as most of the positive ions encountered in water samples. Ferrous iron will, however, cause interference. Fortunately, in most alkaline boiler waters, the concentration is too low to cause difficulty. If a small amount of iron is present, it may be desirable to allow the sample to settle for a few hours before an aliquot is taken for analysis. This will cause some oxidation of the iron and allow it to precipitate. The tannin or lignin itself will not suffer appreciable oxidation over a short period at room temperature.

The method of analysis suffers interference from some organic materials, especially phenolic compounds which might be present in some feedwater. A blank should be run on the feedwater if appreciable interference is suspected.

One ppm of tannin will produce as much color as 4 to 7 ppm of lignin. In general, it would seem undesirable to add tannins and lignins simultaneously to the boiler feed, since this would complicate the analysis.

Summary of Papers Composing the Symposium[1] on Embrittlement[2]

By W. C. SCHROEDER[3] and A. A. BERK,[4] COLLEGE PARK, MD.

FOR over 30 years investigation and discussion of embrittlement have revolved around research from a few laboratories in the United States and in one or two foreign countries. The papers in this symposium advance the study into actual operation and show (*a*) how to determine that a boiler water is embrittling and (*b*) methods which may be followed to make it nonembrittling.

In this summary the results obtained by the contributors to the program are not treated separately; instead they are grouped to evaluate the protective action of tannins, lignins, sodium sulphate, sodium sulphate and sodium chloride, sodium phosphate, and sodium nitrate. Consideration of the combined data for individual chemicals clarifies the picture regarding their protective action and shows the degree of correlation existing between the results of various investigations.

Tannins

The work of Partridge, Kaufman, and Hall (5)[1] is the most extensive reported in this symposium on the use of tannins[5] as protective agents. The results show that these authors have been extremely successful in gaining the interest and co-operation of the plant personnel.

Their preliminary investigation of the effect of the number of adjustments on cracking has furnished the answer to a moot point concerning the embrittlement detector since it was first developed. Their Fig. 2 shows that this factor has no measurable influence on the results. Specimens cracked with as few as 2 or as many as 65 adjustments, and remained uncracked with over 70 adjustments.

Their statistical analysis of all their embrittlement-detector tests definitely shows a decrease in cracking of the specimens as the ratio of tannin to sodium hydroxide in the boiler water is increased. The effect appears to be extremely pronounced up to 250 psi, very low ratios preventing cracks. Above 250 psi, the ratio must in some cases be increased to about 0.4 to secure complete protection, but more data are desirable to establish this value accurately.

For any specific boiler water, these authors have developed a practical test program. If detector tests show that the water will cause cracking, inhibitor is added in progressively increasing amounts until the cracking is stopped. The satisfactory results secured in six illustrative cases, at pressures of 140 to 650 psi, indicate that, under the proper control, the tannin treatment should be generally effective. The authors also mention that this material is useful in sludge control, while Fager and Reynolds[6] have demonstrated its effectiveness in oxygen removal. These features should make it a valuable chemical in boiler-water treatment.

In most of their work, Partridge, Kaufman, and Hall have used quebracho tannins. Bird and Johnson (4) show a few tests with similar materials in their Table 10. Good protection was secured but they find that a small amount of sodium nitrate makes this material even more effective. This point should deserve further attention, although if the nitrate concentration becomes too high it may oxidize and destroy the quebracho so that no protective agent remains in the solution.

Lignins

Bird and Johnson (4) report extensive and systematic examination of the protective action of the lignin compounds. They are to be congratulated on their well-developed embrittlement-detector testing equipment and on the valuable data they have contributed to the symposium.

The lignin-sulphonate compounds which they investigated show definite protective action in most cases. Their observation that a small amount of nitrate greatly increases their effectiveness is an interesting one. In this combination, it would be anticipated that the nitrate would act as an oxidizing agent and largely disappear from the solution during the test. The increased protection may result from the slightly higher state of oxidation of the organic compound, or from the formation of an oxide film on the steel surface which may permit more tenacious adherence of the lignin film. The desirability for further investigation is obvious.

Bird and Johnson concentrated synthetic feedwaters in a small experimental boiler to prepare many of the samples for their detector tests. They show that, with constant alkalinity, more inhibitor must be added to the feedwater to prevent cracking of the detector specimens as the number of concentrations in the boiler increases. The solid line, in Fig. 1 of this summary, represents their data. They also give the concentrations[7] of organic inhibitor as well as the total alkalinity in the boiler water at the start of the embrittlement-detector tests. These values have been used to determine the position of the dotted line in Fig. 1, which indicates the ratio, as measured in the boiler water, of inhibitor to alkalinity required to prevent cracking. The value ranges between 0.42 and 0.58, but for boiler concentrations of 8,

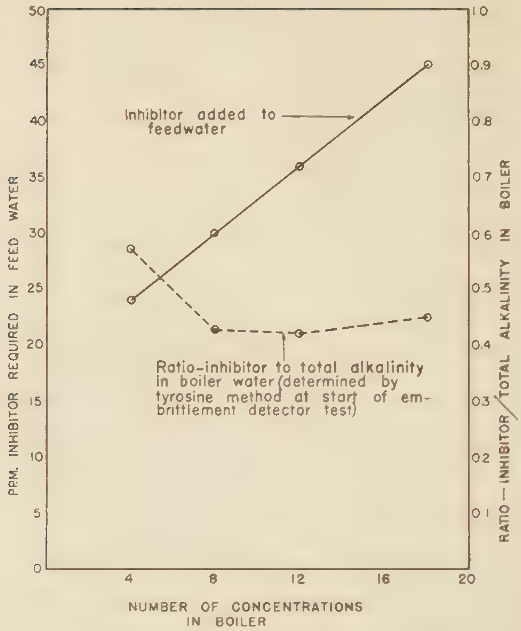

FIG. 1 INHIBITOR REQUIREMENTS VERSUS CONCENTRATION

12, and 18, the range is 0.42 to 0.45. From these data the protective action of the organic material (to which nitrate was added) appears to be independent of the number of concentrations in the boiler. Therefore, inhibitor must be lost between the feedwater and boiler water, and the effect becomes progressively greater as the number of concentrations increases. This might be due to adsorption on precipitating calcium salts, to thermal decomposition (an increased number of concentrations means longer exposures at high temperature), or to destruction by oxygen (the higher alkalinities resulting from increased concentrations would favor the reaction of the organic material with oxygen). *This work by Bird and Johnson emphasizes the necessity for basing treatment on analysis of the boiler water rather than on control of concentrations in the feedwater.*

Bird and Johnson obtained their results from laboratory testing and they have devoted major attention to lignin sulphonate. Bardwell and Laudemann (3), on the other hand, have investigated the use of waste sulphite liquor (which inhibits cracking largely because it contains lignin) in locomotive boilers. They show that this material was entirely effective at five or six locations on the railroad, but in three others the cracking had little direct relation to its concentration. The treatment was also unsatisfactory at Charlottesville, Va., even though the concentration of waste sulphite liquor was raised to nearly 70 per cent of the sodium-hydroxide alkalinity. *In these tests, sodium nitrate was not added* with the waste sulphite liquor, although some may have been naturally present in the feedwater supplies.

Bardwell and Laudemann (3) make the following statements concerning their work: "These tests would indicate that waste sulphite liquor is satisfactory on many waters, but its protective action can fail in some cases. This result seems to be in qualitative agreement with the most recent laboratory studies, although the reasons for the differences are still obscure.[8] In spite of these facts, however, the use of this inhibitor did bring a noticeable reduction in engine cracking over the 2-year period in which it was in use, and no cracked engines have been reported at Parsons, Fulton, or Newport News terminals since this treatment was started in February, 1938, whereas, a number had occurred previously."

This investigation by Bardwell and Laudemann strongly indicates the necessity for testing the action of the organic protective agents under operating conditions. It also shows that the embrittlement detector can be operated satisfactorily by the normal railroad personnel. Bird and Johnson would add greatly to the value of their results by a series of tests on operating boilers similar to those carried out by Bardwell and Laudemann.

SODIUM SULPHATE

Any discussion of the effect of sodium sulphate is usually based upon the arbitrary pressure ranges within which varying amounts of this substance are suggested by the A.S.M.E. Boiler Code. At pressures of 250 psi and above, the data from the entire symposium show that sodium sulphate will not stop cracking or failure of the test specimens. This agreement in results from five different investigations is gratifying, especially as the work covers the field from refined laboratory technique to tests on stationary and locomotive boilers over the entire United States. In the face of such evidence, the present recommendations for the use of this salt to prevent embrittlement lose their significance.

Below 250 psi, the studies by Bird and Johnson (4) show that sodium sulphate does not prevent cracking. The tentative correlation made by Partridge, Kaufman, and Hall (5), on the basis of what they are careful to describe as insufficient data, indicates, on the other hand, a possible protective action for this salt at these lower pressures. It should be noted, however, that these authors have included all the specimens in their statistical analyses and that the absence of cracking in any particular case does not necessarily indicate the effect of sulphate but, instead, *may show the protective action of tannin, nitrate, or other inhibitor.* In their Fig. 13 (5) it is possible to distinguish between the effect of the tannin and sulphate. *In all three pressure ranges cracking is found, in the absence of tannin, for A.S.M.E. ratios near the highest encountered in any of the boiler waters.* In direct contrast, a very small increase in the tannin ratio appears completely effective in stopping cracks in the two pressure ranges up to 250 psi. Above 250 psi, a higher ratio of tannin is necessary.

Partridge, Kaufman, and Hall have referred to published data

concerning the action of sodium sulphate in detector tests on a boiler operating at 130 psi. This work was carried out by The Detroit Edison Company, and the results are shown in Table I of this summary. Tests were run in duplicate and all eight specimens cracked in spite of the fact that the sulphate ratios were held very high.

Straub's plotted data (1) show cracking and failure of a number of specimens at 230 psi with sodium sulphate to total alkalinity ratios well above 2.

There is no consistent evidence from the combined data in this symposium that sodium sulphate will stop cracking of the specimens either at high or low boiler pressures.

Sodium Sulphate and Sodium Chloride

Several of the chemicals for preventing embrittlement, that have been investigated by some of the authors in this symposium, were originally suggested during Straub's early work on embrittlement.[9] As a result of investigation with a new type of testing equipment in 1938,[10] Straub expressed the belief that sodium sulphate and sodium chloride together would prevent cracking up to 250 psi. In the current symposium, he presents further data on the action of these salts (1). Several of the other papers in the symposium offer no support for the belief that these salts act as protective agents.

Above 250 psi, the data from the symposium are in agreement that these salts have no protective action.

Sodium Phosphate

Results obtained by Purcell and Whirl, and Bird and Johnson, as well as by Partridge, Kaufman, and Hall, all show that sodium phosphate will not prevent embrittlement cracking in the presence of appreciable concentrations of sodium hydroxide.

Purcell and Whirl (2), in their tests at Reed Station on a boiler operating at 450 psi, eliminated the embrittling tendencies of the water by the most direct method of all, i.e., elimination of all alkalies which will yield sodium hydroxide when the boiler water is concentrated. The desired pH was secured by the addition of sodium phosphate alone.[11] This treatment must not be confused with the unsuccessful method of using sodium phosphate as an inhibitor in the presence of sodium hydroxide.

The results reported by these authors (2) in their Table I show that their Reed Station boilers unfailingly cracked specimens in 30 or 60 days with free[12] sodium hydroxide concentrations above 33 ppm (OH above 14 ppm); on the other hand, when this constituent was eliminated all cracking stopped for periods at least up to 90 days. The pH in the boiler water, in the absence of free[12] sodium hydroxide and with PO_4 concentrations between 60–70 ppm, was slightly above 10.5.

The unique method developed by these authors for controlling the phosphate treatment further enhances its value. Tricky chemical analyses that are difficult to interpret are avoided. It is only necessary to measure the pH value and the PO_4 concentration to estimate from their Fig. 8 if any free[12] hydroxide can be present.

The treatment used by Purcell and Whirl (2) has other advantages. In cases of steam blanketing, Partridge and Hall[13] have noted that high NaOH concentrations may increase the rate of attack on the metal. They can also increase carry-over and contribute to the stickiness of the solids with consequent turbine-blade fouling. Elimination of the sodium hydroxide may be advantageous in all of these respects.

Purcell and Whirl have conducted their tests in a skillful and thorough manner and have been willing to pioneer in new methods of water treatment.

Sodium Nitrate

Data have been published showing that sodium nitrate will prevent cracking of embrittlement detector specimens at 210 psi.[14] The data in Fig. 10 of the Partridge, Kaufman, and Hall paper (5) are in satisfactory agreement with these published results at pressures below 450 psi. Low concentrations of sodium nitrate did not prevent cracking when the pressure exceeded 600 psi. Purcell and Whirl found that no cracking occurred at Stanwix (105 psi), where the nitrate averages about 20 per cent of the caustic alkalinity.

Bird and Johnson (4) find from their laboratory tests that nitrate is an effective inhibitor in some instances but not in others. Their reported concentrations of nitrate represent the amount added at the beginning of the test and not the amount found at the end. The present writers are inclined to believe that failure occurred where the protecting nitrate was destroyed during the test. This loss might be especially pronounced if the bomb surfaces were coated with organic materials from previous tests, as these would tend to reduce and decompose the nitrate.

Bardwell and Laudemann (3) have carried out extensive testing with sodium nitrate on the Chesapeake & Ohio Railway. This was done with embrittlement detectors attached directly to switch engines at various locations on the railroad. In this work they show that the detector can be operated by the normal railroad personnel to secure consistent results and they outline the method by which they insured the interest and co-operation of each individual engaged in the work. Their suggestions should not be difficult to follow on any railroad well organized for the treatment of boiler waters.

Their results show that sodium nitrate prevented cracking at all locations except one. At Ashland, Ky., Fig. 2 of paper (3), two specimens showed slight cracking, but even this minor trouble has been eliminated. At several locations, the nitrate has proved to be definitely superior to waste sulphite liquor as a protective agent.

Conclusions

Effective chemical inhibition of embrittlement presumably results from the reaction of the treating chemical with the steel surface to produce a protective film. In all laboratory tests reported up to the present time, the same solution has been used throughout the test period. Since it is in contact with a relatively large surface of hot metal, a continuous decrease in the concentration of inhibiting chemical generally occurs. On the other hand, in the tests on operating boilers, any desired amount of chemical, within reasonable limits, can be maintained in the boiler water and this is the solution which is circulating through the detector.

Experiments have already shown that this difference between laboratory and plant tests can profoundly influence the results. It is probably responsible for some of the differences which have been noted in this symposium. However, the results of embrittlement tests carried out on the boiler would more nearly represent the action of the water in the riveted seam than would the

laboratory tests carried out on isolated samples of the boiler water.

The following conclusions concerning the effect of a number of chemicals in preventing embrittlement are based upon all the data that have been submitted in this symposium:

1 Certain tannins, especially those of the quebracho type, will retard embrittlement-cracking in test specimens. Relatively low concentrations are sufficient, even at the higher pressures. The protective action probably decreases around 500 psi, although the tannin has been successfully used in several cases at 650 psi.

2 Lignins will prevent cracking of test specimens in many boiler waters. In some instances, however, they are not satisfactory. One investigation has indicated that their protective action may be increased by the use of a small amount of sodium nitrate. This possibility needs further study.

3 The data in the symposium do not show that sodium sulphate will prevent embrittlement cracking in test specimens.

4 The data in the symposium are in agreement that sodium sulphate and sodium chloride do not prevent cracking at pressures above 250 psi. At lower pressures, the various authors are not in agreement concerning the action of these salts.

5 A boiler water containing sodium hydroxide in appreciable concentration cannot be treated with sodium phosphate to prevent cracking in specimens.

6 Embrittlement can be prevented by eliminating from the boiler water all alkalies which will yield sodium hydroxide when the water is concentrated. The pH in the boiler water is then maintained by the use of sodium phosphate. Simple chemical methods have been worked out for controlling this treatment.

7 Sodium nitrate appears to inhibit embrittlement in the detector tests at least up to 300 psi.

Final proof of the value of the embrittlement-detector method of testing has been provided by Bardwell and Laudemann on the Chesapeake & Ohio Railway. Their work was not a result of academic interest in the embrittlement problem, but instead was due to the pressing necessity for preventing cracks in 22 to 40 locomotive boilers each year. While this condition was unfortunate for the railroad, it furnished perhaps the only chance that will ever be available for determining the effect of protective chemicals in a number of operating boilers otherwise probably destined to crack. At the same time, direct correlation was possible between the action of the water on specimens in the embrittlement detector and in the cracking of locomotive boilers.

Fig. 2 of this summary represents the number of boilers found cracked during each 6 months since 1934. From this time

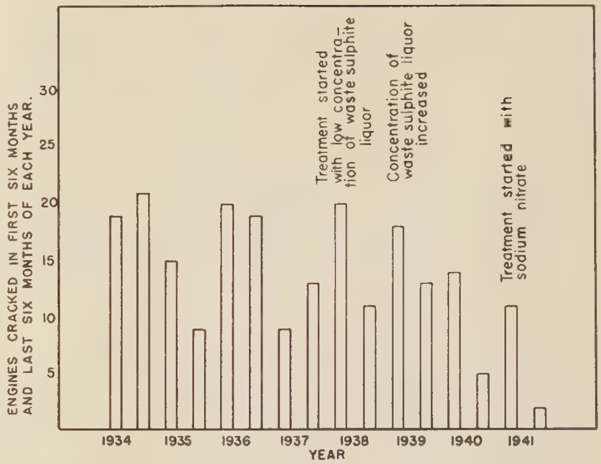

Fig. 2 Effect of Treatment With Waste Sulphite Liquor and Then Sodium Nitrate on Locomotive-Boiler Cracking

through 1938, there were never less than 9 and a peak of 21 was reached.

During 1938 and 1939, treatment was started with waste sulphite liquor. No appreciable decrease in cracking was noted during 1939, nor was it expected, since old cracks in the boilers must be found and repaired, a process that would probably require a few years for completion. In 1940, the last 6 months showed a decrease in the number of cracked boilers. In 1941, cracking rose in the first 6 months but results for the last 6 months are extremely gratifying, for only two boilers were found cracked. This is particularly significant since the engine mileage during this period has been much greater than that for any similar period in the previous years which are shown. The results furnish strong evidence that this railroad is on its way to elimination of its embrittlement troubles.

The fact that the decrease in engine cracking follows the elimination of cracking in the detector specimens indicates that the establishment of nonembrittling conditions, according to this test, is a strong criterion that the water can be used in the boiler without danger. On the other hand, if the boiler water cracks the detector specimens, it will not necessarily crack the boiler, yet it is difficult to guarantee that conditions do not exist or will not arise in the boiler structure from which cracking may result.

Discussion—Symposium on Embrittlement

Comment on Paper by F. G. Straub (1)

T. C. Rathbone.[1] In his discussion of results, the author indicates the possible necessity of modifying the laboratory control tests to conform with actual operating results. It is suggested that some of the difficulty may be caused by unanticipated stresses in the test specimen.

The construction of the embrittlement-testing unit, as illustrated in Fig. 1 of the paper, would indicate the possibility of eccentric loading on the specimen walls in spite of any ordinary guides, by reason of the nonaxial reactions of the compression-spring coil ends on the rigid pull-rod assembly. If this is so, the combined tensile stress on one side of the specimen might become very appreciably greater than the stress arrived at by formal calculation.

The attempt is made to stress the specimens at 40,000 psi, or about 11 per cent above the yield strength, to provide comparable results in a reasonably short time. It was found that if the stress is increased above 50,000 psi, or about 40 per cent above the yield point, no reasonable combination of salts will prevent failure. Differences of a few thousand pounds pressure more or less are apparently critical. Yet the combined stresses possible with eccentric loading may introduce deviations of several thousand pounds.

With no data on the actual dimensions of the test unit at hand to venture calculation of possible eccentric stresses, the following dimensions were assumed by scaling the illustrations: Outside diameter at test section, 0.6 in.; inside diameter, 0.5 in; wall thickness, 0.05 in.; and mean diameter of spring, $2^1/_2$ in. Considerable variations from these assumptions will not materially affect the nature of the results.

Assume that the ground coil ends provide effective and uniform bearing over three quarters of the full circumference. The centroid of this loading would have an eccentricity of 0.3 radius, or 0.375 in. If the load centers of both ends are in line, this would be the moment arm of the eccentric load on the specimen and pull-rod assembly. The area of the tube section is 0.0865 sq. in. With a nominal stress of 40,000 psi, the actual spring load is 3450 lb. The bending moment on the specimen is therefore 1300 in-lb.

The moment of inertia of the section is 0.0033 in.[4] and extreme fiber distance, 0.3 in., from which the bending stress is $S = \frac{cM}{I} = \frac{0.3 \times 1300}{0.0033} = 118{,}000$ psi, to be added to the 40,000 psi direct stress on the tension side and subtracted from the opposite side. The stress on the inner wall will be only slightly less.

Obviously, with these assumed data, the guides must at least be partially effective, otherwise immediate failure would always occur. However, such guides cannot prevent all flexure and still leave the surfaces free to slide; also, the slightest amount of clearance would permit appreciable bending stresses. If the coil-end reaction centroids are diametrically opposite instead of being in line, the test-rod assembly will assume a compound flexural curve, and the guides, near the neutral point, will be still less effective in preventing lateral displacement.

The magnitude of these figures would indicate that even with guides, extraneous stresses of sufficient order to confound the test results may have existed.

The possibility of additional bending stresses can, of course, be explored with extensometers or, more simply, by applying the "stress-coat" method used by Professor de Forest, which consists

[1] Chief Engineer, Turbine and Machinery Division, The Fidelity and Casualty Company of New York, New York, N. Y., Mem. A.S.M.E.

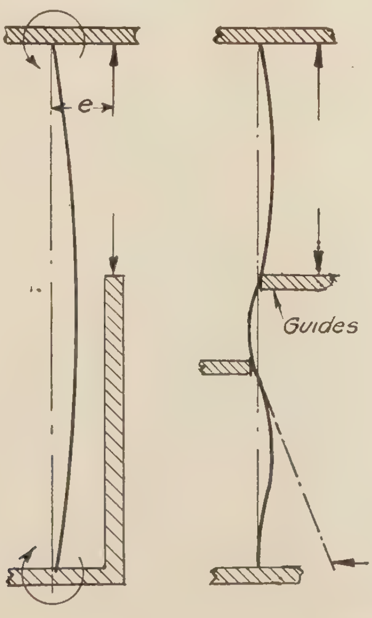

Fig. 1 Showing Possible Bending Stresses

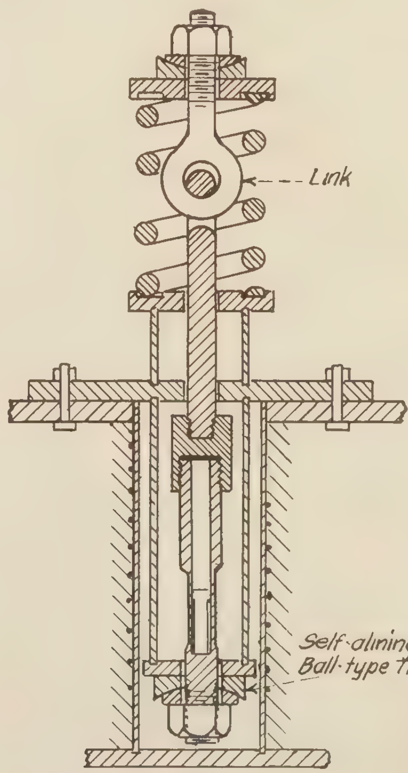

Fig. 2 Suggested Changes in Apparatus to Eliminate Stresses Caused by Both Misalignment and Eccentric Loading

in coating the surfaces with a special brittle lacquer and observing the cracking or "crazing" of this coating when the test piece is loaded. Rough approximations of stresses as low as 20,000 psi can be made. Any nonuniformity of stressing would instantly be exposed by the denser and more closely pitched cracking occurring on the more highly stressed side.

To avoid the possibility of imposing compound stresses on the specimen, either by misalignment or eccentric loading, it is suggested that links be interposed in the extension pull rod, and also that the rigid threaded connection at the bottom be replaced by a spherically seated ball-type thrust bearing.

It is presumed that the spring scale is such that the plastic yielding of the specimen will result in no appreciable change in the loading; that no residual torsional stresses can be imposed by tightening the nut; and that the stress due to the trapped steam pressure is negligible.

Comment on Paper by T. E. Purcell and S. F. Whirl (2)

H. E. Einert.[2] This paper (2) represents a distinct contribution to feedwater treatment and control, particularly for high-pressure boilers. We are primarily interested in pressures in excess of 1000 psi, at which pressure the use of nitrates or organic material such as quebracho and lignin is excluded.

We have found definite indications of cracking of the test bars by means of the Schroeder embrittling detector at 1400 psi, when the hydroxide content has been in the neighborhood of 30 to 50 ppm. Incidentally, the cracking has been identified as truly intercrystalline. On the basis of the curve, as suggested in Fig. 8 of the paper (2), if the pH value of the boiler water is maintained at 11, there must be a PO_4 concentration of approximately 115 ppm. This, of course, is much higher than we would normally recommend. From the standpoint of solids, the hydroxide concentration as determined by the strontium or barium procedure's being entirely eliminated, the solids concentration of the boiler water is increased, but not excessively. Whether the elimination of the hydroxide concentration with an appreciable increase in phosphate would have any effect on carry-over can only be conjectured. It would, however, be our opinion that there should not be any increase in the amount of carry-over.

At plants where corrosion has been experienced in floor tubes and which condition has been diagnosed as sluggish circulation, with the attendant "steam-binding," the pH value has been decreased in order to eliminate the OH radical. With the maintenance of 100 to 120 ppm of PO_4 in the boiler water, the complete elimination of the OH radical is possible, under which conditions the reduction in the pH value need not be made. We have always been opposed to lowering the pH value in the boiler whenever the PO_4 has been held at normal concentrations.

The authors indicate that adjustments of the embrittlement detector are made only once in 7 to 10 days. This is very interesting to us, as most of our clients find it necessary to make adjustments more frequently.

We note that some of the tests were conducted for periods ranging from 90 to 195 days. Certainly, this is a step in the right direction, for we feel that a 30- or 60-day test period is not sufficient, unless, of course, the bars are positive with respect to cracking. In our opinion, tests No. 107-A and B, which were run for 90 days, give conclusive evidence that cracking would not occur, regardless of the length of time the test might be run. The SiO_2 content reported for tests Nos. 106, 107-A, and 107-B are comparable to those tests reported for Nos. 102 and 103, and on this basis, we believe that the authors have eliminated one variable, namely, the silica concentration. The radical decrease in hydroxide concentration is striking and, under the conditions of the test, must certainly be a dominating factor.

No determinations of pH are recorded, but these would have been of interest in the paper. An additional test would have been worth while, in which the pH values were placed on a comparable basis for tests Nos. 101, 102, etc.

This, of course, would mean increasing the phosphate concentration to a value in excess of 100 ppm. On the basis of about 65 ppm of PO_4, we interpolate the pH value to be about 10.7. We do not believe that there would have been any difference in the cracking characteristics of the water if the phosphate concentration had been increased from about 65 to 110 ppm of PO_4.

For those plants that use sea water as cooling water and where the leakage would be predominantly noncarbonate hardness, the soluble PO_4 would be removed without liberating an equivalent sodium bicarbonate, which eventually would decompose into sodium hydroxide. The absence of the hydroxide would permit the control to be carried along much more readily than in plants where the carbonate hardness is relatively high when compared to the total.

Comment on Paper by R. C. Bardwell and H. M. Laudemann (3)

F. G. Straub.[3] In the chemical-engineering department of the University of Illinois, we are primarily interested in research. However, we realize that research, to be of real value to industry, must be at least partially correlated with industrial operation before the maximum industrial utilization of the results is possible. In the development of the embrittlement-testing unit, it was so designed as to give results which were apparently in agreement with available operating data.

The question is often asked: "Where and how have you obtained the operating data?" Early in our research, we contacted the power-plant operators with the purpose of obtaining as many data as possible. At that time many of our sources of information were of a confidential nature. We have summarized the data obtained and published them without revealing the source of the confidential information. Now for the first time since starting this work we find it necessary to betray this confidence placed in us and to reveal the source of part of our confidential information. We do this in the interest of the power-plant industry and only after the identity of the source of our information has been revealed by the authors of this paper (3). We would still hesitate to reveal the source of the data, if it were not for the fact that the authors state that certain data obtained from the same source are contradictory to the data furnished us in 1925 and 1926. The authors state, "In the early experience of the Chicago and Northwestern Railroad with embrittlement, it was noted that embrittlement cracking predominated on the divisions on which the sulphate was high." In his files, the writer finds the following memorandum: "January 29, 1926, I visited Chicago Northwestern Railroad and talked with Messrs. ——— and ——— at the Chicago shops. I was shown analyses of locomotive boilers at the time of washout of eight locomotives. Two were high in sodium carbonate and low in sulphates. One of the locomotives, from which the high-carbonate and low-sulphate water came, operated around Powers and Escanaba, Mich. This locomotive was in the shop with embrittled plates. I also received analyses from raw waters on the Green Bay Division in which this cracking predominated. All of these analyses showed low sulphates. The treatment given these locomotives was 1 lb of soda ash to 1000 gal of water. Such a treatment would produce a boiler water having low sulphates and high alkalinities."

[3] Research Professor of Chemical Engineering, University of Illinois, Urbana, Ill.

From these data, we were at that time led to believe that the experience of the Chicago and Northwestern Railroad showed definitely that their locomotive cracking was confined to boiler waters of low sulphate instead of high sulphate content, as stated by the authors. This being a fact, the writer wonders if the authors' statement that their experience on the Chesapeake & Ohio Railroad is similar to that of the Chicago and Northwestern Railroad might not lead one to conclude that their further statements, to the effect that high sulphates favor embrittlement, could also be reversed to show that their cracking has taken place on low-sulphate boiler waters.

A rather brief survey of the meager operating locomotive-boiler-water data, given in the paper, would indicate that the cracking they described has not occurred in locomotives having boiler waters with a high sulphate-to-alkalinity ratio. A breakdown of the summarized data given in Table 2 of the paper (3) gives data that definitely show that the A.S.M.E. ratios were not maintained in these locomotive boilers. From the data previously published, from which the summary in Table 1 is taken, it is found that, during 7 years, 176 analyses were made on water samples obtained from eleven engines. This amounts to less than $2^1/_2$ analyses per year per engine. A further examination of the analyses indicates that $28^1/_2$ per cent of the analyses have an A.S.M.E. ratio of less than 2; and 24 per cent have a ratio between 2.1 and 2.5. Thus, these analyses would indicate that the ratio had not been definitely maintained in the engines in question.

The authors state: "The history of engine I is especially interesting, as the second course was renewed at the end of 1936, and again in the early part of 1938. During this interval, the analyses showed fairly high sulphate values." A summary of their own analyses during this interval shows one analysis during 1936 with a ratio of 1.5. During 1937, twenty analyses are reported, although they do not state from what locomotives these analyses were taken. Of these twenty analyses, 35 per cent have a ratio less than 2; another 35 per cent have a ratio between 2 and $2^1/_2$; the final 30 per cent have a ratio between $2^1/_2$ and 8. During 1938, twenty analyses were also made, and these in turn have ratios almost identical with those reported for 1937. This analysis of the information given certainly does not indicate that the A.S.M.E. ratio was maintained in these boilers.

Data furnished by the authors indicate definitely that they did not maintain the A.S.M.E. ratio in the cracked boilers which they describe.

The results with the Bureau of Mines detector, which the authors report, relative to the effectiveness of the organic material in the nitrates in preventing failure, are extremely interesting. These results seem to agree with those which appeared in a bulletin[4] by the writer in 1930.

Comment on Paper by E. P. Partridge, C. E. Kaufman, and R. E. Hall (5)

F. R. Owens.[5] The writer is indebted to the authors for their contribution, and particularly for the statement of their conception of the research: "Even though the measurement be rough, the way has been opened to approach the problem of cracking, not by arguing as an advocate, but by testing as an engineer."

The writer can very readily subscribe to this brief and general statement and feels that an expansion of the thought in this discussion will, at least in part, present the authors' reasoning in arriving at the stated conclusion.

A review of the literature on intercrystalline cracking in boilers leads the lay mind and, in many instances, the professional one to confused uncertainties with respect to protective chemical methods. The writer has encountered this expressed criticism innumerable times from operating engineers.

It is obvious, at least to the writer, that the mechanical and chemical environment which promotes intercrystalline cracking is quite involved, and investigations to date have not successfully isolated all factors. In view of this, the controversial status of the subject is a natural sequence.

As the authors point out, even though the detectors developed by Straub[6] and Schroeder[7] and their associates have decided limitations, the fact remains that they have given us a laboratory and plant method for measuring effect. Furthermore, as the authors indicate, even though we may favor the use of a certain inhibitor, on the basis of our present-day knowledge, we can definitely eliminate the possibility of prejudice and determine the chemical environment which effects maximum protection for a specific operation.

The reproduction of existing chemical and mechanical environment in any plant is certainly an ambitious task. In fact, from the viewpoint of circulation; heat input and distribution; stress, applied or residual; the delivery and maintenance of protective materials in the film surface of the liquid; concentration of all salts, and their respective influence on each other; and many other factors, we face seemingly hopeless tasks at such reproduction. Hence, the Straub and Schroeder detectors offer real help in reducing the problem to a more factual basis. It behooves those of us engaged in this particular field of endeavor to encourage their use as additional assurance of safe operation of boilers.

From our experience with the Schroeder detector, we wish to discuss two factors, and suggest that both Straub and Schroeder investigate them, if possible. Our experience tends to indicate that the amount and nature of the precipitated products in the boiler concentrates may be a factor with respect to intergranular cracking.

Also, the solubility of ferrous hydroxide would appear to be pertinent. The work of Whitman, Russell, and Davis[8] showed definitely that a close relationship exists between the rate of corrosion and the solubility of ferrous hydroxide in the presence of certain salts of different concentrations. They further revealed that this is also true of alkalies. Their results demonstrated that, as the concentration of the solution increases, the solubility of ferrous hydroxide, formed in the film surface of the liquid, either increases or decreases. If the solubility of the ferrous hydroxide increases, corrosion increases, and conversely, if the solubility decreases, the rate of corrosion is lowered.

Therefore, it would appear to be feasible to check various inhibitors in boiler waters of various concentrations with the Straub and Schroeder detectors and to attempt, by means of them, to determine the effect and nature of precipitated products.

The authors are to be commended on their suggested use of embrittlement detectors as engineering instruments. Their approach to the problem may well be one which this Society can support, rather than the adoption of definite rules for the maintenance of specific ratios.

[The general discussion of the papers composing the Symposium on Embrittlement follows directly.]

General Discussion

L. D. Betz.[9] The authors of all of the papers presented in this symposium are to be commended upon the details with which their data have been assembled. In the evaluation of these data, however, and in drawing conclusions from them, there are several points which might be clarified yet further.

For instance, in the paper presented by Partridge, Kaufman, and Hall (5), no statement is given to indicate the types of containers used in sampling the boiler waters. If the boiler waters, of an alkaline character, were obtained in glass, then there is a likelihood that the silica values may be high because of a pick-up of silica from the glass. The amount of silica picked up may not be sufficient to alter the general conclusions drawn, but in interpreting the data, it should be borne in mind that the silica values shown are slightly higher than the true values, provided glass sample containers were used.

In the same paper, it is noted that the authors employed the tyrosine method, proposed by Berk and Schroeder, for determining the tannin content of the boiler water. At this point, it is well to raise the question as to whether or not these tannin determinations were made at the plant immediately after collection of the boiler samples, or whether tannin determinations were made at a later period on samples forwarded to the laboratory. If the latter case is true, the values obtained will be considerably lower than were actually present in the boiler water at the time of sampling. Considerable work has been done in our laboratories, which indicates that there is an appreciable change in the tannin content, with an elapse of time, when determined by this method. This change is more pronounced in alkaline tannin solutions. The drop in active tannin is also dependent upon the initial tannin concentration. Such a drop, however, is of sufficient magnitude so that testing of a sample several days after it was drawn would present an entirely erroneous picture of the tannin content of the boiler water at the time of sampling.

A statement from the authors on these points will aid in the interpretation of the data presented.

In the paper by Bird and Johnson (4), covering the laboratory investigations of embrittling characteristics with the Schroeder detector, the authors present a wealth of valuable data and are to be complimented on the excellent manner in which this study was conducted and presented.

In our field experience with the Schroeder detector, many instances have occurred in which nitrates, naturally present in the make-up water, have appeared to be the factor preventing cracking of specimens, even with low concentrations of sulphate and extremely high alkalinity. It is possible that, when nitrate is naturally present, inhibitory properties are possessed by many waters used for make-up.

However, from our experience, we do not feel that it is a safe procedure to rely entirely upon the natural nitrate content of a make-up water for complete inhibition of embrittlement, without periodic checks for the nitrate concentration of the boiler water. We have found that the nitrate concentration present in many raw supplies is subject to considerable seasonal variation and while, at one season, it may be sufficient to prevent cracking of detector specimens, at other periods of the year, it may be reduced to a negligible value and thus afford no protection whatever.

Incidentally, nitrate determination is frequently overlooked in a water analysis. Many will be surprised to learn how often fairly large quantities of nitrate are present in a feedwater, especially if there is any opportunity for the raw supply to become contaminated with sewage.

We have been privileged to work with the Joint Research Committee on Boiler Feedwater Studies and have installed quite a few Schroeder detectors at various plants throughout the United States and Canada. We have not presented separate records of the results of these installations but have forwarded all data and results to Dr. Schroeder. No doubt, he has incorporated these records in his complete files on the subject and has probably included them in the data of his summary.

The subject of caustic embrittlement or intercrystalline cracking has been extensively treated in this symposium as has also the Schroeder detector. That this instrument provides a very greatly accelerated condition of caustic embrittlement is clearly evident. Apparently, specimens in this detector crack far in advance of any actual cracking of the boiler metal. Therefore, the question is raised: Is this acceleration increased to a point beyond that condition reached in the actual boiler metal? In short, does it necessarily follow that cracking of a specimen under the accelerated conditions in a Schroeder detector implies similar conditions to be expected in the boiler metal? Have any cases been recorded where a Schroeder detector showed failure and where the boiler metal showed a similar condition? These detectors have now been in use for a considerable period of time, and it is hardly likely that lack of sufficient time can be the cause for a negative answer to this question. True, anyone who finds cracking in a specimen of a Schroeder detector will waste no time in attempting to establish proper ratios to prevent this action for boilers are expensive equipment. Certainly no operator will deliberately permit a condition such as this to exist, if it can be prevented. But have we any records to indicate that the cracking of a sample in a Schroeder detector forecasts a condition of actual embrittlement in the boiler metal? Bardwell and Laudemann (3) have indicated the other side to this question by showing how embrittlement of the locomotive-boiler metal apparently ceased when failure of the specimen did not occur in the Schroeder detector.

C. B. Bryant.[10] It is noted that the papers, constituting this symposium, have not dealt with one phase of the intercrystalline-corrosion problem, namely, the economic justification of the various methods of embrittlement protection.

It has been clearly brought out that the development of intercrystalline corrosion is a consequence of the simultaneous occurrence of several factors: (*a*) the boiler metal must be highly stressed, (*b*) there must be leakage, (*c*) there must be such conditions that, as a consequence of the leakage, the dissolved solids in the boiler water become highly concentrated in contact with the boiler metal, and (*d*) the chemical characteristics of the dissolved solids must fulfill certain requirements. In other words, the existence of intercrystalline corrosion depends upon a chain of circumstances, hence the destruction of any link in this chain would prevent embrittlement.

It occurs to the writer that the prevention of embrittlement by chemical treatment of the water in the boiler may not be the most economical method of attacking this problem. If stress-relieving a boiler at the time of original construction will prevent the possibility of intercrystalline corrosion regardless of the water characteristics, then a single expenditure will settle the problem for the life of that particular unit. If, on the other hand, the development of embrittlement is prevented by treating the water, there is a continuing expense for the purchase and application of the treating chemicals which, conceivably, during the life of a boiler, might be much more expensive than the original heat-treatment which would accomplish the same end.

The tannins, used by different experimenters as embrittlement inhibitors, come from various sources, and, obviously, are not all

[9] General Manager, W. H. & L. D. Betz, Philadelphia, Pa. Assoc. A.S.M.E.

[10] Engineer of Tests, Southern Pacific Railway System, Alexandria, Va.

of the same chemical composition. It seems likely and has been suggested by some experimenters that there are definite active components of the mixtures we speak of as tannins, which, although present only in small quantity with respect to the total amount of tannin compound, are responsible for the beneficial effects. It seems worth while to suggest the attempt to determine what these active constituents might be, which would perhaps afford a means of better understanding the nature of the protective action, and might even result in lowering the cost of the protective treatment. This situation may be similar to the development of vitamin preparations from fish oils. A number of years ago children were fed a teaspoonful of cod-liver oil per day in order to provide the proper vitamin dosage. Later it was found that the useful and active constituent of cod-liver oil was present only in minute quantity and, by the preparation of concentrates of the beneficial and active constituents, the accuracy of dosage was greatly improved and the amount of material considerably reduced. If it could be shown similarly that certain definite chemical compounds, constituting only a small portion of the tannins used in boiler-water treatment, are responsible for the results secured, then the way might be pointed to better understanding and improvement of the practice as well as toward a reduction in the cost.

L. F. Collins.[11] After carefully explaining why in his test apparatus the metal specimens are stressed only at about 40,000 psi, Straub (1) makes the following statement: "It has been found that if the stress is increased to around 50,000 to 55,000 psi, no reasonable combination of salts, either inorganic or organic, would prevent failure."

The inference is that a "critical stress" exists, at which it is impossible to prevent intercrystalline failures, of the common types of boiler metal, by adding to otherwise embrittling waters chemical inhibitors in amounts commensurate with other boiler-operating considerations. This seems to be attested to by the data of Bird and Johnson (Tables 1 to 7, paper 4), obtained with Schroeder detectors, as summarized by their statement: "The amounts of inhibitors indicated as being required by these boiler-water tests seem excessive . . ."

If the foregoing is a valid outline of the situation, and keeping in mind the uncertainty of the stresses which may be present in various areas of an operating boiler, two important conclusions are unavoidable:

1 The boiler-water chemist has completed his portion of the job of solving the embrittlement problem, because he has disclosed the existence of a number of chemicals which prevent failures when the metal is stressed below the critical value.

2 The ultimate solution of the problem of intercrystalline boiler-metal cracking is not within the province of the water chemist but rather becomes the heritage of the engineer and/or the metallurgist.

In pursuing conclusion 1, it is indicated that in boilers such as, for example, locomotive boilers, which may be subjected to all types and degrees of stress, the use of optimum amounts of inhibitors would conspicuously reduce the number of failures but would not entirely eliminate them. The Bardwell and Laudemann paper (3) discloses precisely this situation.

D. K. French.[12] In the past, there has been some skepticism as to the possibility of tannins' being of value in inhibiting embrittlement. It is difficult for the writer to understand why, at times, there is so much opposition to certain methods of treatment. The use of tannins was given to the engineering public very nearly 15 years ago, and it is felt that Drs. Straub and Parr should be given some credit for this initial work. It might be interesting to state that, even as early as the summer of 1923, the writer was in correspondence with Dr. Parr regarding the use of tannins and endeavored to have explained some of the reasons of the inhibition which was being obtained by tannin treatment of definitely embrittling types of water.

Early in the summer of 1927, when the Boiler Code provisions for the use of sulphates was seriously handicapping the treatment of certain plants under the writer's observation, a meeting was arranged at the University of Illinois, with Drs. Parr and Straub. The difficulties being experienced were explained to Dr. Parr, and arrangements were made to carry out experimental work on three different types of treatment which the writer had recommended for high-alkali waters. It was agreed that samples of the water would be supplied but, in the meantime, because he has always been actively interested in the problem, Dr. Straub obtained some tannic acid from the University of Illinois stockroom and before the week was up had come to Chicago to tell the writer that it had been impossible to break any of the test bars. He was greatly excited over the results. The results of this work were made public.[13] In concluding that report Dr. Parr stated, "As result of the experimental work, new embrittlement-inhibiting agents have been developed." While the writer has used the results then reported as the basis of treatment and has never yet had a case of embrittlement develop, it was very difficult to obtain support for the procedure.

While Dr. Straub was willing to confirm the original results, he did not give them publicity because of the difficulty of determining the presence of tannins in the boiler water. It is quite possible that the work of the Bureau of Mines in developing such a method is responsible for the emphasis on this agent now. An interesting explanation of the action involved appears in a bulletin[14] by Dr. Straub, from which the following statement is taken:

"The action of the organic matter is apparently different from that of the sodium sulphate in preventing the deposits. There is apparently a chemical reaction between the organic matter and the sodium hydroxide in the superheater, which changes the hydroxide to carbonate. This reaction does not take place until the sodium hydroxide reaches a high concentration. Thus, in dilute solutions at boiler temperature, the sodium hydroxide remains as such in the presence of these organic materials. However, as the sodium hydroxide mixed with the organic matter concentrates in the superheater, the concentrated sodium hydroxide reacts with the organic matter to form sodium carbonate."

According to Dr Parr, sodium carbonate, as such, has inhibiting properties.

With reference to specific cases, the writer can mention two without identifying them at this time.

One is a mine in West Virginia, utilizing water, which apparently is collected after passing through a natural green-sand deposit, because it carries between 25 and 30 grains, or 500 ppm of free alkali as sodium carbonate, and practically no hardness. When the writer was first consulted on this plant, the operators were pleased with the nonscaling results obtained from the use of this water supply. The writer gave warning against embrittlement and a year later was retained to prevent it in the future because four out of six drums were then being replaced as the result

of this trouble. The treatment supplied consisted of tannin extract and phosphoric acid, which was added to the water so that 1 part of tannin would be present to each 20 parts of alkali, or 1 part of organic matter of tannic origin to 10 parts of alkali.

The method of ascertaining the presence of tannin was an indirect one in which total alkali, total chloride, and total sulphate were determined and calculated as the soda scale and substracted from a carefully run and corrected solid residue. The difference could be nothing other than organic matter. Based upon this treatment, this plant has been supervised for nearly seven years up to the present time, without the slightest indication of any embrittlement cracking showing, although the boilers are carefully inspected—sometimes twice a year.

The other case is that of a laundry in Winnetka, Ill. In this plant, well water, which has been treated with an exchange silicate softener, supplies feedwater containing approximately 150 ppm of free alkali directly to the boiler. The use of this supply resulted in the replacement of one drum before the writer was called in to supervise the operating conditions. The condensate, collected in the supply lines on the laundry floor, was very highly alkaline, showing about 250 ppm total solids. Apparently it was quite corrosive. A treatment combining tannin, acid phosphate, and acetic acid was used, the tannin content being controlled by indirect methods of analysis just as in the previous case. Operations have improved so greatly that the writer's term of service is apparently an indefinite one.

It might be interesting at this time to comment on one feature of this treatment which, to be perfectly frank, the writer fails to understand himself. While the feedwater introduces its alkali entirely as carbonate and bicarbonate of soda, and while the boiler water shows approximately 75 to 80 per cent of caustic soda in the concentrated alkali, the condensate collected from the longest line on the laundry floor rarely shows in excess of 30 ppm total solids, sometimes a very faint trace of pink to phenolphthalein, and never less than a pH of 7.6.

It would seem that, as this boiler operates and breaks down the carbonate with the release of CO_2, we should find this in the steam. In that event, the condensate should be acid, but such is not the case, and the question arises whether there is any chance of chemical adsorption or reaction. That would remove CO_2 before it has an opportunity to go into the steam.

MAX HECHT.[15] In paper (5) of this symposium, the authors have presented some of their data graphically. Because of the success which has attended the use of the statistical method in evaluating the results of corrosion testing, when large numbers of tests are available, it would seem appropriate that consideration of such mathematical treatment be given to all available tests, using the Schroeder detector, as reported in papers (2, 3, 5). Therefore, the writer would suggest a method which would include (*a*) correlation analysis of the least variation in time of cracking which can be considered significant; (*b*) correlations between water composition and time of cracking, which at the moment appears to be in confusion; (*c*) correlation between concentration of both inhibiting and noninhibiting substances and time of cracking.

Such a statistical analysis might assume that the design of the Schroeder detector and its operation were constant for all data reported, that the composition of the test specimen was similar, and that a uniform stress was applied in all instances. It would be further assumed that the methods of analysis for water composition used by the various authors furnish relatively equivalent data. Thus, the variables under consideration might be operating pressures and temperatures and variation in both composition and concentration of the boiler water. The problem would be simplified if the composition of the water were to be expressed in a uniform manner for all test results reported. As a suggestion, these results preferably might be reported in ions, equivalents per million.[16] The study may show the necessity of labeling the results of the water composition as cracking or noncracking in terms other than a simple ratio, such as that of sodium sulphate to total alkalinity as sodium carbonate.

It is recognized that the statistical study would be an arduous task, but nevertheless the inclusion of the results of such a study with this symposium may produce a clear picture of the field tests. A similar mathematical treatment may also be given to the results reported by F. G. Straub, in paper (1).

The following point is worth consideration. Straub and Schroeder and their co-workers have discovered the beneficial effects of several materials such as nitrates, sulphite liquors, quebracho, etc., and the harmful effects of others such as hydroxide and silica. The statistical study may show that there exist in the water unknown substances of natural occurrence which have inhibiting or accelerating characteristics whose detection escapes routine analysis.[17]

Confirmation of such findings may be secured by comparing the results of laboratory embrittling tests, making parallel runs with the sample of boiler water and with synthetic water of the same nominal composition, but prepared from pure materials. If significant differences are found, a refined analysis of the boiler water may disclose the nature of the materials responsible for the effect. For example, a refined analysis was made on a sample of boiler water from the Stanwix plant, shown by Purcell and Whirl (2), which gave evidence of a sufficient amount of nitrates to prevent cracking of the test specimen.

J. W. NELSON.[18] The development of test equipment by Prof. F. G. Straub, Dr. W. C. Schroeder, and their associates, in which the intercrystalline cracking of boiler steel could be developed, using boiler waters of normal operating concentration, or synthetic solutions of similar concentration, has accelerated greatly the work on this important problem and added considerably to our knowledge and appreciation of this subject. The embrittlement-testing unit, described by Professor Straub, was intended for use under controlled conditions in his laboratory, and it has been possible in a relatively short period of time to test a large number of waters with this testing unit. The embrittlement detector, developed by Dr. Schroeder and his associates at the Bureau of Mines, is designed for use on operating boilers as well as in laboratory testing. Its wide distribution and utilization by engineers responsible for boiler maintenance, operation, design, and feedwater treatment is attested by the results reported.

The embrittlement-testing unit is a spring-loaded device, employing no loss of solution or steam during a test cycle. If it indicates a water to be embrittling in nature, it also gives information as to the time required to produce failure of the test specimen because the tension on the spring-loading arrangement is released when a specimen fails.

The embrittlement detector employs a solution leak past a test specimen maintained in a state of stress, and in most applications a test period of 30 days has been established. If no cracks develop on the specimen in the 30-day period, longer test periods are quite often employed, especially when the detector is being used on an operating boiler. Possible results of this extended test period have been shown by Messrs. Purcell and Whirl in their

report on tests run for periods of 30, 60, and 90 days under similar test conditions. Possible differences in the stress maintained on the test specimen should be considered along with the time of test. The effect of increased stress on the specimen under test has been reported by Professor Straub. In his test unit, no reasonable combination of salts would prevent failure at stresses of 10,000 psi over his established test stress of 40,000 psi.

The development of cracked specimens in any type of test equipment is necessarily dependent on maintained conditions that are favorable to such cracking. That these conditions are developed and maintained in both of the units, that have been devised, is attested by the fact that test specimens may be cracked in either type of equipment in a relatively short test period. That differences may develop in results obtained in the two test units and those obtained in operating boilers can be appreciated. A study of the results obtained in the embrittlement detector is the basis of the work to be herein reported.

Our laboratory equipment follows the general arrangement in which the detector is attached by pipes to a steel-trap body which serves as a reservoir and boiler for the solution under test. All of our equipment is electrically heated and temperatures are automatically controlled.

The personal factor involved in establishing a proper leak past the test specimen in the detector may have considerable effect on the results obtainable with this equipment. An effort to evaluate this effect lead to the development of a system for determining the solution level in the test unit at any time during the test period. This system employs an electrode consisting of a coil of resistance wire applied to the test units through a spark plug. A low-voltage alternating current is connected to this electrode and the electric circuit is completed through a milliammeter grounded to the test unit. We have found that the solution level in the units affects the current flow in the circuit and have calibrated our equipment accordingly. The current flow in the measuring circuit varies with the conductivity of the solution in the test unit, and this factor has been incorporated in our calibrations.

The use of our electrical system for solution-level determination makes it possible to construct graphs showing the rate of solution loss from the test units with respect to time. We believe that this rate of loss is an important factor in the embrittlement-detector test procedure. This knowledge of the rate of solution loss past the test specimens is particularly valuable in studying the extent of the plugging tendencies of various materials and their relation to embrittlement cracking in controlled tests. We have made a series of tests to demonstrate the importance of this factor, and the results obtained are herewith presented in graphical form.

Because of the many places where leaks may develop in the laboratory arrangement of the embrittlement detector, we have used a notation on our graphs to indicate concentration of the solution during the test procedure. Notation X-1 after a graph implies no concentration; X-2, concentrated to twice the concentration of the solution at the start of the test, etc. To minimize this factor and the resulting concentration in our tests, we have regularly tested our assembled units, when prepared for a new test, by immersing them totally in clear water, applying air pressure, and checking for leaks.

On our graphs an uncracked specimen is indicated by an open circle at the end of the graph. A cracked specimen is shown by a filled-in circle. Where a specimen exhibited slight cracks that appeared to be of the intercrystalline type, or where slight cracks were opened on bending the specimen in a hydraulic press, a half-filled circle is employed. Cold-rolled-steel specimens were used in all tests and the test pressure was 210 psi.

The accompanying volume-loss graphs, Figs. 3 to 14, are drawn as straight lines between volumes determined on successive days using the electrical measuring circuit. The indicated occasional increases in volume, shown on some of the graphs, were caused by loose wiring connections from the spark plugs on the trap bodies to the measuring panel. In later tests, all connections were soldered, and the curves obtained are much more presentable.

Fig. 3 of this discussion shows the results obtained from four blank tests where daily leakage adjustments were made in accordance with the standard embrittlement-detector test procedure. The necessity for adjustment was determined by daily inspection of the specimen leak, using a cold watch glass and checking the indication obtained with a medical-type stethoscope. By blank tests is meant tests on solutions containing 500 ppm NaOH and 100 ppm Na_2SiO_3 in distilled water. In the balance of the tests, this same basic solution was used, with additions of other materials made as indicated on the graphs. In all of the tests, a vacuum technic was employed, in filling the test units, to avoid the effect of trapped air on the test solutions. Air was eliminated from the test solutions by boiling, before the solutions were placed in the test units and before inhibitors were added.

The results shown for the blank tests indicate some plugging tendency in the single-adjustment tests, but these results are not sufficiently consistent to warrant any positive conclusions. We have found that, in starting all tests in the detector unit, it is necessary to check and adjust the specimen leak at least twice during the first day of the test. To avoid an excessively large adjustment of the leak on the so-called single-adjustment tests during the first day, these tests are checked and readjusted on the second and third days and are then allowed to continue with no further adjustment, but with a daily record of any evidence of leak past the specimen. From the data presented for the blank tests, it appears that a very slow but consistent leak past the specimen will cause positive cracking even though only 200 cc of test solution is lost past the specimen in the 30-day test period. A leak of about 150 cc during the first 5 days of a single-adjusted test, with no indicated further loss, will cause cracks to open when the test specimen is bent at the conclusion of the test.

Results using sodium sulphate are consistent with results reported by other investigators using this material in tests run in the detector unit. Except for one test, no plugging is indicated for this salt. It must be pointed out that, in our tests with sodium sulphate, we maintained the A.S.M.E. ratios, but we did not use sodium chloride, the addition of which is recommended by Professor Straub.

The results, using quebracho alone and quebracho plus sodium sulphate, indicate that very similar results are obtained in the regular or daily-adjusted tests. In the single-adjusted tests it appears that the plugging action of the straight quebracho protects the specimen; while the mixture with sulphate does not allow for effective plugging of the leak and permits the development of cracks that are intercrystalline in appearance. The sudden breaking of a plugged condition is demonstrated in tests Nos. 52, 84, and 89, and these results may indicate that a theory of embrittlement protection, based on plugging tendencies of the protective materials added, is tenable, providing conditions are not present which may serve to break such chemical plugs as are formed.

The use of waste sulphite liquor appears to provide effective sealing of leaks but, in the concentrations used in our tests, fails to prevent cracking even where relatively small amounts of liquid are lost past the specimen, and even if such loss occurs only during the first few days of the test.

The results obtained with sodium nitrate would indicate very little plugging tendency for this material. The protective action of this material is not indicated by the results we have obtained using an initial concentration of 40 per cent of the available alkalinity.

In the tests herein reported, no attempt was made to maintain a concentration of the inhibitor materials in the test solutions by a regular recharging of the test units with fresh solution. Our tests were carefully started with the desired amount of inhibitor materials added to test solutions which had been freed from air by boiling, and, unless excessive leakage during the test period made recharging of the units desirable, they were operated for the full 30-day period on their original charge of solution. Accordingly, in all of the tests using quebracho extract, an average loss of about 75 per cent of the extract was noted, but in no test was the remaining extract less than 25 ppm. Results of tests to determine possible losses of waste sulphite liquor were inconclusive. In the nitrate tests, it was found that cracking of the specimens could be attributed to there being no residual nitrate at the conclusion of the test period.

We do not consider that the results we have herein reported constitute conclusive evidence that the various materials employed to control the embrittling tendencies of the solutions tested are or are not beneficial in such control. We believe that the graphical evidence, which our equipment has made possible, is helpful in obtaining a better understanding of our results and we are hopeful that the continued use of our equipment will provide some assistance in the clarification of the embrittlement problem.

A. H. Reynolds.[19] It has been our belief, based upon published data and conversations which we have had with other investigators in the field, as well as upon results of tests that we have obtained, that the more practical type of test, as carried out by Dr. Partridge (5), is less severe than the strictly laboratory type of test, on which Dr. Bird (4) has reported.

In other words, we have had instances where specimens would show cracks in the laboratory when using the embrittlement detector, while a boiler operating on the waters tested, or a detector unit connected to the boiler using these waters, failed to show embrittlement cracking.

There are several possible explanations for this real or fancied difference in the results obtained between laboratory tests and the more practical tests where embrittlement detectors are applied directly to boilers in operation. The most logical reason, and one which will immediately be apparent to everyone, is the opportunity for a change to take place in the boiler water during transit to the laboratory. In this way certain salts may be precipitated from the boiler water and others changed decidedly because of coming in contact with oxygen or carbon dioxide.

However, there are at least two other factors which might explain in part the higher percentage of laboratory failures. The first of these possibilities is the much larger metal surface per unit volume of test solution in the laboratory equipment and the possible inhibiting or accelerating effect resulting from it. The second and probably the more important difference is the continued exposure of a limited amount of test solution to high temperature and pressure for periods of 30 days or more without any replenishment or replacement.

It is known that certain constituents of boiler water, particularly many of the organic treatments used in their conditioning, are subject to partial decomposition under the conditions of temperature and pressure used in the tests. Over a period of 30 days, this decomposition may become quite pronounced and may exert a marked influence upon the embrittling tendencies of the water tested, increasing these tendencies or decreasing them as the decomposition products are more effective or less effective inhibitors.

Having equipment and facilities available in our laboratory to investigate some of the factors referred to, a few months ago we undertook such a study. For this purpose, we connected two embrittlement detectors to a laboratory-size, electrically heated, fire-tube-type experimental boiler. The boiler is equipped with a blowdown condenser, a feedwater pump, and a Mercoid pressure regulator which regulates the electrical input to the boiler. Circulation through the detectors was assured by attaching a strip heater to one of the boiler lines. All lines to and from the detectors were heavily lagged.

The capacity of the experimental boiler, while in no way comparable with that of practical boilers, is large with respect to the capacity of the traps commonly used as solution reservoirs, or boilers in laboratory embrittlement equipment. In this type of test, the experimental boiler can be conveniently operated with 17 liters of test solution. In our tests, we proposed to blow the boiler down daily, leaving just sufficient water in it to cover the heating elements, and then to make up the blowdown volume with feedwater of the same composition as that in the boiler at the start of the test. No provision was made to take off steam, as this would introduce another variable into the test.

As a preliminary to running a series of tests to determine how various waters containing known inhibitors would show up under our modified test conditions, we decided to run one or two tests using a solution which Dr. Schroeder and his associates have used as a standard embrittling solution. This solution consists of 100 ppm of anhydrous sodium silicate and 500 ppm of sodium hydroxide in distilled water. During the running of the tests with the experimental boiler, corresponding duplicate tests were run as blanks using the same composition test solution in the small regular laboratory equipment.

The tests were run more or less in accordance with the accepted procedure. The leak past the specimens connected to the boiler and those attached to the individual units were adjusted daily, Monday through Friday. No provision was made to adjust the specimens on Saturdays or Sundays. Leakage past the specimens was determined by two methods, i.e., by sound, using a stethoscope, and visually on a cold watch glass. The experimental boiler was blown down each day, Monday through Friday, about 11 liters being removed from the boiler each time. The standard embrittling solution was used to replace the water removed by blowdown.

At the end of 30 days, the test specimens were removed from the test equipment. The two specimens, which had been attached to the experimental boiler and which had had fresh make-up water added five times a week, failed to show any evidence of embrittlement cracking, even when subsequently subjected to severe bending or microscopic examination.

Of the two specimens taken from the regular small laboratory equipment, one was badly cracked when removed from the detector and the other readily opened up cracks upon subsequent bending.

While showing that different results were obtained from the two types of equipment, the tests indicated that this difference existed to a much greater degree than we had anticipated. We questioned the accuracy of any conclusions which might be drawn from these results and immediately started repeat tests in both types of equipment. While the repeat tests were being run, we took temperature measurements of the detector units attached to the experimental boiler and of the units attached to the smaller test equipment.

Using an accurately checked thermocouple, we found the temperature of the detector blocks connected to the experimental boiler to be 265 F and the temperature of the actual specimens to be only 247 F. Similar measurements made on the smaller laboratory units showed the detector blocks to have a temperature of 335 F and the actual specimens a temperature of 320 F.

From these data, it appears that, while the detector units on

[19] Chief Chemist, Dearborn Chemical Company, Chicago, Ill.

both types of equipment were operated under a hydraulic pressure, corresponding to the 210 psi of steam pressure developed, the temperature in the detector units was very much lower than the 392 F which would correspond to this pressure. As a matter of fact, the temperatures found in the blocks and test specimens, where cracking did not take place, would correspond to only 24 and 14 psi of steam pressure, respectively. In the small units where cracking was obtained, the temperatures corresponded to 95 and 75 psi of steam pressure in the head and specimens, respectively.

The second set of tests which was run on the standard embrittling solution gave results which are substantially the same as those previously obtained.

We propose, by repiping the detectors to our boilers, or by the application of added external heat to the lines leading to the detectors, to obtain temperatures in the blocks and specimens attached to our experimental boiler which will be at least as high as those obtained in our laboratory units.

This may show that the temperature of the detector block and specimen is an unimportant factor in the results obtained by the use of this kind of testing device. It may be found, however, to be an important factor and if so would tend to explain some of the differences found between strictly laboratory tests and the more practical type of field tests, where the detectors are attached to the operating boilers. In the latter type of tests, and particularly in railroad practice, the detectors are usually mounted in exposed places, often with the feed and return lines to and from the units devoid of any lagging. In such cases the possibility for cooling through the detectors is more pronounced than it is in our equipment.

As soon as the effect of temperature of the detector units has been more clearly evaluated, we propose to investigate the factors originally considered, when we started our work, particularly the possibility of partial decomposition of certain constituents influencing the results obtained.

At any rate, regardless of whether or not subsequent results will show that detector tests on operating boilers are somewhat less severe than they might be, because of a drop in temperature through the detectors, or that tests in laboratory units are more severe than they should be, because of decomposition or other causes, there is nothing in the results obtained which would disprove in the least the statement made by Dr. Schroeder that any inhibitor which would prove entirely effective in laboratory detector tests would very probably be a satisfactory inhibitor of caustic embrittlement in operating equipment.

F. G. Straub.[20] A laboratory testing unit is of value to industry only as long as that unit is operated under conditions simulating operating conditions and, then, only when the laboratory data substantiate the operating data.

When this symposium was first suggested, the writer was under the impression that operating data were to be correlated with research data and paper (1) was so prepared as to furnish the research data, with the expectation that the operating engineers would furnish boiler data. However, it appears that the various authors and discussers have merely compared the results of two methods of laboratory testing, without the correlation of either unit with actual operating results.

Early in the development of the laboratory testing of boiler waters from the embrittlement viewpoint, we realized we were on dangerous ground, and we hesitated a long time before publishing our first paper on this method of testing. Realizing the limitations of our method of testing, we delayed placing it on the market as a universal method of testing. Many times we have been condemned for such action, but today we are inclined to believe that we followed the proper procedure. We have certainly prevented a great deal of confusion which would have resulted had we done otherwise.

The statement has been made that a laboratory embrittlement-testing unit should impose so severe a test that, if any inhibitor is found which will prevent failure under these conditions, it would serve as a universal inhibitor. We do not deny this premise; however, we question how such a test which is completely comparable with industrial operation may be devised and still give accelerated results. To obtain acceleration of the time factor, something must be sacrificed. The criticism of the Illinois embrittlement tester has been that it is not a severe enough test. The same critics state that the Bureau of Mines test unit, being a more severe test, should prove of more value. Granting this to be true, we find that the University of Illinois unit shows sulphates to have some protective values, whereas, the Bureau of Mines unit shows no protection. This condition is explained by the apparent severity of testing. The two units appear to agree when using certain organic materials and show evidence that these organic materials are of value even under the severe test conditions of the Bureau of Mines unit. When nitrates are tested, the reverse occurs. Nitrates protect the Bureau of Mines unit and do not protect the steel in the University of Illinois test unit. Is this explainable on the assumption that the University of Illinois

[20] Research Professor of Chemical Engineering, University of Illinois, Urbana, Ill.

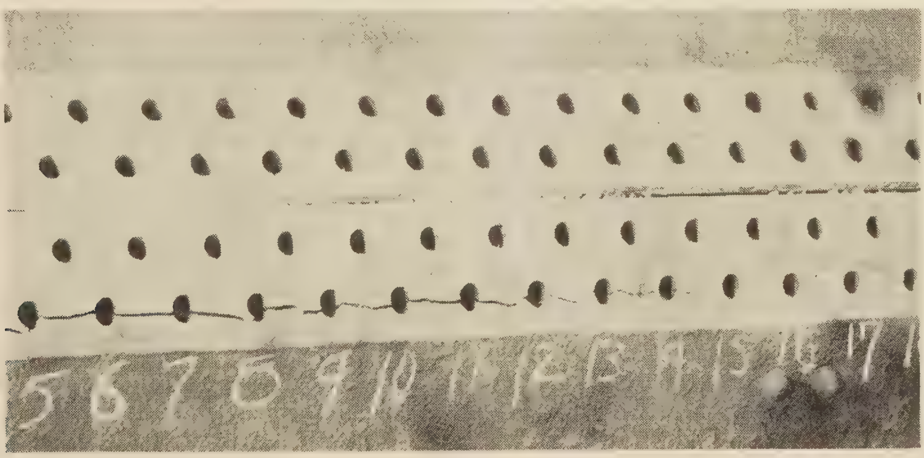

Fig. 15 Section of Cracked Boiler Showing Points of Boiler-Water Concentration

test is too severe on nitrates and not severe enough on the sulphates?

The writer has a different explanation for the results obtained, which the chemists may readily comprehend but which, it is feared, will further confuse the engineers.

Fig. 1 of the writer's paper (1) shows our test unit. The concentration takes place in the capillary space around the filler. Part of this concentration is caused by the reaction between H_2O and Fe to form Fe_2O_4 and H_2. This reaction is accelerated, and the concentration of the NaOH increases, continuing to increase as the reaction proceeds, due to the removal of H_2O by this reaction. If an alkaline nitrate solution is brought in contact with Fe and H_2 is generated, the nitrate is quantitatively reduced to NH_3. Thus, nitrates are reduced to a low value and have no protective value in these tests. Actual tests of nitrate solutions run on specimens not subjected to stress show the reduction of the NO_3 to a very low value.

Fig. 15, of this discussion, shows a section of a cracked boiler. The points of concentration are evident. How in these sections do we have the leak with subsequent concentration as explained by the Bureau of Mines unit? The University of Illinois test unit appears comparable to boiler operation.

Closures

Closure to Paper by F. G. Straub (1)

T. C. Rathbone raises the question of stress concentration caused by possible misalinement of the parts of the test unit. We realize that it is possible to have a stress higher than that actually calculated. However, there are other factors, such as the finish of the specimen, which cannot be definitely controlled.

Our purpose in developing this unit was to devise a test which would not be too complicated, and yet which would give reproducible results. We have had no difficulty in obtaining reproducible results with the unit. Consequently, we have not incorporated the finer points of refinement of construction which have been recommended.

Closure to Paper by T. E. Purcell and S. F. Whirl (2)

Mr. Einert, in his timely and constructive discussion, states that a knowledge of the pH value of the boiler water during tests Nos. 106, 107-A, and 107-B would be of interest. Such data were not deemed necessary when these tests were started and, consequently, only routine measurements were made using Hellige indicator and pH color disks. Irregularities in the alkalinity data of these tests led to the development of the curve of Fig. 8. For test No. 106, the average pH was 10.5; the corresponding value for tests Nos. 107-A and 107-B was pH 10.4. In general, these results are lower than the curve values corresponding to the phosphate concentrations and, in all probability, somewhat below the true values. In subsequent tests, where the curve has been the basis for alkalinity control, the Beckman high-resistance glass electrode has been used.

The authors doubt very much the value of the test suggested by Mr. Einert in which trisodium phosphate alone would be added to increase the pH to the value of tests Nos. 101, 102, etc. If practice conforms with theory, the results would not be expected to vary with trisodium-phosphate concentration, since, regardless of concentration, a saturated solution of this salt presumably exists at the stressed portion of the specimen.

A 90-day test recently completed indicates that some free hydroxide alkalinity can possibly be tolerated when present in conjunction with trisodium phosphate. During the test, the alkalinity was maintained at approximately 4 ppm OH ion, as measured by the modified Winkler method used for tests Nos. 106, 107-A, and 107-B in which strontium chloride was substituted for barium chloride. While both specimens developed cracks, they were not visible at 50-diam magnification until test pieces were severely distorted by cold bending.

At all times the pH was above the curve value for the corresponding trisodium-phosphate concentration. A testing program is now under way to determine the minimum hydroxide alkalinity which will produce failure under the established test conditions. Also in progress are tests to ascertain the effect of increased time.

Aside from the problem of protection against embrittlement, the method of alkalinity control, proposed by the authors, has certain other advantages worthy of mention. Mr. Einert emphasizes one of these in his discussion; namely, it offers a practical boiler-water treatment for those cases of corrosion due to faulty circulation. Instead of lowering the alkalinity to a dangerously low level, as has been practised, it is possible by this method to eliminate the aggressive agent, free OH alkalinity, without reducing the pH. This type of corrosion referred to as steam-blanketing, and so ably described by Partridge and Hall,[21] has been attributed to the chemical action of concentrated sodium hydroxide on hot boiler-tube metal. By the proposed method, the boiler water deposits trisodium phosphate alone on evaporation, sodium hydroxide being absent. Therefore, this type of metal attack is limited to the comparatively mild action of trisodium phosphate. Other advantages are simplification of the alkalinity control and the decreased blowdown, occasioned by notable reduction in boiler-water salines, as compared with the concentrations experienced when treatment complies with the recommendations of this Society. This latter condition, of course, applies strictly only when evaporated make-up is employed.

Closure to Paper by R. C. Bardwell and H. M. Laudemann (3)

The papers and discussions presented in this Symposium have been interesting, indeed, and afford a substantial contribution to the available knowledge on means for overcoming damage from intercrystalline corrosion in steam boilers. The remarks made by Professor Straub concerning the present paper would appear to require a reply.

In railroad operation, we are primarily interested in research, only to the extent that it directly affects our duties and responsibilities and is of assistance in helping actually to solve a working problem. We are not consultants and have no secrets to hide, confidences to betray, nor patents to exploit. The duties and responsibilities of ourselves and co-workers consist in obtaining and properly conditioning the water supply for 1428 locomotives and 78 steam power plants operating in nine states and 16 steamships operating on the Great Lakes and Hampton Roads, which affords a rather wide field for detailed observation. The records show that more than 44,000 water samples of widely varying quality are examined annually in our six laboratories, as well as many tests made in the field by ten full-time chemists who are specially trained for this work. All the reports are maintained in the office of one of the authors. We are constantly in touch with the boiler-inspection department concerning conditions and results in the boilers. It is believed that the correlated information thus developed, which is a matter of record over many years, is of considerable value in formulating opinions on the subject of embrittlement-cracking.

It is not claimed that the A.S.M.E. sulphate-alkalinity ratios were maintained in all locomotive boilers at all times. They were not so maintained and no effort was made to do so, as this

[21] "Attack on Steel in High-Capacity Boilers as a Result of Overheating Due to Steam-Blanketing," by E. P. Partridge and R. E. Hall, Trans. A.S.M.E., vol. 61, 1939, p. 597.

did not seem warranted because of the fact that none or much less cracking has been experienced in the same class of engines, operating at 200 psi or over, where the ratios are normally 0.5–1 to 1 than where they have been between 1.5–2 to 1.

The water used in the switch engines listed in Tables 1 and 2 of the paper (3), which is questioned by Professor Straub, is obtained from a deep well and is softened with lime and soda ash using sodium aluminate or alum as a coagulant. Tests are made at least twice daily, and the quality has been uniform since the plant was placed in service in 1923. The only other water used by these engines is raw city water, which is uniformly of such composition that it would lower the alkalinity and raise the sulphates. The sodium sulphate-alkalinity ratio in the boilers could not be below that in the treated well water for which semi-daily tests are available on which to base judgment. The fact remains that considerable cracking was experienced in these locomotive boilers and it has been eliminated, not by adding sodium sulphate and increasing the foaming troubles, but by treatment with a small amount of lignin and later with sodium nitrate, in accordance with recommendations made by the Bureau of Mines.

Similar results were experienced on the Chicago and Northwestern Railroad. One of the authors has examined several thousand boiler-water analyses on this railroad, which were made over the past 30 years, not merely the analyses for eight locomotives. He has also listened to the discussion of this trouble at a number of meetings of the American Railway Engineering Association Water Service Committee both while the trouble was in progress and since it has been eliminated. The conditions were essentially as noted, in that cracking took place on territories with relatively high sulphates, not necessarily up to or over the A.S.M.E. ratios but still relatively high, whereas no cracking was experienced in the same class of power in other districts using natural high-sodium-bicarbonate water with sulphate-alkalinity ratios of 0.05 to 1, instead of 2 to 1. The trouble has been practically eliminated since 1926, not by following the method advocated by Professor Straub and raising the sulphate content, thus suffering from foaming tendencies, but by adding a small amount of a lignin material which was one of the ingredients of an antifoam compound used in the territory of the high-bicarbonate waters.

It should be remembered that intercrystalline cracking, although troublesome and expensive at times, is one of the minor troubles to be corrected in conditioning water for locomotives and possibly ordinary power-plant boilers. In order of their importance, the real operating problems are (*a*) scale deposition, (*b*) pitting and corrosion, and (*c*) foaming. In locomotive practice, scale can be kept under control by maintaining the sodium alkalinity at 15 per cent or more of the total dissolved solids. The control of pitting and corrosion requires the maintenance of a higher alkalinity ratio, even up to 30 per cent, probably because of the high concentration of dissolved oxygen carried in with the feedwater. In controlling foaming, it is necessary to keep the total dissolved-solids concentration below the critical point for the respective type of power and local conditions. When it is necessary to maintain 30 per cent alkalinity to prevent pitting, it would be impossible, either mathematically or otherwise, to maintain a sodium sulphate-alkalinity ratio of 3 to 1 in 250-lb-pressure locomotive boilers of which there are many in service. If any appreciable amount of chlorides was present, it would be difficult to maintain a sulphate ratio of even 2 to 1. A more satisfactory remedy is needed to control intercrystalline cracking than the A.S.M.E. sulphate-alkalinity ratio, even if it is presumed that sodium sulphate will prevent cracking and the data presented in this Symposium offer no evidence to support this theory.

In our opinion and from our experience, it is felt that steam-power users owe a debt of gratitude to the Bureau of Mines and to Dr. Schroeder for determining and describing the fundamental causes for this trouble, as well as for developing a practical and workable means for controlling and eliminating the embrittling tendencies of various water supplies in boiler use. Our experience has shown us that, where boilers crack, detector specimens will crack and where the water is treated with a small amount of lignin or sodium nitrate, in accordance with the recommendation of the Bureau of Mines, cracking of the detector specimens is stopped and the cracking of boilers appears to be gradually eliminated.

Our paper was prepared and presented at the request of the Joint Research Committee on Boiler Feedwater Studies to afford a record of the extensive work which has been carried out on The Chesapeake and Ohio Railway to develop a practical solution of the troubles experienced with intercrystalline corrosion which would not interfere appreciably with operation. It is felt that much has been accomplished and, if these results are of benefit to others having similar problems, it is considered that the effort will have been worth while.

Closure to Paper by P. Partridge, C. E. Kaufman, and R. E. Hall (5)

Almost any boiler water contains enough silica to promote intergranular attack when the water is concentrated. As Mr. Betz has pointed out, any increase in silica content during shipment would scarcely alter the broad conclusions drawn concerning its effect. Routine samples of boiler water, in connection with plant detector tests, accordingly, are customarily shipped in glass containers. Wherever the silica content of a boiler water is considered to be of special significance, containers which cannot contribute silica to the water are naturally used.

Mr. Betz has also questioned the values obtained for tannin on samples of boiler water shipped in from a plant. To prevent appreciable change in the tannin concentration during shipment, a special sample of boiler water is filtered and acidified at the plant. As an example of the relative stability under alkaline and acid conditions, a boiler water containing approximately 260 ppm of NaOH and 20 ppm of tannin as determined by the tyrosin test at the time of sampling showed only 5 ppm after standing for 5 days, but a duplicate sample which had been acidified still showed 18 ppm of tannin.

It has been suggested by Mr. Owens that the process of intergranular cracking may be affected by whatever precipitates and the amount of it which does precipitate, as boiler water undergoes concentration in a capillary space. One can scarcely deny this possibility; indeed, the guess might be hazarded that many stationary boilers of the era when boiler scale was an inevitable nuisance may actually have been protected from embrittlement by the sealing of the riveted seams by calcium carbonate, calcium sulphate, or calcium silicate. It has been pointed out before that such sealing might easily be less perfect in the seams of a locomotive boiler subjected to the racking stresses of movement over the roadbed.

Turning to the embrittlement detector, it seems reasonable to assume that the daily adjustment to maintain the optimum slow rate of leakage may deliberately discount the possible protective effect of solids which might accumulate in an actual riveted seam in such a manner and to such an extent as to protect the steel. The answer to this, of course, is that anyone using the embrittlement detector deliberately desires to set up the worst possible combination of mechanical conditions so that, if failure does not develop, he may feel assured that the chemical factor in the process of intergranular corrosion has been thoroughly suppressed.

Considerable discussion has centered around the question of whether failure of a detector specimen means that the boiler in question has cracked or will crack. To the extent that the mechanical and chemical conditions in a riveted seam may duplicate those existing in the detector, one would expect the steel in the riveted seam to suffer damage as readily as the steel in the specimen. In few riveted seams, however, will all the necessary conditions be brought together as completely as in the detector. Many a boiler might, therefore, survive to a ripe old age even though the boiler water cracked a detector specimen in less than 30 days. The real significance of a cracked specimen is the mute but emphatic warning that the chemical factor has not been inhibited but is ready to go to work whenever the proper mechanical conditions exist.

Closure to Summary by W. C. Schroeder and A. A. Berk

The widespread interest in these papers, as evidenced by the variety and length of the discussion, has been most gratifying to the participants in the Symposium. A number of questions have arisen concerning the embrittlement detector, its operation, and the exact meaning of the results. The answers in general are provided in a recent Bureau of Mines publication[22] and cannot be repeated here without making this closure unduly long.

While complete agreement does not exist among all the papers, the Symposium shows surprising unanimity of opinion concerning methods which are satisfactory for preventing embrittlement. That the authors have arrived at their viewpoints by investigation in diverse fields, including laboratory research, testing on stationary and locomotive boilers, and actual observation of the sharp reduction in the cracking of locomotive boilers following the use of protective agents based on embrittlement-detector tests, lends strong practical proof of their validity. Nitrates and quebracho tannin have given satisfactory results in a considerable number of applications. The more direct method of controlling alkalinity on the basis of a phosphate-pH relationship offers a solution for the embrittlement problem at the higher pressures. A suitable inhibitor for embrittlement can now be designated for almost every boiler water and every operating pressure at which cracking has occurred.

[22] "Intercrystalline Cracking of Boiler Steel and Its Prevention," by W. C. Schroeder and A. A. Berk, Bulletin 443, Bureau of Mines, 1941.

Heat Conditions in Bearings

An Outline of Problems for Research

By MAYO D. HERSEY,[1] WORCESTER, MASS.

Offered as part of a symposium on temperature relations in bearings, this paper reviews briefly the older and newer research problems in that field.

Experimental data are needed on the over-all heat-transfer constants governing the relation of power loss to the temperature elevation in oil-film bearings. The effect of oil flow on load capacity should be further investigated. Better methods for measuring or calculating film temperature would be useful. Other problems are suggested in connection with the properties of lubricants and methods of bearing design.

The conclusion is reached that a new epoch in bearing design is approaching in which the assumption of constant viscosity must give place to a study of heat conditions. This situation is intensified by the increasing loads and speeds to be dealt with in meeting national-defense requirements.

Introduction

SPEEDING up the wheels of national defense makes the bearings run warmer. This applies literally to all forms of transportation and production. To conserve power, maintain performance standards, and reduce wear calls for improved design, better lubricants, and more intelligent control of operating conditions—accomplishments depending on lubrication education[2] and lubrication research.

Accordingly the Special Research Committee on Lubrication desired to place immediately before the Society for discussion a brief review of the recognized problems associated with heat effects and temperature rise. This has been done to provide a background for research, while reserving for later publication any critical review of the available numerical data. It is hoped that additional data may be contributed during the discussion.

The hydrodynamic theory of lubrication, reaching its most advanced form in the recent investigation by Professor Waters (59), presupposes a knowledge of the viscosity. The fact that the true film viscosity is usually in practice an unknown quantity constitutes one of the reasons why the Committee seeks to encourage research on temperature relations in bearings.

While the present survey is expressed in the language of thrust and journal bearings of the oil-film type, analogous problems are met in the lubrication of ball and roller bearings, gear teeth, cutting tools, engine cylinders, and other mechanical elements. We consider first the problem of steady running conditions, or thermal equilibrium, with special attention to heat transfer, friction loss, and load capacity. Then follow questions relating to transient conditions, nonuniform viscosity, thin-film lubrication, temperature measurement, and properties of lubricants; concluding with notes on bearing operation and bearing design from the standpoint of heat conditions.

Thermal Equilibrium

Under steady running conditions the mean temperature of the oil film in a bearing gradually reaches some maximum limiting value known as the equilibrium temperature. This remains constant as long as the ambient temperature, i.e., room temperature or temperature of the remote surroundings, remains unchanged. The corresponding temperature elevation, or difference between film temperature and ambient temperature, may be anywhere from a very few degrees, or even a fraction of one degree, up to 100 F or more, depending on a multitude of complex factors. Without some means for estimating the temperature elevation it is impossible to assign numerical values to the viscosity of the lubricant appearing in the hydrodynamic equations.

The temperature rise can frequently be estimated from previous experience with similar bearings. A more rational solution has, however, been found (4, 38, 47). This is based upon three simultaneous equations, the physical meanings of which are not difficult to understand.

The first of these equations will be some form of the classical relation expressing the power loss, H, as a function of the mean film viscosity, Z, thick-film lubrication being presupposed. Up to this point no innovation is involved except that we are to regard the speed, load, and all design factors as constants for the time being. We are starting with a single equation connecting two unknowns, H and Z. This equation will be a characteristic of the particular type of bearing.

The second relation needed is a characteristic equation for the cooling system. Such an equation will express the rate of heat transfer, H', from the lubricating film outward as a function of its temperature elevation, T, above the ambient, or room temperature. For the moment all other factors governing the rate of heat transfer are treated as constant, leaving a second equation connecting two unknown quantities, H' and T. Not only will the coefficients in this equation depend on the type of cooling system employed, but the general form of the equation may be quite different according as the bearing is air-cooled, water-cooled, or cooled by oil circulation. For the present purpose H' should be expressed in power units.

Our third relation is the characteristic viscosity-temperature equation for the lubricant, or the corresponding curve if graphical methods of solution are more convenient. The equation should be recast so as to express the viscosity, Z, as a function of the temperature elevation, T, rather than of the actual temperature, θ. This offers no difficulty since T is defined as θ minus room temperature, hence θ in the viscosity formula can be replaced by T plus a constant.

When thermal equilibrium has been reached, H' may be replaced by H since the rate of heat transfer is now exactly balanced by the rate of generating heat. This leaves only three unknowns, H, Z, and T, with three simultaneous equations available for their determination.

While there remain three equations with three unknowns in a physical sense, H can always be eliminated by equating the right-

hand sides of the first two equations, leaving only two equations with two unknowns, Z and T, for the mathematical or graphical work in any particular application.

Heat Transfer

The foregoing outline provides a formal method of solution for temperature-rise and power-loss problems. Its practical use depends on the availability of heat-transfer data. Here lies one of the greatest fields for experimental research in the near future.

For air-cooled bearings with moderate temperature elevations, Newton's law of cooling may be accepted as a first approximation, according to which H' is directly proportional to T. The investigation reduces to the determination of a constant, which in turn depends on the shape and size of the bearing housing, and other factors. Values for thrust bearings have long been available (8) but are based upon bath temperature rather than film temperature. Tentative values for journal bearings have been given by Karelitz and others (15, 38). For geometrically similar bearings this constant may be taken as roughly proportional to the square of the diameter. It varies over a wide range depending on the degree of movement of the air.

With higher temperatures Lasche's law is often used (3). According to this relation the rate of heat transfer varies as the 1.3 power of the temperature elevation. Experimenting with automotive-type bearings in which air cooling was supplemented by forced lubrication, McKee found a variation nearly proportional to the 1.6 power (51).

Water-cooling by coils in the oil bath, or otherwise, is more effective than air-cooling. The rate of heat transfer depends on such factors as the speed of the shaft, shape and size of coil and housing, rate of flow, water inlet temperature, bath temperature, oil viscosity at bath temperature, and the viscosity index or temperature coefficient of viscosity. Test data should be analyzed by the method of dimensions, as in other heat-transmission problems. Little if any research work has been published in this field, though tables are available giving maximum speeds for air-cooled operation of thrust and journal bearings for any given load (8 *a* and *b*).

Forced lubrication with external cooling of the circulating oil is common practice for high-speed journal bearings in the larger sizes (14, 17, 58). The rate of heat transfer now depends on the temperature elevation of the film above the oil inlet, rather than above the room temperature, since air cooling may be neglected or dealt with separately as a small correction.

All three types of heat transfer in bearings—air cooling, water cooling, and oil circulation—require further investigation. In the meantime a slightly better foundation for thermal-equilibrium calculations may be hoped for if the existing data can be more fully collected and coordinated; in particular, data showing values of power loss and temperature elevation when running in a steady state.

Friction Loss

A formal procedure has been outlined above for calculating the temperature rise and friction loss in a bearing under equilibrium conditions when three characteristic expressions are given. These are, first, the friction function, which may be symbolized by $f_1(Z)$; second, the cooling function, $f_2(T)$; and third, the viscosity function, $f_3(T)$. Two simultaneous equations are then set up, one derived by equating $f_1(Z)$ to $f_2(T)$, the other by equating Z to $f_3(T)$. The values of the two unknowns Z and T that satisfy the two equations are the required equilibrium values. Solutions may be obtained analytically when the expressions are not too involved, otherwise graphically.

Generalizations have been proposed in two cases (48): First, when thermal expansion has a noticeable effect on the clearance and hence on the power loss; H will then depend directly on T as well as on Z. In this case an expression $F_1(Z, T)$ takes the place of $f_1(Z)$. Second, when the cooling function has a marked dependence on the viscosity of the lubricant. In this case a more general expression $F_2(T, Z)$ may be substituted for $f_2(T)$. A third generalization may be suggested for any case in which the viscosity-temperature relation cannot be explicitly solved for Z as a function of T, as in the case of Cragoe's "liquidity" function (25). If the relation is given in the form $F_3(Z, T)$ equals zero it may be used in that form, without attempting to solve for Z.

Among the illustrative examples that have been worked out (38, 47) mention may be made of an air-lubricated journal (2) and a 7-in. journal bearing with forced lubrication (44).

The simplest case usually described is that of a high-speed journal bearing following Petroff's law and Newton's law of cooling, for which an analytical solution is obtained (4). This solution is limited to a temperature range within which the viscosity relation may be expressed by a hyperbola. Other solutions have recently been obtained applicable to partial bearings, and to more exact viscosity formulas (48). The friction coefficient for the full journal bearing, when plotted against speed, is given by a curve approaching some fixed upper limit as the speed approaches infinity. The power-loss curve approaches a straight line through the origin. These results are not inconsistent with ZN/P requirements,[3] but imply an inverse variation of viscosity with speed.

Relations of this kind in which bearing performance is expressed in terms of speed, load, etc., not for a given viscosity but for a given lubricant, have been termed "working equations" (4). Such an equation is derived by eliminating the viscosity from the "characteristic" or hydrodynamic equation. This elimination is accomplished with the aid of the heat-transfer relationship; hence the importance of research on heat transfer in bearings.

Load Capacity

The definition of load capacity may be expressed in terms of film thickness, film stability, or temperature rise. These conceptions would seem to reflect the viewpoints of the designer. experimenter, and operator, respectively, though there is much ground in common.

The present-day bearing designer, accepting the hydrodynamic theory, visualizes conditions in terms of film thickness at the point of nearest approach. If rigidity and smooth finish are contemplated, he can allow a relatively low value for the safe limiting thickness (4, 19).

The experimentalist is more conscious of the transition from stable to unstable lubrication which occurs at the minimum point on the coefficient-of-friction diagram. Watching his instruments with increase of load or decrease of speed, he marks the moment when friction torque jumps rapidly up, followed by a sharp rise of temperature. This, to him, measures the ultimate load capacity, which must be avoided by assigning a factor of safety (11, 33, 50).

The operating engineer cannot see the oil film, or slow down to observe minimum points. But by touching the bearing with his hand and examining the outlet oil, he may form some judgment as to the permissible operating temperature (29, 46, 51). A limit of 50 C has been recommended by Thoma (43), while McKee advocates a combination of the minimum point and temperature requirements.

A clear setting forth of all advantages and interrelations of the several criteria would constitute, in itself, a research problem of

[3] Under thick-film conditions the coefficient of friction is fixed by ZN/P where Z denotes the mean film viscosity, N the speed in revolutions per unit time, and P the load per unit of projected area.

no slight magnitude and practical value. In particular, it should be noted that the film thickness and minimum friction criteria are not mutually equivalent, even though both are commonly expressed in terms of ZN/P. The film thickness is fixed uniquely by ZN/P, but the location of the minimum point depends somewhat on the values of the separate variables.

It is instructive to calculate load capacities from the film-thickness criterion under thermal-equilibrium conditions. An analytical solution has been given for the full journal bearing corresponding to the friction calculation described (4, 38). The resultant curve starts out from the origin with load capacity directly proportional to the speed. It then rapidly drops until, at higher speeds, the curve levels off and the load capacity remains constant. This is all on the assumption of a moderate change in viscosity with temperature. For aircraft-engine oils, having higher initial viscosities and steeper viscosity-temperature slopes, the load capacity, as shown by McKee (51), passes through a maximum and diminishes with further increase of speed.

The rated load capacities of thrust and journal bearings are generally (8 *a*, *b*) in fair accord with the analytical solution mentioned, though one catalogue (26) shows loads diminishing as the speed goes up.

The effect of oil flow on temperature rise and load capacity was investigated by Orloff (27, 34) using methods of calculation that appear to be in close agreement with Barnard's experiments (7). Here is an important problem for research on which only a beginning has been made.

Transient Conditions

The shape of the temperature-time curve is a matter of interest in connection with (*a*) heating and possible wiping of bearings when starting from rest under load; (*b*) temperature rise during momentary periods of overload; (*c*) estimating time required to approximate a steady state; and (*d*) predicting equilibrium temperature from observations during a short run.

Some progress has been made on the first two problems by the application of Kelvin's theorem for temperature rise due to a heat source distributed over the surface, with experimental confirmation (23, 28, 36, 37). Satisfactory solutions of the last two problems will require experimentation. It is to be hoped that the results of such tests can be extended to geometrically similar bearings of other sizes by the principle of similarity.[4]

Nonuniform Viscosity

The temperature cannot be strictly uniform in a lubricating film after reaching equilibrium, since the heat originating in the film can be removed only by convection and temperature gradients. It has been established that the temperature distribution across the film is approximately parabolic (5, 16), the principal deviation being due to the change in viscosity with temperature. This problem has been solved graphically and confirmed experimentally by Albert Kingsbury (23). An analytical solution by Donald Bratt will be found in the discussion of Kingsbury's paper. The problem remains of expressing the analytical solution in a more convenient form.

Boswall (12) allowed for temperature change in the direction of motion by assuming linear variation of viscosity. A more exact solution for the circumferential temperature distribution was derived by Hummel (10). It would be of value to compare this solution with the experimental findings of Nücker, Pearce, and others (21, 53) and to extend the hydrodynamic theory, if possible, to include the combined effects of temperature and pressure on viscosity.

Thin-Film Lubrication

When the load on a bearing is increased, and the speed or viscosity sufficiently decreased, the condition of operation changes from one of thick-film lubrication, governed by the hydrodynamic theory in its simpler form, to a mixed condition known as thin-film lubrication, in which the high spots on the two rubbing surfaces are beginning to experience boundary lubrication. With further increase of load and decrease in speed or viscosity, boundary lubrication predominates and finally gives way to an extreme condition of imperfect lubrication characterized by wear and seizure. Thick-film lubrication and pure boundary lubrication may be regarded as the two limiting cases of thin-film lubrication.

Wear and seizure phenomena have been investigated at great length, particularly in connection with cylinder lubrication, running-in, bearing metals, and the development of extreme-pressure lubricants (40, 46, 50, 54). These investigations have brought an increasing realization of temperature as a factor for consideration in future studies.

Relatively less has been done in the field of pure boundary lubrication (38, 50) because of the difficulty of isolating such phenomena and avoiding wear or contamination. Bowden has reported on the stick-slip phenomenon, correlating friction with surface-temperature measurements (37). Needs discovered such characteristics as directional rigidity and thixotropy in boundary films, taking care to avoid heat effects (52). It would be of interest to learn to what extent these useful, load-carrying characteristics persist in conjunction with heat effects at the higher speeds.

Thin-film lubrication embraces a variety of phenomena induced by surface irregularities, quite apart from the adsorption phenomena constituting boundary lubrication. Since these phenomena are physically simple, being complicated only in a geometrical sense, they offer inviting problems for dimensional analysis. For example, the heat generated locally by the rapid tangential motion of high spots on opposite sides of the film must have some effect on the total frictional resistance. This effect depends both on the heat capacity of the lubricant per unit volume, h, and its temperature coefficient of viscosity, a (the fractional change in viscosity per degree rise of temperature). Dimensional theory then shows that the coefficient of friction will be a function not only of ZN/P (in which Z represents the mean film viscosity) but also of h/aP (22). Thus the coefficient of friction for a given load and speed depends not only on the viscosity, Z, of the lubricant but also on the property h/a.

The same relationship was later pointed out by Vogelpohl, who found confirmation in the experiments by Voitländer (30, 45). This method of reasoning has been extended to include the effects of thermal conductivity and the pressure coefficient of viscosity (38). Further comparison of theory and experiment is therefore desirable in the field of thin-film lubrication.

Temperature Measurement

For research purposes the procedure of placing a mercurial thermometer in a drilled hole or in the oil bath or drain, is not always reliable. Thermocouple technique is now well standardized. Copper-constantan or similar couples with a direct-reading millivoltmeter of low range form a convenient setup. A vacuum flask is useful for the cold junction which may either be in melting ice, or in atmospheric air with a room-temperature thermometer attached. The hot junction may be brought close to the rubbing surface (21, 45), and thus an approximation to the bearing temperature is obtained.

[4] Thermally similar models are discussed on pp. 95–96, 119–120 of reference (38). In Equation [42], p. 95, H represents power loss per unit length; if defined as total loss, multiply left side by diameter, D.

Astonishing differences are often found when this method is substituted for older procedures, including the orthodox procedure of averaging the inlet- and outlet-oil temperatures (44, 58). It remains to correct for the temperature gradient across the film, discussed above, before the effective film temperature can be determined.

The film temperature may be estimated from observations of oil-bath temperature by formulas based upon the assumption that the oil is a perfect insulator, so that heat is removed from the film only by convection (43). When this method is applied to thrust bearings it is commonly assumed that the bearing metal remains at the bath temperature. From figures given by Michell it would appear, however, that in heavily loaded thrust bearings not more that 10 per cent of the heat is carried away by the oil, the remainder being conducted through the film into the bearing shoes (41). The two assumptions just mentioned cannot therefore be generally valid, and further research is required.

The difficulty of measuring film temperatures with perfect or imperfect lubrication has prompted the suggestion of novel methods. These range from the use of microscopic suspended particles of known melting points to the thermoelectric effect of dissimilar moving surfaces. The latter method had been suggested by Lyman J. Briggs (9, 28). When applied to large areas it involves an averaging effect recently studied by Emmons (49). In view of the widespread use that has been made of the thermoelectric method it might be of value to investigate its accuracy and methods of calibration for various applications, particularly for use under high pressure.

Properties of Lubricants

The physical properties of chief interest for lubrication in the present state of our knowledge are viscosity (regarded as a function of pressure and temperature); heat capacity per unit volume (product of density by specific heat); and thermal conductivity. If we understood better how to define and measure adhesion, wetting, and other surface properties, it is possible that significant differences between lubricants might be found and correlated with their performance.

Vogel's equation is generally accepted as an accurate expression for the viscosity-temperature relation (6) and has been used in developing the A.S.T.M. charts for kinematic viscosity (18). Similar charts for absolute viscosity are needed. Further mathematical studies of the viscosity-temperature relation have been conducted by Cragoe (13), Erk and Eck (29), Lederer (32), and Barr (35). In the meantime unpublished observations have been accumulating which could usefully be made available to extend the temperature range.

Viscosity-pressure relations have been formulated by Kiesskalt, Cragoe, Suge, and others (25, 31) while a general coordination of high-pressure data is in progress under a committee of The American Society of Mechanical Engineers. This line of experimentation has recently been extended to include preliminary studies of the consistency of oils undergoing apparent solidification under pressure (57). There is need for improvement in technique and extension of observations to higher temperatures.

A correlation of specific heat with density and temperature was given by Cragoe for petroleum lubricants (13). From these tables the heat capacity per unit volume at 100 F, in the case of an oil of specific gravity 0.90 at 60 F, may be taken equal to 136.7 in-lb per cu in. per deg F. To correct for temperature, add 0.7 per cent for every 10 deg above 100 F; and for specific gravity, 0.6 per cent for each 0.01 above 0.90.

The foregoing applies to oils of a medium V.I. (viscosity index). For 100 V.I. (low slope on viscosity-temperature diagram) add 2 per cent; for 0 V.I. (steep slope) subtract an equal amount. Cragoe's investigation is based on tests completed before 1929. Additional data have been published by Kraussold (20). An improved method of correlation has been proposed by Watson and Nelson (24). There is an opportunity for research in bringing heat-capacity values up to date, and extending them to other lubricants than straight petroleum oils.

Thermal-conductivity determinations on oils are difficult. Relatively few investigations have been reported (13, 23, 38). With increasing need for conductivity data, new determinations and correlations are in order.

To meet lubrication requirements of the near future, every encouragement must be given toward the development of improved lubricants having lower viscosity-temperature slopes, greater heat capacities per unit volume, and higher thermal conductivities.

Operating Troubles

Some bearing surfaces are expected to run warm because of heat from other sources, notably those of engine cylinders (40, 46) and steam-turbine bearings on the high-pressure side (42, 56). Others overheat from excessive friction, which in turn may be due to misalignment, eccentric loading, aeration or failure of the oil supply, and similar causes not anticipated by the designer (14, 42, 43, 55).

Graphite in some form is often recommended for high-temperature lubrication (39). Denton found that heavily loaded bearings, when overheated, ran cooler after throwing a liberal quantity of sand or emery into the lubricant (1). Possibly this combination may be regarded as the forerunner of modern E.P. lubricants (40).

While special lubricants may be necessary for gears and cutting tools, the rational treatment of bearing problems seems to lie in correct design, finish, adjustment, and selection of bearing metals (50, 54). Aircraft-engine bearings and roll-neck bearings are now designed to carry normal operating loads well above 3000 psi of projected area.[5] A good bond between bearing metal and backing, in fact good contact between all adjoining parts is essential to facilitate conduction.

Trouble analysis offers a starting point for research. The customer's plant makes an excellent laboratory if supplied with recording instruments and sufficient mutual understanding. There is constant need for coordination and intercomparison of theory, experiment, and field data on service performance.

Bearing Design

In the prehydrodynamic era, bearing design was governed by Thurston's rule according to which the load per unit area is taken inversely proportional to the surface speed. Interpreted on the assumption of imperfect lubrication with a constant coefficient of friction, this corresponds to a fixed rate of heat generation per unit area and a nearly constant upper limit of temperature. If two journal bearings of equal diameter were to be designed for different speeds, the faster one would be given the greater length.

Following the work of Reynolds it came in time to be realized that in well-lubricated bearings, the load corresponding to any fixed film thickness is proportional to the product of the viscosity by the speed (4). Thus if two bearings of the same diameter and operating at equal film viscosities are designed for different speeds, the faster one may be the shorter. Present-day methods of bearing design are based on these principles, and have been applied to a variety of problems on the assumption of a constant viscosity (19).

Length-diameter ratios have been reduced from 2 or 3 in the days of Thurston to as low as $^1/_2$ or $^3/_4$ in modern connecting-rod

[5] Reference (50), pp. 157–159, 214–215.

and roll-neck bearings. Determination of clearance-diameter ratios is more difficult, and hardly compatible with the constant-viscosity assumption, since a slight change of clearance may produce a marked difference in oil flow and temperature rise.

All signs point now to the arrival of a third epoch in bearing design, in which heat conditions must be explicitly considered (33, 43, 51). This situation can only be intensified during the national-defense period. It imposes two new requirements on bearing design, (*a*) more efficient lubricating and cooling systems, and (*b*) the calculation of film temperatures, load capacities, and other relations without assuming constant viscosity.

Recent patent literature on thrust and journal bearings shows increasing attention to cooling devices such as internal water circulation and even thermal contact between movable parts. Thus requirement (*a*) has clearly been foreseen. It is to be hoped that the necessary calculations will rapidly follow and be applied to such interesting problems as, for example, optimum clearances in journal bearings.

Conclusion

It has been predicted in this paper that with the increasing loads and speeds to be dealt with in bearing practice, a more systematic study of heat conditions will be required. Bearing design can no longer be approached as a problem in pure mechanics. Tentative methods of solution have been indicated, particularly in the case of thermal equilibrium, and some of the research problems that seem to lie just around the corner have been described.

Discussion

A. L. Beall.[7] It is not difficult to agree with the conclusions expressed in this paper in dealing with the type of practice for which there are no useful precedents. While heat conditions are extremely important, it is possible to design lubricant supplies to a bearing with a part of the lubricant directed to maintaining the film, while much of it is used only for cooling.

It is axiomatic that any design to provide extra cooling must insure the availability of an adequate supply of lubricant to maintain the film, and that the film supply is not subjected to a sufficiently high temperature to lower its viscosity dangerously.

Aircraft-engine bearings are now regularly designed to carry loads in excess of 8000 psi of projected area for limited periods of operation, and, in practice, frequently carry this load for extended periods. Major difficulties to overcome are eccentric loading and distortion of the material of the bearing, which are hardly legitimate lubrication problems but definitely come within the designer's province.

Highly loaded gear teeth do show the advantage of lubricants with extreme pressure properties under high-temperature operating conditions, but both in the case of gears and bearings the means of providing the lubricant, the material and finish of the surfaces exert a substantially greater effect than differences in the load-carrying ability of the lubricants thus far tested.

[7] Research Engineer, Wright Aeronautical Corporation, Paterson, N. J. Mem. A.S.M.E.

J. T. Burwell.[8] The author has devoted a section of the paper to transient conditions, referring to occasions when the temperature is changing with time. The writer wishes to point out that there is another kind of transient condition, namely, when the geometry is changing with time, such as occurs during the running-in of bearings and other moving surfaces. Here the surface profile changes from the initially formed surface to the steady-state one, which is finally achieved when the run-in is complete. The mechanism is little understood, but it is known that the degree and efficacy of running-in is strongly dependent upon the temperature at which it takes place. Conversely, the amount of heat produced depends upon how well the surfaces are run in.

This question of change in surface profile brings us to the matter of surface finish per se. A great deal more work needs to be done on its effect on bearing performance. In the thin-film region, this means its effect upon the rate of heat production and tendency to gall.

Finally there is a class of phenomena which, while not related to the question of heat at all, should be mentioned because of their rather unexpected electrical nature and also because very little work has been done on them other than by the workers who postulated them. Kyropoulos[9] has suggested that a difference in dielectric constant will exist between the bulk of the lubricant in the film between moving surfaces, whose molecules are aligned by flow in the direction of motion, and the adsorbed layers of lubricant on the two surfaces, whose molecules are oriented essentially perpendicular to the direction of flow. The resulting electric field between these two regions will make dispersed solid particles in the oil stick to the surfaces, thus forming an artificial roughness which increases wear. He states that this trouble may be mitigated either by connecting the two surfaces electrically through an external circuit or by adding ionizing constituents to the oil.

Schnurmann[10] has suggested that among the many factors contributing to the phenomenon of dry solid friction should be included that of contact electrification. When two solids, one of which is a dielectric, are brought into contact and then separated, they develop residual electrostatic charges of opposite sign which can then attract each other, thus increasing the normal force holding the two together. He points out that this can become appreciable in the case of long strips of paper running over metal rolls during the course of manufacture.

The relative importance of these electrical phenomena under various conditions of friction should certainly be investigated further.

T. M. Gunn.[11] Most of us remember well the old rules of thumb used a short generation ago for the design of bearings and the rating of their loads. Their virtue consisted mainly in their simplicity, the ease with which one man could apply them as well as another. Then experimenters started work, and it was not long before the world knew that the old rules of thumb were inadequate and misleading. Technical papers galore show how misleading the old rules are, and in a spotty way begin to fill in the

information for new rules, new formulas, new charts. Today there are a few research workers, a few designing engineers, and still fewer operating engineers who are familiar enough with present knowledge to apply it to certain specific problems.

However, today as never before the situation demands immediate results. The pressure of these times necessitates drafting men from one field of effort to another where they have had little or no experience. Such men are forced to make decisions. Correct design is vital. The inexperienced engineer will have little time for study, and so his information must be reduced to the simplest form that will provide a safe basis for his work.

It may be said that this is a problem for technical writers. But who is the logical person to gather data, record it in useful form, correlate, plot, and show the extent to which extrapolation is safe? Does not this call for research methods and mentality? Is not this the time for investigators to review notebooks, and pick out such data as will bear on this subject; to offer the information with suggestions on correlation and methods of presentation? The results of such assembled facts and formulas should finally be drastically systematized and simplified, so that a publication will result that leads its user unfailingly to the best available answer to his problem by analysis as definite as the classification of a wildflower by reference to a book on systematic botany.

The last few years have seen the disclosure of much valuable information, but it is still arranged for the use of the research worker rather than for the practical user. The viewpoint of the latter, the ultimate consumer of this knowledge, must be kept in mind if research work of the last several years is to render its full service at this time when it is most needed.

A campaign of concerted effort along these lines will benefit all parties. The investigator will gain by the review. The mechanical designer will save time and will be able to avoid perilous guesswork. Machine operators may then determine correct operating conditions for their equipment, and even the lubricant manufacturer should find valuable information for his guidance.

J. H. Hitchcock.[12] Probably no one is better qualified than the author of this paper to point out the gaps in our present knowledge regarding the theory of lubrication, and the author has lived up to his qualifications admirably in this instance. He has outlined the phases of the problem which require further investigation, and he has simplified the task of future investigators by appending to his paper an excellent bibliography of sources on this subject.

With the present widespread use of oil-film bearings in enormous numbers, and in applications of the most varied character, and with the growing trend in this direction, resulting from the current congestion in production of antifriction bearings, it is important that effort be continued to fill in the missing parts of the lubrication picture. In the writer's opinion, the points which are in most urgent need of clarification are determination of the actual viscosity prevailing in the loaded oil film, as affected by local temperature and pressure, and evaluation of the optimum quantity of oil supply. Study of the conditions under which thin-film lubrication occurs, and determination of the friction loss and limiting load capacity with thin-film lubrication, are also essential items. It is hoped that the Special Research Committee on Lubrication will carry on its program relentlessly until workable solutions have been provided for all of these questions.

A. B. Lakey.[13] That the temperature rise in the oil film of a Kingsbury thrust bearing is proportional to the unit loading and independent of speed, in the absence of heat transfer from the film to the bearing surfaces, may be seen as follows:

The rate of oil flow in cubic inches per minute from n shoes is approximately

$$F = nhx(\pi D_m N/2) \qquad [1]$$

where h is the film thickness, x the radial width of the shoe, and D_m the mean diameter of the bearing, all in inches, and N the revolutions per minute. From hydrodynamic theory

$$h = (0.0215\ \mu a D_m N/w)^{1/2}/K \qquad [2]$$

where μ is the viscosity in pound-seconds per square inch, a the mean circumferential length of the shoe in inches, w the load in pounds per square inch, and K a side leakage factor equal to 1.6 for square shoes ($a = x$). Similarly the friction horsepower is given by

$$H = 3.29(10)^{-6}KA(\mu D_m{}^3N^3w/a)^{1/2} \qquad [3]$$

where A denotes the total area nax, in square inches.

The ratio of the horsepower loss to the flow in gallons per minute is 231 H/F. The maximum temperature rise of the oil in passing from the leading to the trailing edge of the shoe will be 12.4 times this if we assume 12.4 hp per gpm, as the heat capacity of the oil per degree F. The mean temperature rise Δt_m may be taken equal to one half as much, or 1432 H/F. Substituting from the foregoing equations gives

$$\Delta t_m = 0.052\ w \qquad [4]$$

i.e., the mean temperature rise in degrees F is equal to about one twentieth of the load in pounds per square inch under the conditions assumed.

Little information exists on the effect of suspended air under conditions of steady supply. In cases observed, the air content, although apparently high, was not enough to decrease the films to the point which caused actual bearing trouble while the supply was maintained. No means were available to trace the effect on bearing friction.

It has sometimes been assumed that the narrow entrance to the film in a thrust bearing would act as a sort of strainer for the bubbles, permitting only solid oil to enter. The throttling effect of the bubbles would probably in many cases prevent the entrance of sufficient oil to permit the film to attain its normal thickness.

We have occasionally used test tubes to trace the influence of various arrangements of baffles on aeration. We would immerse a tube in the bath permitting it to fill with the oil; then, keeping its mouth submerged, would shift it to an inverted position with the closed end above the bath. We have then noted the rate at which air has accummulated in the tube, displacing the oil. We have made point-to-point explorations of oil baths in this way and have derived some idea of the distribution of air bubbles, as affected by depth below the free surface and other circumstances.

Indirectly, aeration can be a definite cause for lubrication failure. Consider, for instance, an horizontal-shaft installation in which the nominal oil level is carried close up beneath the shaft. Then, especially if the free surface area of the oil in the system, whether in the bearing housings themselves or in reservoirs or sump tanks, is small, the introduction of air may cause an immediate rise in the oil levels, permitting the oil to touch the shaft, which will thrash up the bath into foam at a cumulative rate. Oil will be lost from the system, especially where the shafts pass out of the housings, and, if the equipment is shut down, the oil after giving up its air may end up at a dangerously

[12] Engineer, Morgan Construction Company, Worcester, Mass. Mem. A.S.M.E.

[13] Chief Engineer, Kingsbury Machine Works, Inc., Philadelphia, Pa. Mem. A.S.M.E.

low level. If this loss is not made up before the next start, there is danger of the bearings' not receiving their proper supply of oil on that run.

With the free-oil surface restricted as noted, there will be slight opportunity for the oil to give up its air in operation; hence, in such a situation, it is especially important to see that aeration cannot even start. This condition also implies that a small change in volume of the bath, whether due to aeration or other causes, will produce a large change in the elevation of the free surface of the baths.

Rapid oxidation of oil has sometimes been traced to aeration. Oxidation of bearing parts was noted in certain of these cases.

It is further true that aerated oil, especially if there is a little water present in the emulsion, will not readily give up its heat in the coolers, or indeed flow properly in piping or other passages.

M. Muskat.[14] The author has presented an excellent summary and review of the various factors involved in determining and controlling the heat and temperature conditions in bearings. He has outlined a method for calculating bearing temperatures by equating expressions for the frictional-heat generation to that for the heat-transfer dissipation, through the intermediary of an independently determined relation between the lubricant viscosity and its temperature. This method is physically sound. However, it involves the conception that the bearing or oil film has a so-called effective or average temperature. On the other hand, it requires a knowledge of heat-transfer constants and coefficients which are not readily obtainable directly. In fact, if there were a satisfactory method available for determining the bearing or lubricant-film temperature independently, the procedure suggested might perhaps be better used for the calculation of the effective heat-transfer constants.

In order to establish any theoretical procedure for calculating heat conditions in bearings it is necessary to compare the calculated temperatures with those determined by some other independent process. Such independent methods have been a subject of much consideration and the source of great difficulty in the past. Suggestions have been made that the bearing or film temperature be taken as a direct or weighted average of the inflow- and outflow-lubricant temperatures. Proposals have been made for, and some measurements reported on, the direct temperature-distribution determinations in actual bearing systems. These have involved the question as to how such bearing-temperature distributions should be averaged, and that of the relationship of the temperatures at or near the surface of the bearing to those within the lubricant film. Moreover, even if the latter could be directly measured, the problem would still remain of averaging these lubricant-film temperatures, since in all the theoretical methods for temperature calculation thus far suggested, such as the one outlined in the paper, the temperature is represented by a single parameter and hence must correspond to some type of average.

In view of these difficulties, it is proposed, at least for the purpose of establishing any general method of calculating bearing or film temperatures, and of obtaining data on actual effective or average temperatures in test bearings, that the procedures heretofore considered be reversed. That is, instead of adjusting the temperature so that the calculated heat dissipation by heat transfer should equal that generated by friction, it is proposed that the temperature be calculated directly from friction coefficients measured with the test bearings.

The basis for such a procedure lies in the observations that the Reynolds hydrodynamic theory of lubrication is strictly valid under thick-film conditions, and that there are now available satisfactory theoretical calculations for the friction performance of journal-bearing systems, even for large journal eccentricities. The former has been established quite conclusively by experiments with both journal bearings and thrust bearings,[15] which were found to give results in almost exact agreement with those predicted theoretically for the particular conditions obtaining in the experiments. It may therefore be concluded that the hydrodynamic theory can be "trusted," as it were, in the prediction of the numerical values of the friction coefficients of bearing systems operating under thick-film conditions.

The second observation refers to the extensive theoretical calculations for the friction coefficients of partial journal bearings of finite width recently reported by E. O. Waters.[16] By using Waters' results directly, or by simple extension to other partial bearings, or even to full journal bearings, we now have available means of predicting quantitatively what the friction coefficient of a particular journal-bearing system should be for a given journal speed, bearing load, and lubricant viscosity; and if the system be operated at high speeds or low loads, even the simple Petroff theory should be applicable.

In the light of this situation, the suggested procedure is essentially as follows: Quantitative friction-coefficient determinations should be made on journal-bearing systems under accurately controlled conditions and operating at speeds for which the temperature rise in the bearings may be anticipated to be comparable to those occurring in practice. For these same bearings, the theoretical friction coefficient versus Sommerfeld variable curves should be constructed. One should then simply adjust or choose the value for the lubricant viscosity entering the expression of the Sommerfeld variable to be such that the theoretically calculated friction coefficient will agree with that observed. Thus, an effective hydrodynamic average lubricant viscosity will be obtained. From the independently determined relation between the viscosity of the lubricant and its temperature, the corresponding effective hydrodynamic average film temperature will be readily obtained. By applying a heat balance one can then also determine the heat-transfer coefficients.

By this procedure one should obtain automatically the physically significant and appropriate average of the true temperature distribution of the lubricant film. The accuracy of such determinations naturally rests upon the accuracy of the measurements and the degree to which a journal bearing under ideal conditions would agree in performance with that calculated by the Reynolds equation. The latter question has already been discussed; the former is one inherent in all experimental work and should involve no greater difficulties here than generally encountered elsewhere. On the other hand, it may be noted that the errors in the calculation of the effective temperature may be significantly lower than those for the viscosity, because of the relative insensitivity of the lubricant temperature to its viscosity in the ranges normally encountered in practice in journal-bearing systems. Moreover, this method should be especially applicable to transient conditions where direct bearing temperatures would be even more susceptible to difficulties of interpretation than those for steady-state conditions.

It is, of course, realized that the method here suggested relates only to experimental test bearings. However, it is felt that it should serve to provide data, hitherto difficult to obtain satisfactorily, which may serve as a basis for developing suitable

methods for predicting film temperatures and heat conditions in bearings to be used in commercial practice.

S. J. Needs.[17] Referring to the author's statement that unpublished data on the viscosity-temperature relation have been accumulating, the absolute viscosities of several oils were measured over a considerable temperature range in Dr. Kingsbury's laboratory several years ago. These measurements were made with the tapered-plug viscosimeter, an instrument of the rotational type, described in a previous publication.[18] With this instrument, it is believed that the viscosity of an oil may be measured with an error not exceeding plus or minus 0.2 per cent.

Results of the the investigation mentioned are shown in Fig. 1 of this discussion, from which it appears that, for each of the oils tested, there is a linear relationship between logarithm of temperature and logarithm of viscosity over the temperature range from approximately 100 F to 225 F. In general, the measured viscosities are below the straight line at temperatures less than 100 F and above the line at temperatures greater than 225 F.

When an oil is raised to a high temperature, the lighter fractions are driven off and the viscosity increases. For this reason observations above 300 F were made as rapidly as possible. Nevertheless, it is probable that observed points above that temperature may be somewhat high. After the original observation at 300 F with Valvoline Edgewater cylinder oil, it was found that the viscosity at 100 F had increased 0.3 per cent. After the reading at 400 F the viscosity at 85 F had increased 4.9 per cent and after readings were completed at 562 F the viscosity at 85 F had increased 27.9 per cent. While this is an example of the instability of oils at high temperatures, it accounts for only a small part of the deviation from the straight-line law.

One interesting exception to the general rule that observed points on the viscosity curves (plotted as in Fig. 1) fall below the straight line at temperatures under 100 F was found in the case of Valvoline Edgewater cylinder oil. Here the viscosity began to rise above the line at 100 F and at 70 F the measured viscosity was 45 per cent above the point on the straight line. This unusual behavior was also observed by Fortsch and Wilson,[19] who found a sharp upturn in the curve for road oil at temperatures below 200 F. They suggested that this behavior was probably a colloidal phenomenon and due largely to adsorption of a film on the walls of their viscosimeter capillary at lower temperatures. In our case, this seems unlikely, since the formation of adsorbed films on the walls of the tapered-plug viscosimeter would quickly be detected by the resulting change in location of the zero film thickness. Possibly the upturn of the viscosity curve is due to the presence of an additive not in perfect solution at temperatures below 100 F.

E. A. Ryder.[20] It is stated in the paper that thermocouple technique is now well standardized. The author probably has in mind the use of thermocouples instead of glass thermometers. However, as to the actual technique of using thermocouples, there is need for much more precise methods than seem to be available at present. Under conditions at which temperature gradients in the metal parts are low, there is no great difficulty in getting accurate temperature measurements. However, where high gradients exist, there is very considerable difficulty.

We have done considerable work on the development of a thermocouple technique for measuring temperatures in the metal walls of a combustion chamber and cylinder barrel and this is equally applicable to measuring temperatures in bearings and their surrounding parts. We are now able to weld small wires to

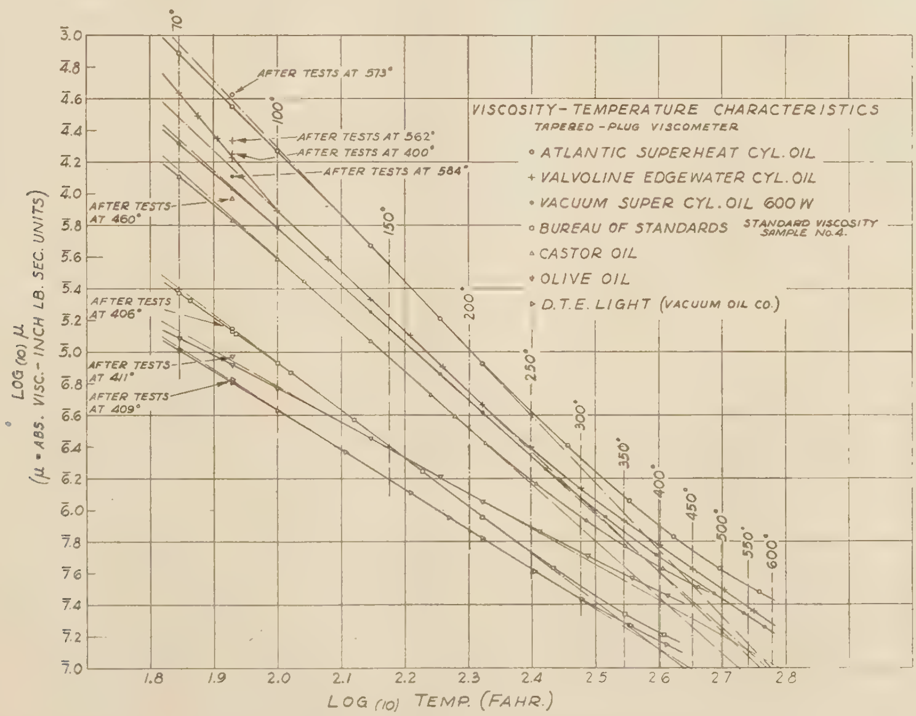

Fig 1 Viscosities of Various Oils Measured by the Tapered-Plug Viscosimeter Over a Wide Range of Temperatures

the bottom of small holes which may be drilled into the cylinder walls to any desired depth and feel that we can know the location where a certain indicated temperature exists to within 0.03 to 0.04 in. This is none too close when studying gradients in walls of only $^1/_8$ to $^1/_4$ in. thickness. It is fairly good for a cylinder-head wall which may be about 0.8 in. thick. We would like to know of some means for measuring spot temperatures to yet closer location. Stated another way, the problem is to know where the temperature exists which is read on the meter.

The author mentions as an operating trouble, excessive aeration of the oil supply. We would like to know what conditions were in mind in making this remark. We have made tests on engines in which air was introduced from the shop air line into the oil supplied to the main bearing and were never able to find much difference in the operation, that is, we could not cause bearing failure by introducing a considerable quantity of air into an otherwise satisfactory bearing.

L. M. Tichvinsky.[21] The author's outline of problems for research will undoubtedly be welcomed by everyone who works on bearing problems and on bearing design. It is hoped that bearing investigations, as outlined, will be carried on successfully and without undue duplication.

It seems to be appropriate to mention specific Diesel-engine-bearing problems. The performance of a Diesel engine is complicated because of several variables which are not encountered in stationary-power bearings.

The "rotating" load characteristic of a Diesel-engine bearing indicates that loads of various magnitudes might act along the entire circumference of the bearing. This is illustrated in Fig. 2 of this discussion, on which representative polar diagrams are given of a power bearing and of arbitrary Diesel-engine connecting-rod and main bearings.

The loading of a power bearing is produced by the weight of rotating masses and by such additional forces which might be due to gear reaction or steam force. The direction of the resultant load, therefore, varies along a relatively small angle spanning the lower bearing shell. The direction of the resultant force of Diesel-engine bearings varies during a working cycle along an arc of 360 deg. The magnitude and the direction of such resultant forces depend upon gas pressure, inertia forces of reciprocating masses, and on the resultant centrifugal force of rotating masses. The effect of gas and reciprocating forces is predominant in connecting-rod bearings of low- and medium-speed engines. The effect of centrifugal forces is usually predominant in main bearings. Unfortunately, the available literature on performance and experimentation of dynamically loaded bearings is meager and incomplete (60, 61, 62, 63, 64).[22]

[21] U. S. Naval Engineering Experiment Station, Annapolis, Md.

Operating bearing temperatures of Diesel-engine bearings are considerably higher than of power bearings. It is difficult to cool Diesel-engine bearings efficiently in poorly ventilated crankcase space, using a low-heat-capacity lubricating oil as a coolant. Heat dissipation from small bearing housings to the crankcase ambient air takes place at a low rate.

All these unfavorable conditions are particularly aggravated in marine Diesel engines which are built to definite restricted weight and space diagrams (65).

Various types of lubricating oils used in Diesel engines might be contaminated by products of combustion. This, together with the effect of high operating temperatures endangers the satisfactory performances of bearings which are often subjected to prohibitive corrosion (66).

There is urgent need for more information pertaining to the performance of Diesel-engine bearings.

Author's Closure

Mr. Beall points out that eccentric loading and other factors may have greater effect than differences in lubricants. Attempts to take into account an eccentric load system of moment M seem to have been made in the testing machine of Fickel (67). To specify this condition dimensional analysis requires a new variable M/PD^3, where P is the resultant load per unit area and D the journal diameter, in addition to ZN/P.

Dr. Burwell discusses running-in and surface finish, and describes electrical phenomena that should be investigated.

Mr. Gunn may have put his finger on the Achilles' heel of our whole research situation, especially as applied to national defense. It is to be hoped that some codification and elucidation of results can be organized, and that in the meantime every encouragement may be given to those few teachers offering courses on lubrication in the engineering schools.

The program urged by Mr. Hitchcock should improve the efficiency of industrial bearings, and seems to call for a further development of field observations on film temperatures. The problem of optimum oil flow dovetails with optimum clearance, and might be advanced by combining Orloff's theory (27, 34) with that of Burwell (68).

[22] Numbers in parentheses for (60 to 66), inclusive, refer to the Bibliography at the end of the closure.

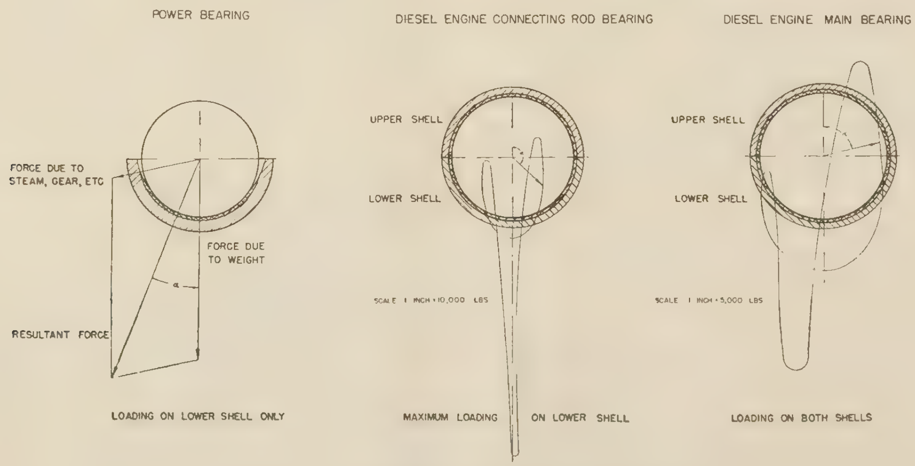

Fig. 2 Typical Bearing-Loading Diagrams

It is fortunate to have on record the derivation given by Mr. Lakey for temperature rise on the adiabatic assumption, thus providing a base for future inquiries into the effects of thermal conduction. The consequences of aeration are described in a way that should be of practical value.

Dr. Muskat offers a procedure for determining the effective film temperature in test bearings from torque observations. This procedure is logical and has something in common with the reasoning applied by Kingsbury in his study of temperature distribution across the film (23). Careful measurements of clearance are essential. It is to be hoped that these experiments may be carried through.

The viscosity-temperature data contributed by Mr. Needs were obtained with an absolute viscosimeter of unique design, and serve not only to extend the range of data available, but to reveal complications that should not be overlooked.

Our knowledge of thermocouple technique has been advanced by Mr. Ryder's discussion. It is reassuring to learn from tests that no serious aeration troubles need be feared in aircraft-engine bearings. The author had in mind conditions reported by steam-turbine operators and others (pp. 56, 69, 248, and 392–393 of Ref. 40, vol. 1). Further light is thrown upon this subject by Mr. Lakey's discussion. Experiments at Göttingen (69) show that the hydrodynamic theory gives correct results only when entry of air into the bearing is prevented.

Mr. Tichvinsky calls attention to the Diesel engine, where load diagrams are complicated and cooling arrangements restricted. A beginning has been made on the theory of fluctuating loads by Harrison (70) and Swift (71), but further study is required.

Among the problems outlined, those relating to optimum clearance and heat transfer have been discussed by Burwell (68) and Karelitz (72) in separate papers, while solutions for non-uniform viscosity due to the combined effects of pressure and temperature are given by Christopherson (73).

The Effect of Diametral Clearance on the Load Capacity of a Journal Bearing

By J. T. BURWELL,[1] CAMBRIDGE, MASS.

It has been found that there is an optimum value of the diameter-clearance ratio of a journal bearing for any given applied load. When the ratio has this value, operation is characterized by a minimum temperature rise in the bearing and a constant value of the Sommerfeld variable $\left(\frac{D}{C}\right)^2 \frac{\mu N}{P}$. These values of the diameter-clearance ratio, while considerably larger than those used in commercial practice, are quite possible of attainment by present machining methods. The use of these closer fits will result in increased load capacities and lower operating temperatures. The present paper is devoted to an investigation of the effect of D/C on the load capacity in a quantitative manner, considering both the hydrodynamic and thermodynamic aspects of bearing operation.

Introduction

It has been shown by the use of dimensional analysis (1)[2] that when a journal bearing is operating hydrodynamically, the friction coefficient, the minimum film thickness, and other dependent operating variables of the system will depend upon the dimensionless products $\mu N/P$, D/C, and L/D, where μ is the viscosity of the lubricant, N the revolutions per unit time, P the load per unit projected area, D the diameter of the bearing, L the axial length of the bearing, and C the difference in diameters of shaft and bearing. If all the quantities are expressed in the same system of units, then the numerical values of the products are independent of the particular system used. If the heat balance in the bearing is taken into account, then, as we shall see later, the operation will also depend upon the thermal properties of the system. Furthermore, Sommerfeld's (2) work on the infinitely long bearing and the subsequent approximate treatment by Muskat and Morgan (3) of bearings of finite axial length make it seem fairly certain that operation of a bearing with a given axial length-to-diameter ratio L/D is determined by the composite expression $\left(\frac{D}{C}\right)^2 \frac{\mu N}{P}$ often called the Sommerfeld variable and denoted by S.

Indeed, numerous experiments have shown that bearing assemblies of a given type, i.e., made of the same materials, using the same oil, and having the same finish on the rubbing surfaces, will all be characterized by the same minimum value of $\left(\frac{D}{C}\right)^2 \frac{\mu N}{P}$ which marks the limit of safe operation of the assembly, and hence determines its load capacity. It would appear from the foregoing that it is necessary only to increase the ratio D/C indefinitely in order to carry any desired load and keep $\left(\frac{D}{C}\right)^2 \frac{\mu N}{P}$ above the minimum. On the other hand, the smaller clearance would result in higher rates of shear in the lubricant and, hence, higher temperatures with correspondingly lower viscosity so that the net result might even be a decrease in $\left(\frac{D}{C}\right)^2 \frac{\mu N}{P}$. It is the purpose of the present paper to investigate the question of the effect of D/C on the load capacity in a quantitative manner, considering both the hydrodynamic and thermodynamic aspects of bearing operation.

This question has now become of practical interest for two reasons, as follows:

1 Several trends in modern bearing design have been such as to favor the use of smaller clearances. These include the use of smaller axial length-to-diameter ratios which makes the effect of shaft deflection and misalignment much less important; the use of more accurate machine tools and techniques as applied to both shaft and bearing which makes better and closer fits possible; and finally the fact that the attention of both designers and builders has been attracted to the importance of controlling and improving the surface finish. Improvement in each of these three respects will render smaller clearances possible. It will be shown in the present work that the use of small clearances, smaller than are generally used at present, has very distinct advantages.

2 The question of the effect of the diameter-clearance ratio on operation becomes important in studying the mechanism of the running-in process. During the running-in of hard bearing materials it seems probable that the only change in geometry of the system is the smoothing of rough surfaces and local wear on isolated high spots but when softer bearing materials, notably babbitt, are run-in a momentary failure of the oil film may result in a wiping of the entire loaded side of the bearing by the shaft. As a result, the curvature of this portion of the bearing is appreciably changed and the diameter-clearance ratio becomes different. It is of great interest to know how this change will affect the operation of the bearing; to know whether it will be advantageous or detrimental. The application of the results to this type of running-in of soft bearing materials will be discussed.

Equations for Thermal Equilibrium

The treatment given here follows that outlined by Hersey[3] and employed by McKee (4) to determine the safe load capacity of a bearing as a function of the speed and other variables.

The rate of heat production in a journal bearing is given by the equation

$$H = fPLD \cdot \pi DN \qquad [1]$$

where H is the rate of heat production, f is the friction coefficient, and the other symbols have their previously assigned meanings.

The rate of heat dissipation in bearings can be described (4, 5) by the equation

$$H' = B\pi LD(\Delta T)^a \qquad [2]$$

Here ΔT is the rise in temperature of the bearing above its surroundings, and B and a are empirical constants, depending upon the type of housing and surroundings, but are roughly independent of the dimensions.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

[3] Bibliography reference (1), chap. 5.

The condition for thermal equilibrium is given by equating H and H'

$$fPLD \cdot \pi DN = B\pi LD(\Delta T)^a \qquad [3]$$

As previously stated, it is now well established that the friction coefficient is some function of $\left(\frac{D}{C}\right)^2 \frac{\mu N}{P}$ and $\frac{L}{D}$, and the relationship, as shown by the theoretical work of Sommerfeld (2) and Muskat and Morgan (3), is of the form

$$\frac{D}{C} f = \varphi\left[\left(\frac{D}{C}\right)^2 \frac{\mu N}{P}, \frac{L}{D}\right] \qquad [4]$$

The explicit form of the function φ has never been derived from hydrodynamic theory, but the wealth of experiments on the Equation [4] relationship have produced a number of empirical expressions. Very careful experiments (6) indicate that Equation [4] can be described approximately by an equation of the form

$$\frac{D}{C} f = K_1 \left(\frac{D}{C}\right)^2 \frac{\mu N}{P} + K_2 \qquad [5]$$

where K_1 and K_2 depend upon L/D and the length of the bearing arc, but are independent of D/C. There is some indication (3, 7) that, in cases where sufficiently low values of $\left(\frac{D}{C}\right)^2 \frac{\mu N}{P}$ can be attained, the friction-coefficient curves cease to be straight lines and curve downward toward the origin. Indeed, theory would indicate an intercept of unity on the D/C axis when the friction torque is measured on the shaft, and an intercept of zero when it is measured on the bearing. In this case, the exponent of $\left(\frac{D}{C}\right)^2 \frac{\mu N}{P}$ in Equation [5] should be less than unity.

Finally it is well known that the viscosity of a lubricant is strongly dependent upon both the temperature and pressure, and this furnishes us with the third necessary relation. It will be sufficiently accurate for our purposes to take this relationship in the form

$$\mu = \frac{\mu_0 e^{bP}}{(T_P + \Delta T)^m} \qquad [6]$$

This form of the temperature dependence was first suggested by Slotte (8). Here μ_0, T_P, m, and b are constants for a given lubricant, and T_P may be considered the difference in temperature between the solidifying point of the oil and room temperature at atmospheric pressure. In this treatment the dependence of m on P and of b on T is neglected although they may be quite appreciable for the naphthenic oils (9).

Two Conditions for Stable Operation

We have the three Equations [3], [5], and [6] in the three quantities f, ΔT, and μ. Now there are two conditions which limit the practical operation of a journal bearing. The first is the hydrodynamic condition that $\left(\frac{D}{C}\right)^2 \frac{\mu N}{P}$ must always exceed a definite minimum value, say S_0, which is characteristic of the particular assembly and is dependent upon nonhydrodynamic properties of the system. Below this point metal-to-metal contact takes place between bearing and journal, and additional heat is produced, which in turn thins and reduces the carrying capacity of the supporting oil film, so that more metal-to-metal contact can take place. This is an unstable condition and automatically leads to seizure. Above this minimum value, operation is hydrodynamic and stable.

The second condition for safe operation is that the temperature rise in the bearing ΔT shall not exceed a certain amount, otherwise the oil deteriorates rapidly and the softer bearing materials may even melt and flow.

These two conditions lead to two different equations. First put

$$\left(\frac{D}{C}\right)^2 \frac{\mu N}{P} = S_0 \qquad [7]$$

where S_0 is a constant. This determines a value of f by Equation [5]

$$\frac{D}{C} f = K_1 S_0 + K_2 \qquad [8]$$

Substituting this value of f in Equation [3] and eliminating μ and ΔT between Equations [3], [6], and [7], we obtain, after rearrangement, the relation

$$e^{bP} \cdot bP = \frac{bS_0}{\mu_0 N} \cdot \left(\frac{P}{D/C}\right)^2 \cdot \left[\left(\frac{\{K_1 S_0 + K_2\} DN}{B}\right)^{1/a} \cdot \left(\frac{P}{D/C}\right)^{1/a} + T_P\right]^m \qquad [9]$$

This form of the equation is chosen because it is convenient for calculation.

If next we set ΔT equal to a constant ΔT_0 in Equations [3] and [6], and then eliminate μ and f between Equations [3], [5], and [6], we obtain after rearrangement

$$e^{bP} \cdot bP = \frac{bK_2(T_P + \Delta T_0)^m}{K_1 \mu_0 N} \cdot \frac{P}{D/C} \cdot \left[\frac{B(\Delta T_0)^a}{K_2 DN} - \frac{P}{D/C}\right] \qquad [10]$$

This equation also gives the load capacity as a function of the clearance ratio, but this time for a given temperature rise in the bearing.

In Figs. 1 to 5 we have chosen particular numerical values for the quantities occurring in Equations [9] and [10], and have plotted P as a function of D/C for values of S_0 equal to 0.005, 0.05, 0.267, and 0.5, and for values of the temperature rise of 170 F, 220 F, and 270 F. As an example, we have employed the dimensions and operating data of the friction-testing machine described elsewhere (7). It employs a partial bearing of 147-deg arc, and the friction-coefficient curves given in the reference can be best fitted with $K_1 = 7.5$ and $K_2 = 2$. The radius of the bearing is $2^1/_{16}$ in., and its axial length 1.08 in. Lasche (5) found experimentally that for the conventional type of bearing housing $a = 1.3$, while McKee (4) found $a = 1.65$. We have taken $a = 1.5$ in plotting these curves. Following Lasche, we have taken $B = 2.9$, when H is expressed in Btu per hour, L and D are in feet, and ΔT is in degrees F. The measured viscosities of both grades of oil considered over the temperature range from room temperature to 350 F are well represented by Equation [6], if m is taken as 3. In all the plots except Fig. 2, $b = 2 \times 10^{-4}$ sq in. per lb which from the data of Dow (9) is intermediate between a Pennsylvania and a California oil. In Fig. 2 the effect of neglecting the dependence of viscosity upon pressure, i.e., $b = 0$, is shown. Term T_P has been taken as 80 F. Calculations are made for three speeds, 500, 1500, and 2500 rpm, and two grades of oil, an S.A.E. 10 for which $\mu_0 = 0.096$ when the viscosity is expressed in lb-min per sq in., and the temperature in deg F, and an S.A.E. 30 oil for which $\mu_0 = 0.225$.

For large values of P the curves of constant S_0 bend toward the P axis as shown in Fig. 4 but for most of the range of practical interest, it can be said that the load capacity for a given S_0 increases as D/C increases.

The curves for a constant temperature rise show an increase in load capacity with increasing D/C up to a certain point after which it decreases again to zero. From this point of view there

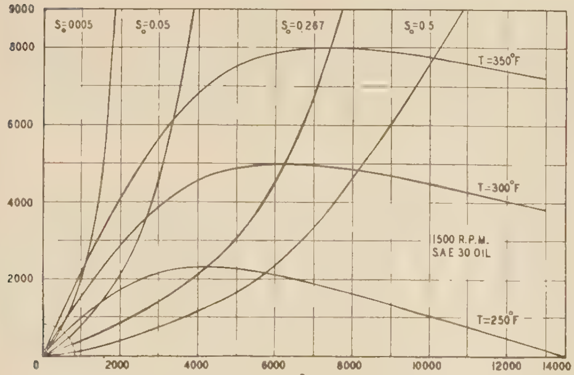

FIG. 1 DEPENDENCE OF LOAD ON DIAMETER-CLEARANCE RATIO FOR CONSTANT VALUES OF TEMPERATURE RISE AND CONSTANT VALUES OF SOMMERFELD VARIABLE
(Speed 1500 rpm; oil S.A.E. 30.)

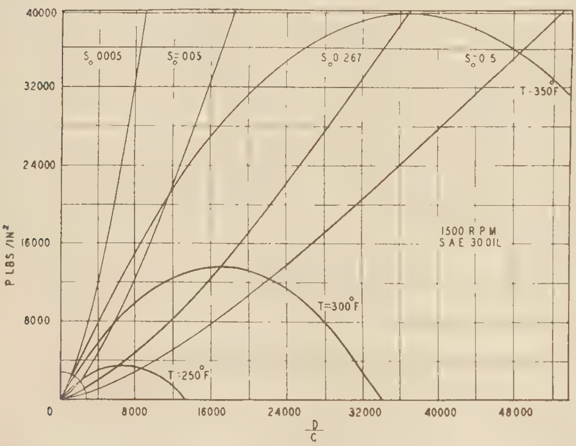

FIG. 2 DEPENDENCE OF LOAD ON DIAMETER-CLEARANCE RATIO FOR CONSTANT VALUES OF TEMPERATURE RISE AND CONSTANT VALUES OF SOMMERFELD VARIABLE, NEGLECTING DEPENDENCE OF VISCOSITY ON PRESSURE, I.E., $b = 0$
(Speed 1500 rpm; oil S.A.E. 30.)

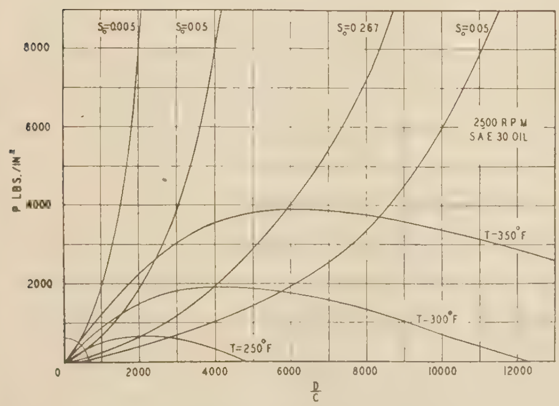

FIG. 3 DEPENDENCE OF LOAD ON DIAMETER-CLEARANCE RATIO FOR CONSTANT VALUES OF TEMPERATURE RISE AND CONSTANT VALUES OF SOMMERFELD VARIABLE
(Speed 2500 rpm; oil S.A.E. 30.)

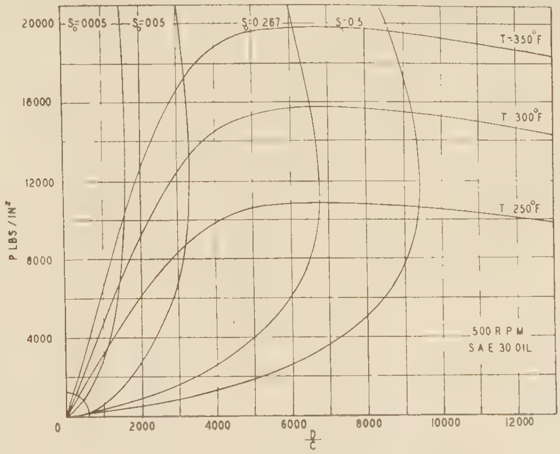

FIG. 4 DEPENDENCE OF LOAD ON DIAMETER-CLEARANCE RATIO FOR CONSTANT VALUES OF TEMPERATURE RISE AND CONSTANT VALUES OF SOMMERFELD VARIABLE
(Speed 500 rpm; oil S.A.E. 30.)

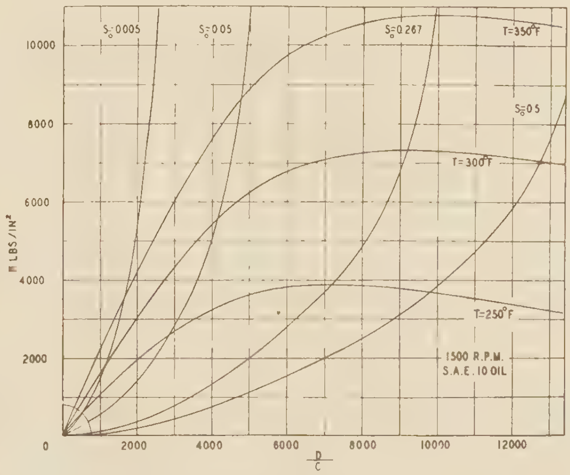

FIG. 5 DEPENDENCE OF LOAD ON DIAMETER-CLEARANCE RATIO FOR CONSTANT VALUES OF TEMPERATURE RISE AND CONSTANT VALUES OF SOMMERFELD VARIABLE
(Speed 1500 rpm; oil S.A.E. 10.)

is a limit as to how much it is desirable to increase D/C. It will be noted from Fig. 2 that when $b = 0$, these curves become parabolas.

The maxima of these curves are of interest. Since $e^{bP}bP$ is an increasing function of P for all positive values of P, then a maximum in the value of the function will yield a maximum value of P, hence

$$\frac{d}{d(D/C)}\,(e^{bP}\,bP) = \frac{bK_2(\Delta T_0 + T_P)^m}{K_1\mu_0 N}\cdot\left[\frac{B(\Delta T_0)^a}{K_2DN} - 2\,\frac{P}{D/C}\right]\cdot\frac{\frac{D}{C}\cdot\frac{dP}{d(D/C)} - P}{(D/C)^2} = 0$$

At the maximum $\dfrac{dP}{d(D/C)}$ is also zero so that the only maximum occurring for positive values of P is characterized by the expression

$$\frac{D}{C} = \frac{2K_2DN}{B(\Delta T_0)^a}\cdot P_{\max} \qquad [11]$$

Substituting this value of D/C into Equation [10], we obtain the expression for P_{max}

$$e^{bP_{max}} \cdot bP_{max} = \frac{bB^2(\Delta T_0)^{2a}(T_P + \Delta T_0)^m}{4K_1K_2\mu_0D^2N^3} \quad \ldots\ldots [12]$$

If Equations [11] and [12], together with Equation [6] for μ, are substituted into the expression $\left(\frac{D}{C}\right)^2 \frac{\mu N}{P}$, we find

$$\left(\frac{D}{C}\right)^2 \frac{\mu N}{P} = \frac{K_2}{K_1} \quad \ldots\ldots [13]$$

This is independent of the temperature rise and shows that the maximum load that can be carried for any temperature rise will always yield the same value of $\left(\frac{D}{C}\right)^2 \frac{\mu N}{P}$, namely, $\frac{K_2}{K_1}$. Hence, if the diameter-clearance ratio can be varied to obtain the maximum load capacity, the bearing should never have to operate below this value. It will be seen from the illustrations that the curve $S_0 = \frac{K_2}{K_1} = 0.267$ passes through the maxima of all three curves.

Discussion

Safe operation of the bearing requires that both criteria must be satisfied. This means that the region in Figs. 1 through 5 which lies below both the curve for the selected S_0 and that for the operating temperature, represents the region of safe operation, i.e., a bearing with a given D/C will safely carry a given load P if the point determined by these two values lies in this region. All the rest of the area of Figs. 1 through 5 represents a region of unsafe operation, one or both of the conditions being violated. It is seen that, in order to remain above the limiting value S_0, the clearance ratio should be increased as the load is increased but, for a given temperature rise in the bearing, there is a maximum load which cannot be exceeded no matter how the diameter-clearance ratio is varied.

The locus of these maxima is the curve $S_0 = \frac{K_2}{K_1}$ which is independent of the temperature rise. The axial length of the bearing does not appear explicitly in either Equation [9] or [10]; it does, however, enter implicitly through K_1 and K_2 which depend, not upon the absolute value of the axial length, but rather on its ratio to the diameter L/D. Term K_2/K_1 decreases as L/D increases and, although the exact functional relationship is unknown, Equation [5] being only an approximation, K_2/K_1 is rarely less than 0.05, so that it is generally possible to operate a bearing safely at this value of $\left(\frac{D}{C}\right)^2 \frac{\mu N}{P}$.

This being the case, we are now in a position to find the optimum value of the diameter-clearance ratio for any given set of conditions. If a bearing whose characteristics are known is required to carry a given load at a given speed using a given oil, then Equation [12] will give the temperature rise to be expected. Using this calculated temperature rise the correct value for the diameter-clearance ratio can be calculated from Equation [11]. This is the least temperature rise that can result from that load as far as variation in D/C is concerned; but if even that temperature is excessive, then a lighter oil will have to be used as shown by Equation [12].

It is evident from the illustrations that these optimum values of the ratio are considerably larger than those in common use today. However, these are quite possible of attainment with the more refined machining techniques at present available. In order to produce these closer fits, more and more accurate geometry is required, both as regards large-scale trueness and also small-scale roughness. For instance, at 1500 rpm, using an S.A.E. 30 oil, the bearing for which the graphs in Fig. 1 are calculated should have a diameter-clearance ratio of 1 part in 2300 to carry a load of 1000 psi, and a ratio of 1 part in 6250 to carry a load of 5000 psi. The bearing will in both cases operate at a value of $\left(\frac{D}{C}\right)^2 \frac{\mu N}{P}$ of 0.267.

It should be pointed out that Equations [9] and [10] are quite general and show the dependence of the load capacity not only on the diameter-clearance ratio, but also on the speed, the oil, and the characteristics of the bearings. Hence, for a bearing whose ratio has already been determined, it may be found from Equations [9] and [10] what grade of oil to use for a given load and speed. In this connection it is clear from Equation [9] that McKee's statement (4) that an increase in viscosity increases the load capacity for a given minimum value of $\left(\frac{D}{C}\right)^2 \frac{\mu N}{P}$ is only true if the change of viscosity with pressure is neglected. If the latter is taken into account, a lighter-grade oil can carry the load at the higher pressures. Equation [10] shows that this is definitely desirable from the point of view of minimizing the temperature rise. For example, an S.A.E. 10 oil at 5000 psi may have the same viscosity, and hence the same load capacity, as an S.A.E. 30 oil at atmospheric pressure and will run much cooler.

These results were obtained by assuming a particular form of the function φ in Equation [4] for the friction-coefficient curve although this form has been shown by numerous experiments to simulate actual operation closely. However, the general features of the plotted curves are preserved for a wide variety of assumed forms for φ so long as they approximate the experimental values. The general shape of the curves of constant S_0 do not depend upon the form of φ anyway, and it can be shown by minimizing the friction force $fPLD$ that the curves of constant temperature rise will always show a maximum provided that

$$\frac{\partial \varphi}{\partial S} = \frac{1}{2}\frac{\varphi}{S}$$

where $S = \left(\frac{D}{C}\right)^2 \frac{\mu N}{P}$. This condition will always be satisfied at some point on any curve having the same general shape as the experimental friction-coefficient curve. Hence, our conclusions about an optimum diameter-clearance ratio are not affected by the particular assumed form of φ.

As stated in the introduction, the running-in of soft bearing materials may, under high loads, produce a wiping of the bearing surface with a resultant change of curvature. This change is always in the direction of conforming more closely to the shaft, which means that the D/C ratio for the assembly has been increased. It is apparent from the accompanying illustrations that such a change will always increase the operating value of $\left(\frac{D}{C}\right)^2 \frac{\mu N}{P}$ which is in itself advantageous. Furthermore up to a certain point which is characterized by $S_0 = \frac{K_2}{K_1}$, it will decrease the bearing temperature, which is also advantageous; but beyond this point the temperature will rise again with accompanying thinning and increased deterioration of the oil. This will increase the tendency of the surfaces to wipe, thus producing an unstable condition leading to failure. This wiping may prove beneficial or it may prove detrimental. This will depend upon whether it takes place gradually so that when the optimum value of the diameter-clearance ratio is reached the bearing has an opportunity to operate stably, or whether the change takes place in one step producing a D/C far to the right of the optimum value, thus producing high temperatures and leading to failure. How-

ever, if the temperature rise for the given applied load is excessive even with the optimum clearance, then failure is bound to result and the only possibility is to use a lighter oil. It may be concluded then that under certain controlled conditions the change of curvature of a soft metal bearing surface during running-in may be beneficial.

Summary and Conclusions

The effect of the diameter-clearance ratio on the load capacity of a journal bearing has been investigated, considering both the hydrodynamic and thermodynamic aspects of its operation. It has been found that, from the point of view of remaining above a minimum value of $\left(\frac{D}{C}\right)^2 \frac{\mu N}{P}$, the ratio must be increased as the load is increased. It has also been found that for any given applied load there is a minimum temperature rise when the ratio has the proper value. This value can be calculated from the formulas given. It varies with the applied load, but the value of $\left(\frac{D}{C}\right)^2 \frac{\mu N}{P}$ at these points of minimum temperature is independent of all the variables except the axial length-to-diameter ratio of the bearing. The actual value of $\left(\frac{D}{C}\right)^2 \frac{\mu N}{P}$ is such that it is entirely feasible to operate bearings at these points of minimum temperature. The values of the diameter-clearance ratio thus required, while considerably larger than those used commercially today, are quite possible of attainment. The use of these closer fits should result in increased load capacities and lower operating temperatures.

From the formulas presented one can also determine the correct oil to be used for a given load and speed in a bearing whose diameter-clearance ratio has already been fixed.

Discussion

B. L. Newkirk.[4] The author has not dealt with the question of stability of operation of bearings with large D/C ratios. If the journals ran more nearly concentric with these bearings than in ordinary bearings with smaller D/C ratios, we might question whether whirling might not develop at speeds well below twice the critical speed of the rotor. It is known that the speed at and above which whirling due to oil action occurs in bearings with smaller D/C ratios may be increased by increasing unit loading or by other measures which cause the journal to run farther from the bearing center. Conversely a lightly loaded journal will support whirling at lower speeds. If the theoretical possibilities of these large D/C ratios look attractive, it would seem that experimental studies should be made to throw light on the whirling characteristics of bearings of such proportions.

Author's Closure

The author agrees with Professor Newkirk that any experimental investigation of the performance of journal bearings with large D/C ratios should include a study of their stability with reference to oil whirl. It seems doubtful that whirling will develop at speeds appreciably below twice the critical since this is not observed even with vertical shafts in guide bearings where the shaft and bearing are most nearly concentric. The unusually small clearance may, however, be expected to affect this stability in two ways. First, the amplitude of the whirl will be small, and second, small displacements or deflections which bring the journal and bearing into contact might induce whirling in the reverse sense under the impulse of dry friction.

Heat Dissipation in Self-Contained Bearings

By G. B. Karelitz,[1] New York, N. Y.

Heat Dissipation

The losses in self-contained bearings[2] are caused usually by the viscous friction in the fluid film separating the journal from the bearing. After a steady state of temperature has been reached (from 1 to 3 hr after starting the machine), the heat generated by friction is equal to that dissipated by the housing into the surrounding air, plus the heat conducted through the shaft, and through the pedestal to the foundation or bearing support.

The portion of the heat carried off by conduction is rather small. The thermal conductivity of the common structural metals is comparatively low, as shown in Table 1.

Furthermore, the temperature gradient along the shaft or along the pedestal is small, 1 or 2 deg F per in. (The pedestal is frequently separated from the machine by an air gap.) For instance, in a 5-in. bearing, with a loss of, say, 0.5 hp = 1273 Btu per hr, with a temperature gradient of, say, 1.5 deg F per in., the heat conducted through the steel shaft would be only $2[(\pi/4)\ 25]\ 1.5 = 58$ Btu per hr. In the first approximation, it can be assumed that the heat generated by friction is dissipated entirely through the housing surface.

TABLE 1 THERMAL CONDUCTIVITY OF COMMON STRUCTURAL METALS

Metal	Thermal conductivity — Calories, Sq cm × sec × deg C/cm	Thermal conductivity — Btu, Sq in. × hr × deg F/in.	Remarks; composition, per cent
Carbon steel.......	0.109	2.02	C-0.6
Nickel steel........	0.074	1.38	Ni-5

Gun metal.........	0.170	3.18	Cu-85, Sn-9, Zn-5, Pb-1
Bronze............	0.118	2.20	Cu-88, Sn-10, Zn-2
Babbitt...........	0.075	1.40	Sn-85, Sb-10, Cu-5

The rate of dissipation was determined[3] for bearing housings of common finish by direct measurement of heat input and surface temperature

$$K = 0.0075\ \frac{\text{Watt}}{\text{Sq in.} \times \text{deg C}} = 2.1\ \frac{\text{Btu}}{\text{Hr} \times \text{sq ft} \times \text{deg F}}$$

in quiet air

$$K = 0.021\ \frac{\text{Watt}}{\text{Sq in.} \times \text{deg C}} = 5.9\ \frac{\text{Btu}}{\text{Hr} \times \text{sq ft} \times \text{deg F}}$$

in a draft of 500 fpm velocity

The values are in line with generally accepted heat-dissipation factors from metal surfaces. Within the temperatures encountered in bearings, the rate of heat dissipation is $H = KSt$, where S is the hot outside area of the pedestal or box, and t is the temperature rise of this outside surface above the ambient temperature.

Heat Transfer From Oil Film to Bearing Bushing

The source of heat in a bearing is the oil film between the rubbing surfaces. Since heat flows from this source outward, to be finally dissipated either through the housing surface or through the shaft, the oil film is the seat of the highest temperature in the bearing. An exception may be encountered, however, in improperly designed disk-lubricated bearings, where a substantial volume of oil is entrained at high speed and thrown off by centrifugal force against the housing, thus creating another parasitic source of heat.

In loaded bearings, the rate of heat generation is not uniform circumferentially. It is highest where the film is thinnest, at the point where the surfaces approach most closely to each other. In fact, this region predominates vastly the rest of the film as a source of heat. Now, one must differentiate between bearings which have a copious supply of lubricant (class 1), such as oil-ring-lubricated bearings, and those which are starved (class 2), such as drop-feed-lubricated machine-tool bearings, or waste-packed railway bearings. In class 1, the journal carries along a portion of the film circumferentially; hence the oil is brought in contact with the shell all around the circumference. Heat is brought to the bearing bushing at all points, and there is not much difference in temperature along the circumference of the bushing. On the other hand, in the bearings which are fed a drop of oil per minute, or even less, the bearing clearance is substantially empty, filled with air; not only is the heat generation more concentrated than in the bearings of class 1, but also the transmission of heat to the shell is localized to the pool of oil at the closest approach. Consequently, temperature differences, as great as 30 deg F, are observed between opposite circumferential points in bushings of class 2 bearings.[3]

This distinction also holds true axially. In class 1 bearings, oil flows axially through distribution grooves provided for this purpose, and the heat generation is approximately uniform along the entire axial width of the bearing. In class 2, the source of heat is localized, and an appreciable axial heat gradient may be observed in the bushing.

It may be mentioned that, since the heat generated in the "bulk" of the oil film must be transferred to the metal of the bearing (journal and bushing), a temperature gradient must exist from the middle of the film thickness toward the two metal surfaces. This gradient is, of course, small but not negligible. However this question is not under discussion here. It was indicated in its first approximation by A. Kingsbury.[4] Its further development, theoretical and experimental, would be of interest.

Temperature Drop From Bushing to Housing Surface

The heat generated in the film is carried away along three paths toward the surrounding atmosphere. In the first place, a part of the heat travels from the oil film through the shaft; this part, as mentioned previously, is small. Each point of the shaft surface sweeps the film once each revolution. Therefore, the temperature of the shaft is equal to the average temperature of the oil film.

Further, the two classes of bearings mentioned earlier must be considered separately. In class 1, the oil, flowing in bulk through

or over the bushing or shell, carries away a substantial portion of the heat into the oil sump. There, the oil is agitated and mixed more or less vigorously. A good supply of cooler oil is carried by the oil ring, chain, or disk for lubricating the bearing. Furthermore, the agitation increases the transfer of heat to the sump wall, and through it to the surrounding air.

The transport of heat by the oil is rather effective. For instance, in the 5-in. bearing mentioned, the total heat loss was assumed to be 1273 Btu per hr = 0.5 hp. With oil-ring lubrication, the amount of oil carried over would be, say, $^1/_4$ gpm, or 105 lb per hr. Assuming that the oil temperature rises approximately 10 F, while passing over the bearing bushing, the heat transported by the oil to the sump is $105 \times 10 \times 0.52 = 546$ Btu per hr, or nearly 40 per cent of the total heat generated. The greater proportion of the heat is transmitted through the body of the bearing by conduction.

In starved bearings of class 2, this mechanism of heat transfer does not exist. The total heat in bearings of class 2 must be transferred from the bushing to the heat-dissipating surface of the housing by conduction through the metal body of the bearing, or, in a small part, by radiation and convection through the air spaces between the shell and the housing. The thermal conductivity of the common metals used in the construction of bearings has been shown in Table 1 to be comparatively low. Furthermore, the bearing supports are frequently designed with a view to light weight, flexibility of supports, or economy in manufacture, without due consideration being given to good heat transfer. As a result, the temperature gradients between bushing or shell and housing surface are rather high, particularly in bearings of class 2.

There is but scant information available on the numerical values of these gradients for bearings of various designs of either class.

A numerical estimate of the gradient is hardly possible, in view of the complicated geometry of the path from bushing to housing surface. However, for a rational design of self-contained bearings, knowledge of the gradient is imperative. The losses depend in a calculable way upon the viscosity of the film, i.e., on its temperature, while the heat dissipation is governed by the temperature of the wall. The difference between the two temperatures dictates the thermal equilibrium of the bearing.

The author previously suggested[3] a table giving the approximate gradient as a function of the temperature rise of the wall above the ambient-temperature oil-ring-lubricated pedestal bearings.

However, Mr. Fast recently called attention to the fact that, in his bearings,[5] he had observed gradients considerably lower than given in Table 2. In view of this, it will be of interest to compare the values in the suggested table with the findings of E. S. Pearce[6] who experimented with a railway-journal-box bearing. On the suggestion of the Lubrication Committee, Mr. Pearce recorded the temperatures of the bearing under controlled conditions at more than 50 stations in the box, both at the bearing brass and box surface. The tests were made with a $5^1/_2 \times 10$-in. bearing

under a load of 20,000 lb, at speeds of 186, 372, and 558 rpm in still air, and with air blown against the housing, simulating surface conditions. The tests were made under two conditions of lubrication: (1) With the usual waste pack supplying oil to the journal; and (2) with the waste pack removed and the journal partly immersed in an oil bath. The temperature rise F at the various stations in the bearing above ambient temperature was tabulated and presented in one instructive graph. It may be mentioned that the experiments were run during the summer, so that the ambient temperature was near 90 F. An analysis of the data[7] is given in Table 3, in which the relations between the temperature rise of the wall and the temperature gradient from shell to housing surface are indicated.

The data given in Tables 2 and 3 are plotted in Fig. 1. With the oil-bath lubrication, the agitation of the oil was very effective; transportation of heat from the shell to the box wall was very efficient. The temperature gradient was therefore low, very much lower than for the waste-packed bearing. The figures suggested in Table 2 may be too high for bearings working in still air; instead, the range indicated by shading might be suggested for use with oil-ring-lubricated bearings. It is of interest to note that the temperature rises of the wall are appreciably higher for the case of oil-bath lubrication. The difference was approximately 30 per cent, caused by the higher viscosity of the cooler oil. In moving air, the bearing temperatures were lower, the viscosity of the oil was higher; consequently, the bearing losses were also higher. The corresponding temperature gradients between the brass and box wall were considerably greater. A detailed analysis of the losses cannot be made, since the heat-transfer coefficient K for the case of moving air is not known; K depends upon the air velocity which was not recorded.

Conclusion

It is self-evident that considerable improvements could be made in the operation, wearing properties, and safety of self-contained bearings, simply by providing a better path for the heat from the source of generation to the surface of the bearing housing. As a first step in this direction, it may be hoped that further experiments will be undertaken to determine the temperature gradients and the rates of heat dissipation in self-contained bearings of various types, operating under a wide range of conditions.

Relaxation Resistance of Nickel-Alloy Springs

By B. B. Betty,[1] E. C. MacQueen,[2] and Carl Rolle[3]

As a result of a series of tests reported in this paper, stresses required to produce 2, 4, and 6 per cent load loss, or relaxation, in coil springs, held at constant height and constant temperature, have been determined by the authors for several alloys, namely, Monel,[4] "K"[4] Monel, "Z"[4] nickel, and Inconel.[4] Successive test temperatures from 300 F to 700 F were used. The range of temperature over which these several alloys can be used successfully, when load loss is a criterion, has been determined. "K" Monel, "Z" nickel, and Inconel have been found to be comparable, in this respect, to high-alloy spring steels, while Monel is more nearly comparable to low-alloy steels.

Inasmuch as the high-nickel alloys retain their strength to a considerable degree at elevated temperatures and resist oxidation and corrosion as well, they have been useful in many elevated-temperature spring applications. Unfortunately, quantitative data have been lacking on the extent to which coil springs of these materials would retain their load-carrying capacities. As a result of this situation, and in co-operation with the A.S.M.E. Special Research Committee on Mechanical Springs, the authors have undertaken to supply accurate laboratory data for Monel, "K" Monel, "Z" nickel, and Inconel.

Throughout this discourse the term "relaxation" will be used to denote load loss occurring, at constant height, in closely coiled helical compression springs. In this case elastic strain in the outer fibers of the wire, produced by the external load on the spring, is converted gradually to plastic strain, or permanent set. The amount of elastic, or recoverable strain is thereby reduced and there is a proportionate reduction in the load supported by the spring. The percentage loss from the original load is expressed as "per cent load loss" or "per cent relaxation."

The data and conclusions presented herein are based upon tests of springs loaded to a constant height. However, many applications involve the use of springs at constant load rather than constant height. It is felt that, within stress and temperature limits which would produce not more than about 10 per cent relaxation, these data could be applied to cases of constant-load service also. McKeown (1)[5] has discussed the case in which springs are subject to creep deformation under constant load at elevated temperatures.

Some previous load-loss data for Monel have been published in a paper by Zimmerli, Wood, and Wilson (2). The results of an outstanding experimental investigation of load loss, involving approximately 120,000 test springs, have been presented recently to this Society by Zimmerli (3).

Description of Test Springs

The springs tested were $1^1/_4$ in. OD, $2^3/_4$ in. free height and had $6^1/_4$ total coils and $4^1/_4$ active coils. The 0.148-in-diam wire was produced and cold-drawn by the Huntington, W. Va., works of the authors' company. Table 1 gives the chemical analyses of the various alloys and metals investigated. The specimens were coiled by the Barnes-Gibson-Raymond Division of the Associated Spring Corporation. After coiling, ends were ground flat for 270 deg.

All springs were given a thermal treatment before being tested. The two solid-solution alloys, Monel and Inconel, were given appropriate low-temperature stress-equalizing anneals, while the precipitation-hardenable alloys, "K" Monel and "Z" nickel, were heat-treated to take full advantage of that property. In the latter cases, the hardness and general mechanical properties produced in the wire by cold-drawing are augmented appreciably by the heat-treatment component.

On completion of a series of preliminary tests, it was found that optimum resistance to relaxation was produced in Monel by a 650 F stress-equalizing anneal for 1 hr, and in Inconel by a 900 F anneal for 1 hr. Further discussion of these tests will be given in Appendix 1. These stress-equalizing treatments were used on all Monel and Inconel springs involved in the main investigation.

All "K" Monel springs were given a heat-treatment of 1000 F for 6 hr, followed by 900 F for 16 hr. All "Z" nickel springs were aged at 900 F for 6 hr.

The influences of these thermal treatments upon the mechanical properties of the materials may be observed by inspection of Table 2. The data in this table were determined from wire samples which were given the same respective treatments as the coiled test springs.

Care was taken not to compress the springs beyond the height used during the test, thus the specimens received no benefit from cold-working prior to testing. Springs generally would be pressed solid as a manufacturing operation, but this operation was omitted since it is not universally used in practice. Actually some of the stresses used in testing were in excess of the elastic limit of the wire. However, in such cases any immediate relaxation taken by the spring automatically was included in the relaxation reported in this paper. The reason for this is that, as covered later under "Test Conditions and Procedure," the springs were loaded to the test height and then held there without making any allowance for set which may have taken place.

Test Conditions and Procedure

A second preliminary series of experiments was run to determine the necessary duration of exposure to insure that practically all the relaxation had occurred. It was found that a 7-day period was appropriate. Figs. 30 and 31, showing relaxation of Monel and Inconel, subjected to various stress-equalizing treatments, show also that there is no consistent difference in per cent relaxation experienced during 7-day and 10-day tests under identical conditions.

[a] Average of two specimens.
[b] Average of five specimens.

As a result of these observations it was decided to employ a 7-day testing period for all springs used in the main investigation.

In the performance of these relaxation tests, the loads required to produce the desired stresses in the springs were first calculated. These calculated loads were applied to the springs in a weighing attachment mounted upon a Toledo scale, the sensitivity of which was 1 oz. The loaded length of each spring was measured to 0.001 in. by a caliper and micrometer. The spring then was compressed to the measured loaded length and held firmly to that length upon a special bolt and nut. The bolt was of $^7/_8$-in-diam Monel, so that no creep could be expected to occur in it during the course of the test. Washers, larger than the outside diameter of the test spring, were welded to the head of the bolt and to the nut. The faces of these washers were machined flat and parallel to facilitate length measurements.

The assembled bolts, nuts, and springs were placed inside a nickel box and into an electrically heated oven for the heating period. Sixty springs were tested simultaneously. A temperature uniformity of 3 F was observed to exist throughout the box, and temperature control within 5 F was maintained during each heating period.

After the 7-day heating period, the springs were removed from the furnace and cooled in air. After removal of the holding bolts, the springs were compressed to the original loaded length in the spring-weighing machine. The load supported after test was measured. The difference between the originally applied load and the load the spring supported after the heating period is the basis of the "load-loss" calculation.

Load and Stress Calculations

The loads applied to the springs, in order to impose the desired arbitrarily chosen values of maximum fiber stress, were calculated by the use of the formula

$$P_t = \frac{S_t \pi d^3}{8DK} \qquad [1]$$

where

P_t = load at test temperature, lb
S_t = maximum fiber stress at test temperature, psi
d = wire diameter, in.
D = mean coil diameter, in.
$c = \frac{D}{d}$
K = stress-correction factor, developed by A. M. Wahl (4) $= \left(\frac{4c-1}{4c-4} + \frac{0.615}{c}\right)$

All maximum fiber stresses stated in connection with the results of this investigation are those prevailing at the test temperature. In order to convert values of P_t into load required for the same deflection at room temperature, a correction was applied for the change in torsional modulus of elasticity. The change in modulus, from room temperature to test temperature, produces a proportionate change in the calibration rate of the spring.

To effect this correction, therefore, the load obtained from Equation [1] was converted to room-temperature load by the formula

$$P_r = P_t \frac{G_r}{G_t} \qquad [2]$$

where

P_r = load at room temperature, lb
G_r = torsional modulus at room temperature, psi
G_t = torsional modulus at test temperature, psi

The value obtained for P_r was used in the initial loading of each spring.

A discussion of the method used for obtaining values of G_r and G_t is given in Appendix 2.

It should be noted that Zimmerli (3) stated his results in terms of stress on the spring at room temperature, although the method for adjusting these values was outlined. The correction used in this investigation results in reported stress values which are lower, for any given design and deflection, than if the correction had not been applied.

No attempt was made to correct the data for changes in the length of the springs and bolts due to thermal expansion. The maximum error involved occurs in the testing of Inconel at 700 F and in this case the difference between the computed expan-

sions of the spring and the Monel bolt is only 0.0007 in. per in.; less than the probable accuracy of measurement.

DISCUSSION OF RESULTS

The experimental values of per cent relaxation from given initial stresses at various test temperatures are plotted in Figs. 1 to 22, inclusive. These figures represent the results, respectively, for Monel at 300 to 500 F; "K" Monel at 400 to 600 F; "Z" nickel at 400 to 650 F; and Inconel at 400 to 700 F.

Each test point plotted represents the average value observed for a set of three springs. The notation "2" which appears beside some points indicates that the averages for two independently tested sets fell at the same point. In drawing the curves through the test points, due consideration was given to the data obtained for the same material at temperatures immediately above and below that of the curve in question, so that a consistent family would be obtained if all curves for one material were assembled on a single sheet.

This group of charts indicates that even after averaging together the results on a set of three springs there exists a fair degree of scatter in the data. In many cases a single determination would be sufficiently inconsistent to "throw off" the average of three. The data are plotted in this manner, using a separate chart for each curve, so that the degree of scatter might readily

be observed and considered. It will be noted that the curves were drawn so as best to represent the entire group of data rather than to encompass the extreme points of low stress or high per cent relaxation.

In adapting these data to practical design, therefore, due consideration should be given to the scatter of results.

Compiled in Table 3 are the stresses required to produce 2, 4, and 6 per cent relaxation in the 7-day testing period, as obtained from the curves in the previous figures. It was not possible to determine, with any degree of accuracy, similar data for 0 per cent relaxation.

In Fig. 23, the stress values required to produce 2, 4, and 6 per cent relaxation in Monel springs are plotted against test temperature. Figs. 24, 25, and 26 are similar figures in which are plotted corresponding data for "K" Monel, "Z" nickel, and Inconel, respectively. This set of charts illustrates the fact that much higher working stresses may be used for any of these alloys when slightly higher percentages of relaxation or load loss are permissible.

By inspecting the respective values for torsional proportional limit given in Table 2, it will be noted that these values are exceeded considerably by the stresses required to produce only 2 per cent load loss at the lower temperatures. This follows the characteristic behavior of these alloys in that, when the proportional limit is exceeded, a sudden yielding does not take place. Instead, there is a considerable increase in load-carrying capacity with only a relatively small degree of permanent set.

The degree of flatness of the stress-temperature curve for any given percentage relaxation is, of course, governed by the degree to which each material retains its room-temperature properties at elevated temperatures.

Fig. 27 is a chart showing the stress required to produce 2 per cent relaxation plotted against test temperature for all the alloys discussed, while Figs. 28 and 29 are drawn in a similar manner to show 4 and 6 per cent relaxation, respectively. These figures

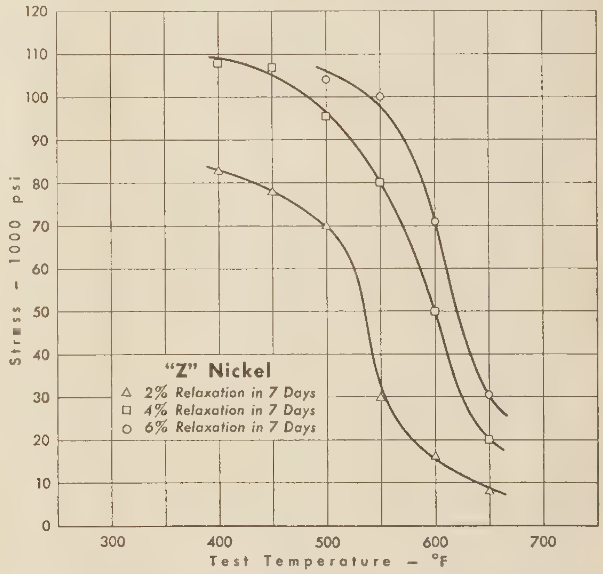

Fig. 25 Stress Required to Produce 2, 4, and 6 Per Cent Relaxation of "Z" Nickel Springs in 7 Days

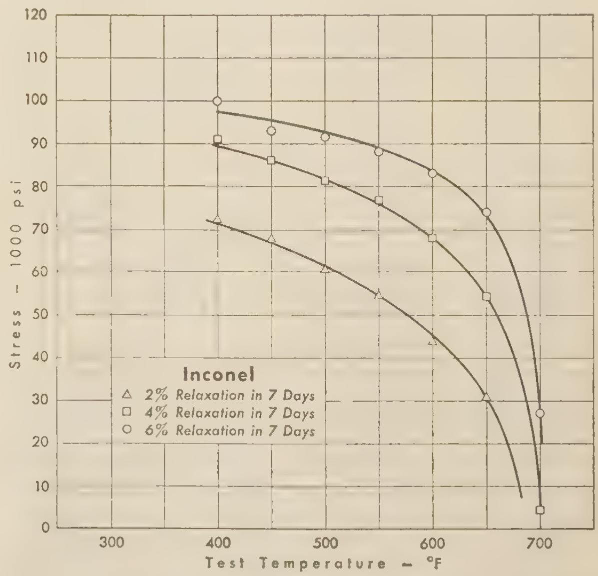

Fig. 26 Stress Required to Produce 2, 4, and 6 Per Cent Relaxation of Inconel Springs in 7 Days

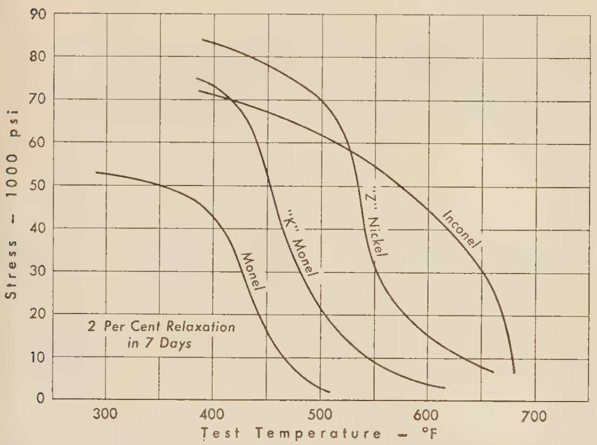

FIG. 27 STRESS REQUIRED TO PRODUCE 2 PER CENT RELAXATION OF MONEL, "K" MONEL, "Z" NICKEL, AND INCONEL SPRINGS IN 7 DAYS

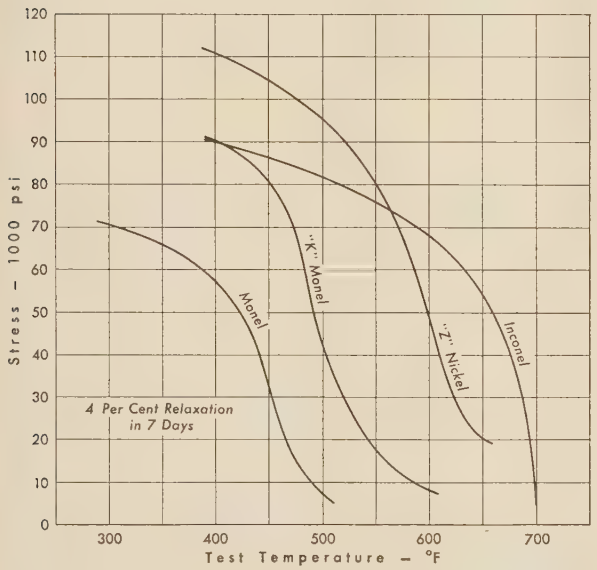

FIG. 28 STRESS REQUIRED TO PRODUCE 4 PER CENT RELAXATION OF MONEL, "K" MONEL, "Z" NICKEL, AND INCONEL SPRINGS IN 7 DAYS

illustrate the relative positions of the several alloys studied with respect to the stress and temperature scales.

It is evident that, at temperatures up to about 400 F and where severe stress conditions must be met, "K" Monel or "Z" nickel would be the choice, with "Z" nickel maintaining a preferred position up to about 550 F. At higher temperatures, however, where somewhat lower stresses would be necessary, Inconel would be preferable. Monel appears to be useful only up to about 400 F and then only at moderate stress levels.

In applying these data to design, the size and strength of the wire used in making the test springs should be borne in mind. While the tensile properties were typical of those obtained in 0.148-in-diam wires of these alloys, they cannot be assumed as minima. Furthermore, these materials, especially Monel and Inconel, show lower tensile strengths for larger diameters; hence, for any specific design problem, the wire size also should be considered. However, the data presented herein should be representative for all wire diameters up to about 0.148 in.

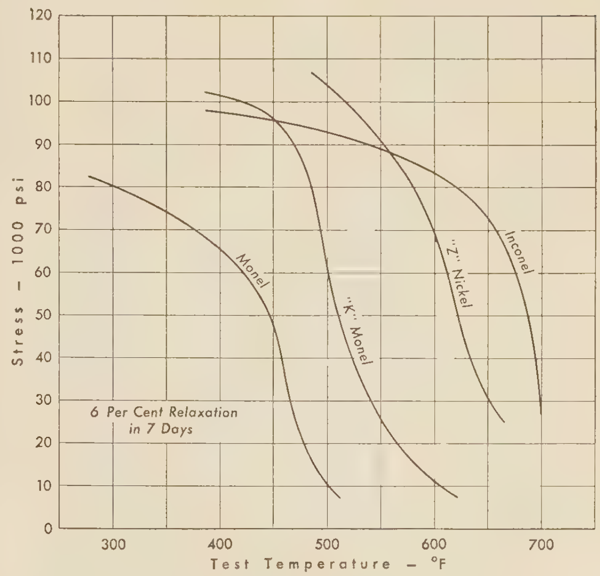

FIG. 29 STRESS REQUIRED TO PRODUCE 6 PER CENT RELAXATION OF MONEL, "K" MONEL, "Z" NICKEL, AND INCONEL SPRINGS IN 7 DAYS

CONCLUSIONS

1 Inconel resists relaxation up to high temperatures and may be used at high stresses up to 650 F. Above this temperature the stress must be lowered considerably and a slight degree of relaxation must be tolerated.

2 "Z" nickel and "K" Monel will withstand higher stresses than Inconel at the lower temperatures, consistent with their generally higher level of mechanical properties.

3 "Z" nickel may be used with high stress at temperatures up to 550 F and with reduced stress up to 600 F.

4 "K" Monel may be used with high stress up to 450 F and with reduced stress up to 500 F.

5 Where other factors such as corrosion resistance are involved, Monel offers possibilities as a spring material for temperatures up to about 400 F and at moderate stress levels.

6 Monel springs should be stress-equalized for 1 hr at 650 F where relaxation resistance is desired.

7 Inconel springs should be stress-equalized for 1 hr at 900 F for service at elevated temperatures.

Appendix 1

OPTIMUM STRESS-EQUALIZING TREATMENTS

Several series of tests at various stress levels and at various test temperatures were carried out on Monel and Inconel springs for the purpose of determining the optimum stress-equalizing treatments.

Fig. 30 shows the results of a typical series for Monel under test conditions of 40,000-psi stress, and 400 F. Each test point represents the average relaxation value for three springs. Tests were conducted for both 7 days' and 10 days' duration.

Fig. 31 shows the results of a similar series for Inconel at 65,000 psi, and 600 F.

In the case of Monel it was concluded that a treatment of 1 hr at 650 F would provide practically minimum relaxation under any test conditions suitable for the service of this material. A temperature of 650 F affords almost complete freedom from heat-tarnishing. Since this is a factor in some applications, and since 650 F produces essentially maximum relaxation resistance, higher temperatures are not suggested.

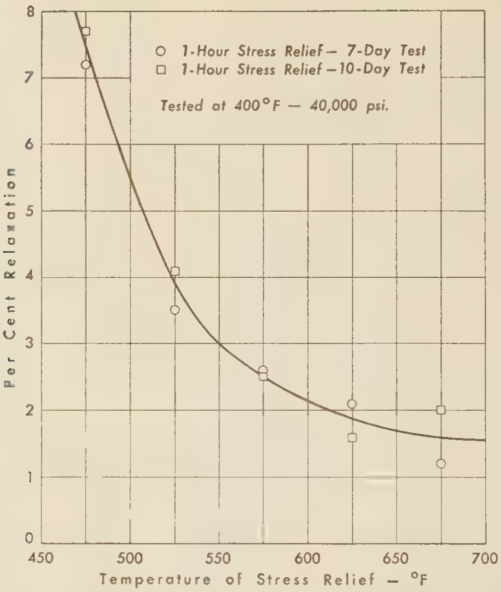

FIG. 30 EFFECT OF STRESS-EQUALIZING TEMPERATURE UPON RELAXATION OF MONEL SPRINGS IN 7 AND 10 DAYS
(Tests run at 400 F and 40,000-psi stress.)

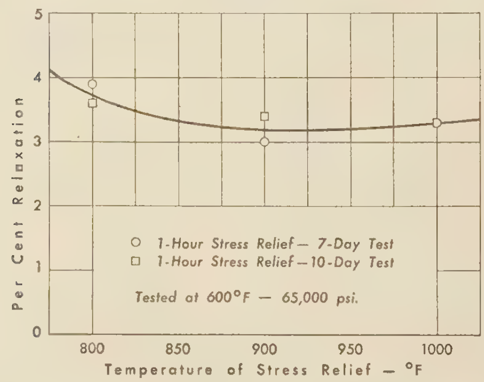

FIG. 31 EFFECT OF STRESS-EQUALIZING TEMPERATURE UPON THE RELAXATION OF INCONEL SPRINGS IN 7 AND 10 DAYS
(Tests run at 600 F and 65,000-psi stress.)

It is not possible even to approach maximum resistance to relaxation in Inconel and still prevent heat tarnishing. As is indicated by Fig. 31, the optimum heat-treatment conditions for this alloy would be 1 hr at 900 F. This treatment was used, therefore, in all subsequent work and is suggested for commercial practice.

Appendix 2

VARIATION OF MODULUS OF ELASTICITY

The question of variation of modulus of elasticity with temperature has received relatively little attention in the way of actual test determinations. Zimmerli, Wood, and Wilson (5) have obtained values of torsional modulus for a number of spring materials, including Monel.

Keulegan and Houseman (6) made determinations on a number of materials, including Monel, using only the temperature range —50 to +50 C. These data are particularly pertinent to precision spring work where modulus changes under ordinary atmospheric-temperature ranges are significant. They found a drop of 3.2 per cent in the torsional modulus of Monel with a temperature rise of 100 C.

Jasper (7) has reviewed this subject extensively and quotes the following formula as initially proposed by Sutherland (8)

$$\frac{G}{G_0} = 1 - \left(\frac{T}{T_m}\right)^2 \qquad [3]$$

where

G = torsional modulus at any absolute temperature, psi
G_0 = torsional modulus at zero temperature absolute, psi
T = absolute temperature at which G is to be computed
T_m = absolute temperature of melting point of material

Equation [3] is checked excellently by data of nine investigators using eight different pure metals having a wide range of melting points. Jasper also quotes tests on several steels which provide an additional check on the formula.

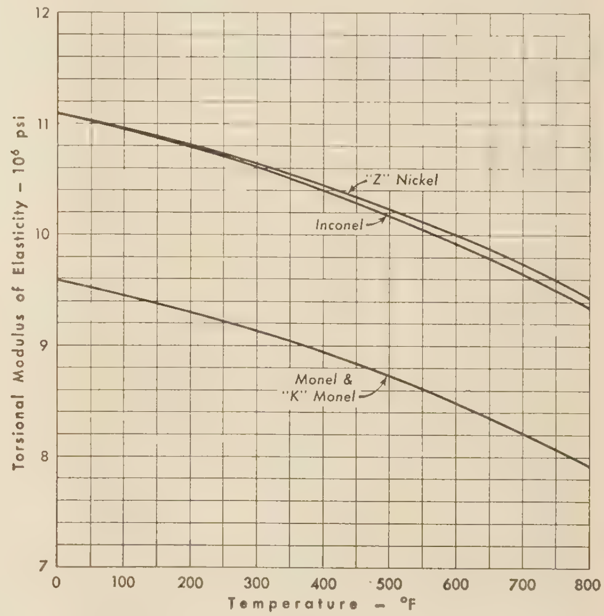

FIG. 32 TORSIONAL MODULUS OF ELASTICITY VERSUS TEMPERATURE FOR MONEL, "K" MONEL, "Z" NICKEL, AND INCONEL, ACCORDING TO SUTHERLAND'S EQUATION

The data for Monel obtained by Zimmerli, Wood, and Wilson, if plotted with G/G_0 as ordinate and T/T_m as abscissa, also provide a reasonable check. These latter data come generally higher than the curve plotted from Sutherland's equation. Thus corrections made according to Equation [3] and applied as explained under "Load and Stress Calculations" in this paper, would constitute overcorrection on the basis of the Zimmerli, Wood, and Wilson data. Such corrections, therefore, would be on the side of safety in that the fiber stress in the springs might actually have been slightly higher than the values reported herein.

Because of these considerations, therefore, values of G_r/G_t for use in Equation [2] were obtained from the curves in Fig. 32. These curves are plotted from known average values of G at 70 F for the materials, together with appropriate values of melting point.

It should be noted that it is not necessary to know the actual value of G for the specimens tested. The values of 11×10^6 for Inconel and "Z" nickel and of 9.5×10^6 for Monel and "K"

Monel are subject to variations of plus or minus approximately 0.3×10^6 from lot to lot. Whatever the value at room temperature for a given sample, the ratio G_r/G_t would not change and, hence, the correction from P_t to P_r by Equation [2] would not be affected.

Discussion

A. Nádai.[6] The authors subject helical springs to an axial load while they maintain the lengths of the springs unchanged during a time of seven days. The springs are exposed to elevated temperatures during this time. The decrease of the load of these springs is measured by the change of the lengths of the springs. While, however, these are subjected to relaxation at elevated temperatures, all the measurements are made at room temperature. The authors are aware that this introduces the necessity of certain corrections containing unknown factors. They also restrict their observations to the statement of the drop of the load after a given time (one week). It would have been preferable to extend observations over a longer period of time and to record decrease of load as a function of time.

The writer introduced this method of testing many years ago for running relaxation tests and believes that it is necessary to plot load as a function of time for the purpose of being able to extrapolate such observation curves to the service times of the order of several years. If plots are recorded on semilogarithmic charts, it is comparatively simple to extrapolate readings so that the final drop of the load can be predicted for service conditions of several years' duration. An example of such a set of relaxation curves is given in Fig. 33 of this discussion, showing the drop of the load for a Cr-Mo-W steel at 500 C. Several such curves have recently been published in a paper by W. E. Trumpler.[7] That paper also contains reference to several other papers in which tests on the relaxation of steels have been reported, and various methods are suggested for observation and for the manner of recording such information. The writer wonders that the authors have not made more use in their work of these methods to test and to record the relaxation behavior of steels at high temperatures.

If a cylindrical bar is subjected to a tension load at an elevated temperature and the length of the bar cannot change, the load will decrease because of the creep of the material. There is an exchange between the elastic strain and the permanent strain, the latter increasing at the expense of the former one. After having seen a great number of such relaxation curves, in which the load is plotted as a function of the time, it seems probable that two phenomena combine in these relaxation curves: (*a*) There usually occurs a comparatively rapid drop of the load. This may be due to small plastic strains which were connected with the loading of the bar, or it may be due to the presence of large internal stresses. (*b*) After this first initial readjustment period has passed, which usually does not take a long time, the load further starts to drop and decreases continuously. This second period of the relaxation may be called the "steady readjustment period," or steady relaxation. It is due to the creep under stress and demonstrates the fact that any given stress must produce a certain rate of plastic flow. In some tests run with copper at room temperature, there was still observable this second or steady relaxation of the copper. Therefore, the writer questions the usefulness of recording a drop of the load in a helical spring after a given time, such as 1 week. The most essential question which is not answered by the authors' tests is how will the load decrease under the second steady-relaxation period in the springs? This question cannot be answered without running the tests in the manner described and only after plotting load against time.

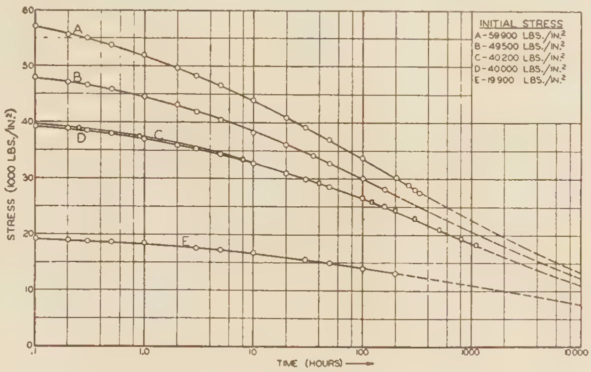

Fig. 33 Relaxation of Cr-Mo-W Steel (2) at 500 C

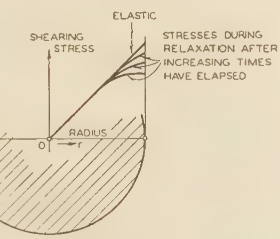

Fig. 34 Relaxation of Shearing Stresses in a Bar Under Torsion

If the case of pure viscous flow is excluded, in which stress is proportional to the rate of flow, relaxation in a helical spring cannot take place without a disturbance in the distribution of the shearing stresses in the wire of the spring. Equation [1], used by the authors, can serve to compute the initial load, assuming a linear distribution of the shearing stresses with the radius from the center of the circular cross section of the spring; however, after relaxation has set in, this distribution must necessarily change gradually in a manner as shown in Fig. 34 of this discussion. It is not difficult to predict also the changes which will occur in the stress distribution during what has been termed

[6] Westinghouse Research Laboratories, East Pittsburgh, Pa. Mem. A.S.M.E.

[7] "Relaxation of Metals at High Temperatures," by W. E. Trumpler, *Journal of Applied Physics*, vol. 12, 1941, pp. 248–253.

previously as the second or the steady readjustment period, after taking into account the actual laws of creep which have been observed for many of the metals. Under the assumption of a purely speed-dependent flow, it is not difficult to compute such stress distributions during the relaxation in a spring. The writer believes that some such analysis is needed and, if more reliable and exact information should be gathered on the relaxation of helical springs Equation [1] must be modified correspondingly.

A formula was quoted for expressing the modulus of shear G as a function of the absolute temperature. The formula which the authors use is based on an assumption, namely, that at the melting point of the material the modulus of shear vanishes. This is highly improbable for theoretical and practical reasons. It is believed that sufficient experimental material is available to show the fallacy of such a formula. If the modulus of shear should vanish at the melting temperature, a piece of ice could not be deposited in an ice box, nor could a skater move on ice. There is an abrupt drop of the shearing modulus from a definite finite value at the melting temperature to the value zero at the liquid state. Thus, in the solid state, G cannot become zero at any temperature.

Authors' Closure

The authors wish to thank Dr. Nádai for his very interesting discussion of several points not particularly emphasized in the paper. One of these to which attention was called is that relaxation might well have been studied as a function of time. The technique suggested involves making an intensive and detailed study of a few specimens; whereas the authors chose to investigate many specimens with a simplified procedure already described. As a matter of fact, the procedure used was established by those who had conducted the very extensive studies of the relaxation of steel springs. The authors have provided data on nickel-alloy springs to supplement those for steel ones. A detailed study of the time-relaxation characteristics of a few specimens would make an interesting and illuminating supplement to the present observations.

The validity of the formula by which the shearing stress was calculated has been questioned on the ground that the stress distribution assumed by that formula does not prevail under conditions of relaxation. The authors recognized this from the outset of the work, but felt justified in using the formula inasmuch as this same formula will be used by the spring designer. Whatever error there might have been in the authors' use of this equation will be erased when the designer substitutes back in this same formula the safe working stresses which have been determined experimentally by the use of this formula.

Some comments were made on the use of Sutherland's formula for the variation of torsion modulus of elasticity with temperature. Emphasis was placed on the invalidity of Sutherland's assumption of zero modulus at the melting point. Inasmuch as the range of temperatures over which the formula was used was about 2000 F below the melting point for the nickel alloys it does not seem to be justifiable to attach undue importance to this objection. Furthermore, the authors showed that from the experiments of Zimmerli, Wood, and Wilson, the Sutherland formula is very nearly correct within the temperature range studied in this relaxation work and that the error is on the side of safety.

Dr. Nádai states that the most important question not answered by the experiments reported is: "How will the load decrease under the second steady relaxation period?" The authors recognize the importance of this question and are making this the subject of the next phase of their experimental investigation.

Symposium on Formulation of Code for Design of Helical Springs

In response to the evident need for the correlation of data on mechanical springs and the formulation of a standard code of design for helical springs, suggestions are made in this symposium by a group of spring specialists which will tend to crystallize the matter into early action. The papers presented cover the scope of the problem of formulating a practical working code, and then in detail discuss such matters as design stresses, preparation of spring tables, research work required, and the preparation and use of nomographic charts as a design method.

What Does the Practical Spring Designer Need?

By J. K. WOOD[1]

EIGHTEEN years ago the Special A.S.M.E. Research Committee was created for the purpose of correlating and expanding our knowledge of the functionally important art of spring design which at that time was in a more or less chaotic state. During the intervening time, the committee has sponsored many research projects and papers, those of its own and those of co-operative members, but the job still remains of correlating both the old and new knowledge in a compact and simplified form suitable for safe practical use.

Most of this research has been done in connection with helical springs, and the committee considers this the opportune time to correlate the accumulation of knowledge in this phase of spring design in the form of a code. This subject is so unusual in many respects that it is a problem as to how we should best proceed to formulate a code which will serve as a useful tool to the great mass of mechanical designers. Those participating in this symposium represent that very small group of men specializing in spring research. Therefore if we are to keep in mind the greater mass of practical designers, who are interested only in getting quick and effective results with the new tool, we will have to restrain ourselves from the natural inclination to wade in the deep waters of our pet hobby.

The purpose of this symposium is to discuss the formulation of a code of design for helical springs. A helical spring, in the unstressed state, is an elastic bar of constant cross section, the normal axis of which conforms to the helix or screw thread. This excludes other types of coil springs, the radius of curvature of which varies, such as "hourglass," conical, "barrel," and spiral springs.

When the load is applied along the axis of the helix (spring axis) in such a manner as to reduce the space between unstressed coils, the bar is stressed principally in torsion, and we have what is known as a "compression helical spring." When the load is applied in the reverse direction along the spring axis in a manner to increase the space between unstressed coils, the bar is also stressed principally in torsion, and we have what is known as an "extension helical spring." When the load is applied as a torque about the spring axis so as to increase the number of coils, the bar is stressed principally in flexure, and we have what is known as a "torsional helical spring." Therefore, consideration is to be given to these three types of springs, namely, compression, extension, and torsion helical springs.

When a load is applied to a straight bar along the normal axis of its cross section, as in "pure" tension or compression, every "fiber" is stressed equally. Using this type of stressed member as a standard of 100 per cent elastic efficiency, the compression and extension helical springs vary in elastic efficiency from 25 to 50 per cent, depending upon the spring index (curvature correction); and the torsion helical spring varies in elastic efficiency from 20 to 33 per cent, depending also upon the spring index (curvature correction). Springs are peculiar with respect to all other types of stressed elements in mechanical design in that the deflection component of the stored elastic energy is relatively very large. This fact makes it very important to consider the relation of any spring design, specifically its natural period of vibration, to the motion involved. It also gives rise to that general feeling among some practical men that springs are "temperamental."

The following brief topical outline is submitted as the scope of the proposed code:

1 *Service Requirements.*

(*a*) Load-deflection rate.
(*b*) Available space.
(*c*) Frequency and regularity of operation which have a bearing on resonance and fatigue.
(*d*) Temperature and atmospheric conditions during operation.
(*e*) Precision.
(*f*) Number of springs required in a given time, i.e., production.
(*g*) Purchase cost and liability in case of failure.

2 *Materials Available.*

(*a*) Shape: Rounds mostly for the compression and extension types, and both rounds and rectangulars for the torsion type.
(*b*) Size: Existing wire gages and formulation of a new single wire and bar gage with number of sizes reduced to minimum and progressive increases in size, arranged logically both from the manufacturers' and calculators' standpoints. Tabulation of available bar lengths.
(*c*) Composition: Ferrous, nonferrous, and nonmetallic.
(*d*) Physical properties: Ferrous, nonferrous, and nonmetallic.
(*e*) Tabulation of all important spring-material specifications in use.
(*f*) Tabulation of commercial variations in size, composition, and physical properties of some of the more important materials.

3 *Manufacture.*

(*a*) Effects on material and bar dimension when coiling cold with and without mandrel, and coiling hot on mandrel. Effect of spring index. Effect of surging compression springs.

[1] Vice-President and Chief Engineer, General Springs Corporation, New York, N. Y. Mem. A.S.M.E.

Papers presented at the Mechanical Springs Session of the Annual Meeting, New York, N. Y., December 1–5, 1941, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

(*b*) Heat-treatment.

(*c*) Surface defects due to hot coiling and heat-treatment.

(*d*) Effects of plating on material.

(*e*) Control of quality by manufacturing specification; classification of springs according to maximum variations to be expected in spring dimensions.

(*f*) Shipping methods.

(*g*) Cost analysis.

4 *Design.*

It is proposed that the three following procedures of design be included in the code:

(*a*) General Engineering Procedure. The usual formulas supplemented by nomographic charts and tables, showing the relation of spring dimensions and ultimate spring constants (safe working stress and modulus of elasticity) to service requirements should be given here. The curvature correction factor, spring-end design, correction for initial tension in extension springs, and solid closure in compression springs, buckling criterion, elevated temperature, and natural period of vibration should also be included in this procedure.

(*b*) Scientific Procedure. In scientific research and in design of highly precise instruments, the usual spring formulas are inaccurate and incomplete. Formulas of a much more complicated kind, which take into account such factors as variation in modulus of elasticity with stress, eccentricity of loading, correction for pitch angle, hysteresis and creep effects, change of spring diameter with loading, change of dimensions due to thermal expansion, spring-end effects, and a number of others should be used in this instance. These formulas could conveniently be made an appendix to the code.

(*c*) Field Procedure. One of the greatest deterrents to popularizing the art of spring design among the great mass of practical designers has been the difficulty in applying the rather complicated types of formula associated with springs, including as they do terms raised to the 3rd, 4th, and 5th powers. Suppose Ohm's law instead of being the simple relation "current equals voltage divided by resistance" was "current equals voltage cubed divided by resistance raised to the fourth power," the effect on practical progress in the electrical art, while not serious, might have been sufficient to cause an appreciable lag.

Approximate Spring Determination for Field Work

We of course cannot change the laws underlying spring formulas, but we can provide a few simple relations that will permit a quick determination in the field of a spring that is approximately near the exact solution. Therefore it is proposed to supply the field engineer or mechanic, or in fact anyone who wants to make a quick exploratory survey, with a design procedure which might be called a field tool. This procedure will also serve to give a greater number of people a better mental picture of the apparently broad and complicated field of helical-spring design.

Referring to Fig. 1 and Table 1 of this presentation, a proposed field procedure has been developed for ordinary carbon-steel helical extension and compression springs in which the curvature correction factor has been taken into account, and a safe maximum stress of 80,000 psi and a torsional modulus of 11,500,000 psi have been assumed.

No matter what size wire or bar is assumed, the maximum percentage of compression or extension given in the second column of Table 1 should not be exceeded. To obtain the corresponding safe maximum loads, the constants given in the third column are simply multiplied by the square of the wire or bar diameter. For exploratory purposes diameters of 0.1, 0.2, 0.3 and so on up by tenths to 1 in. or more can be used to great advantage. Of course it should be borne in mind that this procedure should be used only for making a quick and preliminary solution of a spring problem, and that ultimately the "engineering" or "scientific" procedure should be resorted to.

TABLE 1 QUICK METHOD FOR GAGING LIMITATIONS IN HELICAL-SPRING DESIGN

Spring index	Maximum percentage,[a] compression or extension, F_m/H_l	Maximum load, P_m, lb	Maximum deflection, F_m, in.	Value P_m/F_m, d = 1 in. and H = 10 in.
4	22	5000 d^2	0.22 H	2273
5	39	4500 d^2	0.39 H	1154
6	60	4000 d^2	0.60 H	666
7	85.5	3600 d^2	0.855 H	421
8	115.5	3250 d^2	1.155 H	281

[a] In cases of initial tension in an extension spring and uneven solid closure in a compression spring, the percentages may be only 90 per cent of these values.

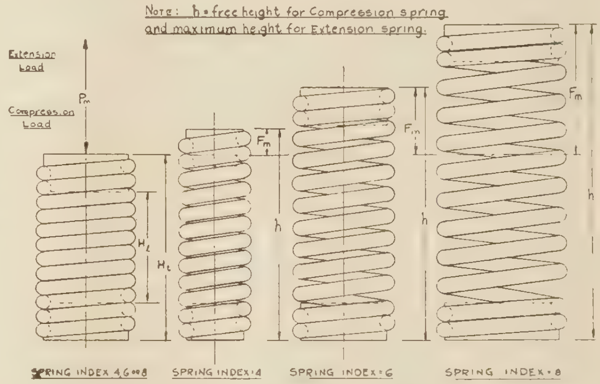

Fig. 1 Relative Safe Maximum Deflections Versus Spring Index in Helical-Spring Design

Summarizing, it is proposed by the writer that a tentative "Code for Design of Helical Springs," along the lines suggested, be drawn up by a subcommittee for submission to the whole committee for approval. It is further proposed that this subcommittee be made permanent in order to revitalize and improve the code from year to year in accordance with the experience gained from suggestions made by engineers using it and with new facts learned from future research projects.

Helical-Spring Design Stresses for a Standard Code

By A. M. WAHL[2]

Introduction

In choosing the design or working stresses for a proposed standard code of helical-spring design, it seems to the writer that one must be guided by the fact that it is clearly impossible in such a code to take into account all the variables which may arise in actual practice. In evaluating these design stresses it therefore seems advisable to use fairly large factors of safety; in other words, the stresses chosen should be quite conservative. This means that the code will be of value chiefly to engineers or designers who are occasionally faced with the problem of selecting a spring for a given application, but who do not have the time to make a complete study of all the limiting factors present. In cases where the number of springs required for a given application is large or the space available for the spring is limited, it is probable that a thorough study of the problem is justified. In such a case, higher working stresses than those given in the code may often be justified.

[2] Research Engineer, Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa. Mem. A.S.M.E.

Among the more important factors which influence the choice of working stress the following may be mentioned:

1 Material properties.
2 Condition of surface.
3 Kind of loading (static or fatigue).
4 Corrosion effects.
5 Creep or loss of load (static loads).
6 Temperature effects.
7 Surging or vibration effects.
8 Effects due to eccentricity of loading.
9 Completeness of knowledge regarding actual loads or deflections.
10 Seriousness of spring failure.
11 Method of stress calculation (i.e., whether curvature effects are included or not).

While most of these factors do have an effect on the allowable stress, they cannot all be accurately evaluated in a code simple enough for practical use. In addition, our knowledge concerning many of these factors (such as the fatigue properties of springs) is incomplete.

It is the primary purpose of this discussion to point out some of the fundamental principles involved in the choice of design stresses for a standard code and to suggest some values which may be used as a basis for further discussion.

For purposes of working-stress evaluation, spring applications may be grouped into two fundamental classes as follows:

1 Springs under static or infrequently repeated loading.
2 Springs under variable or fatigue loading.

Springs Under Static or Infrequently Repeated Loading

For springs which are subjected to a static load (or a load repeated but a relatively few times during the life of the spring), it is suggested that either the yield point or elastic limit in torsion be taken as a basis for choosing the working stress. Since the determination of elastic limit in torsion is subject to some variation depending upon the accuracy of the instruments used to measure torsional deflection, it is believed that the yield point of the material in torsion would probably be a better criterion for the present purpose than the elastic limit.[3] Since spring materials usually do not have a pronounced yield point, a satisfactory value may be taken as that point where the plastic strain is 0.2 per cent.[4]

If the yield point in torsion is not known, its value may be estimated by taking a figure of about 60 per cent of the tension yield point. This will usually give a fairly reasonable figure for most spring materials; however, figures based on actual torsion tests would be preferable.

In calculating the stress for helical springs under static loading, all evidence points to the fact that the stress augment, due to curvature of the bar or wire, may be considered as a condition of stress concentration since the peak stress is more or less localized near the inside of the coil. Such localized stresses may usually be neglected in so far as static loads are concerned. However, the stresses due to direct shear loading are not localized but are distributed over the cross section, and hence should be included in the stress calculation.[5] The working stress, figured in this way, would then be taken equal to the yield point in torsion divided by the factor of safety.

As an example of the use of this method consider an oil-tempered wire with a yield point in tension of 180,000 psi. The yield point in torsion would be about 60 per cent of this or 108,000 psi. Taking a factor of safety of 1.5 with respect to the yield point, this gives a working stress for static loading of 108,000/1.5 = 72,000 psi. If a factor of safety of 1.25 is used, the working stress would be 108,000/1.25 = 86,000 psi. (These stresses would be higher if the stress augment due to curvature were included.) Such values are in line with values frequently used in practice. (It should be noted that even when the yield point is reached in the outer fibers, the spring can still carry perhaps 30 per cent more load before complete yielding over the entire cross section occurs.) For purposes of a code where static loads and normal temperatures are involved, a factor of safety of around 1.5 on the torsional yield point is suggested as a basis for further discussion.

For higher temperatures, the effects of creep or relaxation (loss of load) must usually be considered. Not many data are available for springs under such conditions, and it is questionable whether the proposed code should provide for these situations. However, some limitation on the temperature at which ordinary steel springs may be used should be given.[6]

Variable or Fatigue Loading of Springs

Where springs are subjected to variable or fatigue loading (an example is the automotive valve spring), the most important quantity is the stress range, i.e., the difference between the maximum and minimum stresses. Since stress concentration affects the fatigue strength of materials, it is logical to include the stress augment due to curvature, in calculating the stress range of actual springs.[7] Usually this stress range will not vary a great deal as the mean stress increases, provided the elastic limit or yield point is not exceeded, so that, for purposes of the code, a minimum value of the range should probably be taken as a basis for design. Actually the endurance range will decrease somewhat as the mean stress increases but, if the value corresponding to the highest practical mean stress is taken as a basis, the design will be on the safe side.[8] The allowable stress range in the spring is then equal to the endurance range divided by the factor of safety.

In addition, to avoid excessive creep or loss in load, it should further be specified that the peak load for fatigue loading should not exceed the permissible value for static loading. The stresses due to this peak load may, however, be calculated by neglecting the curvature effect.

As an example of the method of choosing working stress for fatigue loading, assume that it is desired to determine working stresses for a music-wire spring of about 0.1-in. wire diam subject to a minimum stress of 20,000 psi (calculated with curvature correction). Tests show the endurance range of this material

[3] "Working Stresses," by C. R. Soderberg, Trans. A.S.M.E., vol. 55, 1933, paper APM-55-16, pp. 131–140.

[4] The use of this value for yield point was suggested by C. R. Soderberg, loc. cit.

[5] A more complete discussion of this is given in "Analysis of Effect of Wire Curvature on Allowable Stresses in Helical Springs," by A. M. Wahl, *Journal of Applied Mechanics*, Trans. A.S.M.E., vol. 61, 1939, p. A-25; also "Calculating Springs for Static Loading," by A. M. Wahl, *Machine Design*, June, 1941, pp. 66–71.

[6] A considerable number of data on load losses in springs under elevated temperature were given in the paper, "Effect of Temperature on Coiled Steel Springs Under Various Loadings," by F. P. Zimmerli, Trans. A.S.M.E., May, 1941, pp. 363–367.

[7] Because of lack of full sensitivity to stress concentration in actual materials, the use of the full curvature-correction factor may result in too high a calculated value for the stress range when compared to the results of fatigue tests. However, until further test data are at hand, it is believed that the full correction for curvature should be made for fatigue loading.

[8] See, for example, "Permissible Stress Range for Small Helical Springs," by F. P. Zimmerli, University of Michigan, Engineering Research Bulletin No. 26, 1934, for a number of endurance diagrams. A more accurate method would be to assume a variable stress range as a function of mean stress, but this complication would probably not be justified for use in the code.

to be 0–75,000 psi. Assuming a factor of safety of 1.5 on the stress range, this gives an allowable range of 75,000/1.5 = 50,000 psi. The peak stress would then be 20,000 + 50,000 = 70,000 psi (with curvature correction). If the spring index is 8, the calculated stress at the peak load, neglecting curvature effects, would be 63,000 psi, which is low compared to an estimated torsional yield point of around 130,000 psi for this material. Hence no loss in load due to creep would be expected.

Because of the fact that the fatigue strength of springs is greatly influenced by variations in surface condition, it may, however, be desirable when fatigue conditions are involved to use an even larger factor of safety than 1.5 in the proposed code.[9]

In calculating stresses for helical compression springs, it also seems advisable to take into account eccentricity of loading, particularly if the spring has relatively few turns. This might be done by using the formula given by Keysor.[10]

Examples From Practice

As an example of working stresses occurring in practice, the writer would like to mention the spring tables used as a basis for design by his company. These spring tables are based on the stresses shown in Table 2 of this discussion (curvature correction included). It is assumed that no corrosion is present and that temperature effects are not involved.

TABLE 2 WORKING STRESSES IN SHEAR; HELICAL COMPRESSION SPRINGS[a]

Wire diam, in.	Severe service, psi	Average service, psi	Light service, psi
Up to 0.085	60000	75000	93000
0.085– 0.185	55000	69000	85000
0.185– 0.32	48000	60000	74000
0.32 – 0.53	42000	52000	65000
0.53 – 0.97	36000	45000	56000
0.97 – 1.5	32000	40000	50000

[a] Made of good-quality steel such as music or oil-tempered wire. Curvature correction included.

Light service as indicated in Table 2 would correspond to statically loaded springs or those loaded infrequently. For most cases, the values given in the table are conservative and may frequently be increased. For springs of average index, the values for light service correspond roughly to a factor of safety of 1.5 with respect to the torsional yield point.

The values given in the table for severe service correspond to factors of safety of 1.5 to 2 on the estimated endurance range.

W. R. Berry in a paper before The Institution of Mechanical Engineers of Great Britain[11] suggests that, where fatigue conditions do not enter, springs be designed on the basis of a working stress of 70 per cent of the torsional elastic limit of the spring material, the curvature correction being considered. Since the yield point would be somewhat above the elastic limit, and since the effect of wire curvature is considered, this method would correspond to a factor of safety of somewhat more than 1.5 for springs of average index, based on the suggested method of calculation for static loading.

Values of stress equal to 100,000 psi (with curvature correction) are suggested for a good grade of steel wire by Wallace Barnes Company[12] for extension springs where excessive fatigue or corrosion are not factors. This would correspond to stresses of about 90,000 psi, figured by neglecting curvature effects for springs of average index. Assuming a yield point in torsion of around 120,000 psi for good-quality steel wire, this stress would correspond to a factor of safety of about 1.33.

From these figures it would appear that the suggested figure of 1.5 for factor of safety is not out of line with values in actual use.

Conclusions

In fixing design stresses for helical-spring applications at normal temperatures, and where the load is static or repeated a relatively few times, it appears reasonable to use the yield point of the material in torsion as a basis. For this type of loading the stress should be calculated by neglecting stress-concentration effects due to curvature (but including the stress augment due to direct shear). The design or working stress is then equal to the yield point divided by a factor of safety which is required to take into account unknown variables. To determine allowable stresses to be used in a standard code, this factor of safety should probably be taken slightly high, a figure of 1.5 being suggested as a basis for further discussion. This would be done with the reservation that after careful consideration higher stresses than those suggested in the code may be used in many cases.

For springs subjected to elevated temperatures, it seems difficult at present to fix on allowable working stresses until more data are at hand.

For helical springs, subjected to fatigue or repeated loading, it is suggested that that the range of stress (calculated with curvature correction) be taken as a basis for design. To obtain the allowable working-stress range to be used in the code the minimum endurance range of the material (assuming a peak stress below the yield point) is divided by a factor of safety. For purposes of the code, values of this factor of safety of 1.5 to 2 are suggested as a basis for discussion. To avoid excessive creep or loss in load, the peak stress (calculated by neglecting the stress augment due to curvature) should not exceed the allowable value as determined for static loading.

[9] A factor of safety of 1.25 to 1.5 on the stress range (figured with curvature correction) is suggested in "Die Federn," by S. Gross and E. Lehr, V.D.I. Verlag, Berlin, 1938.

Helical-Spring Tables—Scope and Arrangement

By H. C. KEYSOR[13]

THE primary function of a spring table is to save time by eliminating formula calculations. For the accomplishment of this end, scope and arrangement are of vital importance.

As regards scope, the table should be extensive enough to cover the complete range of bar sizes and coil diameters with increments sufficiently small to include any reasonable design. The importance of this requirement will be appreciated by anyone who has had occasion to use a short table and has found that the design wanted was missing. While no table can be made to cover every design, the user has a right to expect coverage of all but some unusual cases which comprise a negligible proportion of the total. The actual time-saving possibilities of a spring table can be realized only when the designer has learned to turn to it with the feeling that the required entries are almost certain to be there. The following range of sizes is reasonably satisfactory according to the author's experience in hot-wound-spring design:

$$\text{Bar diameters}\begin{cases} {}^3/_8 \text{ in. to } 1^1/_4 \text{ in., inclusive, by } {}^1/_{32}\text{-in. increments} \\ 1^5/_{16} \text{ in. to 2 in., inclusive, by } {}^1/_{16}\text{-in. increments} \\ 2^1/_8 \text{ in. and } 2^1/_4 \text{ in.} \end{cases}$$

[13] Mechanical Engineer, American Steel Foundries, Chicago, Ill.

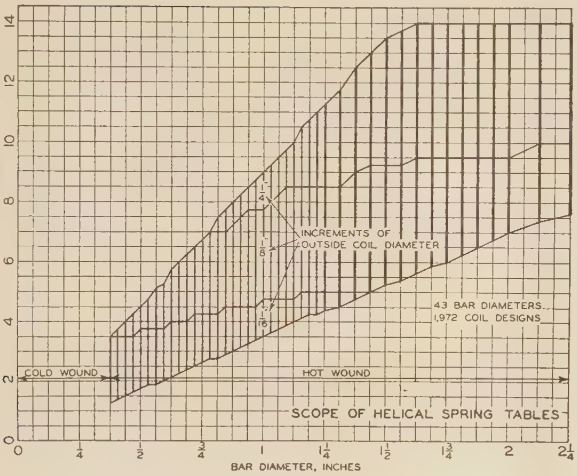

FIG. 2 SCOPE OF HELICAL-SPRING TABLES

Outside coil diameters { minimum $3^1/_2 \times$ bar diameter; maximum 9 to 10 $\times$ bar diameter up to 14 in. diam }

Fig. 2 of this presentation shows the scope of the table, together with the increments in bar and coil diameters. The rather minute subdivisions of bar diameters are made necessary by the fact that the load rate of a spring varies directly as the fourth power of bar diameter. Thus, the change from a $1^3/_{16}$-in. bar to a $1^7/_{32}$-in. bar results in a load-rate increase of 10.3 per cent; changing from a $1^1/_4$ to a $1^5/_{16}$-in. bar, the rate increases 19 per cent. A load-rate differential of 10 per cent is small enough for most practical purposes, hence $1^7/_{32}$ in. represents the upper limit of $^1/_{32}$-in. increments of bar diameter. Naturally, the use of such an odd size as $1^7/_{32}$ in. would be avoided except where special load and space limitations required it. Sometimes an odd-size bar must be figured for other reasons, as in a recent case in the writer's experience, where it was necessary to use a $1^{15}/_{16}$-in. bar, because it was the only adequate size available for a rush job. The usual short table would not list such sizes, thus requiring a formula calculation—work that is time-consuming for the busy designer.

RANGE OF NUMBER OF TURNS: 2.667 TO 26.67

EXAMPLE: $5\frac{3}{8}$" O.D. $7\frac{5}{8}$" SOLID HEIGHT

SOLID LOAD = $11{,}350 + \frac{5}{8}(11{,}500 - 11{,}350) = 11{,}440$ LBS.

FREE HEIGHT = $9.004 + \frac{5}{8}(10.389 - 9.004) = 9.870$"

LOAD RATE = $\dfrac{11{,}440}{9.870 - 7.625}$ = 5,096 LBS. PER INCH

STRESS RATE = $\dfrac{140{,}000}{9.870 - 7.625}$ = 62,360 PSI PER INCH

FIG. 3 TYPICAL SPRING TABLE FOR USE IN DESIGNING AND CHECKING

The conventional spring table assumes axial loading and shows the load for a given stress and the deflection, at this load, for one active turn. Three supplementary numerical operations are required:

1 Determination of the total number of turns.
2 Deduction of the inactive end turns.
3 Multiplication of the number of active turns by the deflection per turn to obtain the total travel.

A fourth operation is necessary to find the stress augment due to load eccentricity which is present in compression springs, deflected between parallel planes. While this factor is usually omitted, it is of importance in short springs.

The elimination of this supplementary arithmetical work would be a distinct advantage. A table which gives results without recourse to formulas was made by the author five years ago and its practicability has been proved by daily use in designing and checking. The arrangement is shown in Fig. 3 of this discussion, the essential feature being that free heights and solid loads are given for a selected series of solid heights, interpolation being used for solid heights intermediate between tabular values. The basic solid stress is 140,000 psi, including Wahl's factor and an allowance for loading eccentricity. Each bar diameter occupies a separate page, various coil diameters are shown in the left-hand vertical column, and for each coil diameter there is a double horizontal row of figures, the top row being solid loads and the bottom row free heights, corresponding to the solid heights given at the top of the table. The range of solid heights corresponds to $2^3/_4$ to 30 turns, approximately.

This table possesses several advantages over the conventional type:

1 The deduction for inactive end turns is contained within the table by reason of free and solid heights being given. Therefore, it is not necessary for the designer to make this deduction or to know the number of turns, a marked advantage, especially for those users who are not familiar with spring calculation.

2 The effect of load eccentricity, in reducing capacity for any given stress, is also contained within the table by decreasing the solid load with decrease in the number of turns.

3 Since the use of formulas is eliminated, calculation is merely a matter of interpolation, just as in the familiar trigonometric tables. This feature reduces the chances for numerical error, as the tabular values are available for rapid mental checking of results.

4 When only load and loaded heights or free heights are given, as is often the case, the required bar diameter and solid height can be found approximately by inspection, thus avoiding much numerical work which would be necessary with the conventional table. This feature is especially helpful in designing double and triple coil springs.

5 Frequently load and space requirements are not closely restricted, which permits a satisfactory design to be taken directly from the table without any calculation.

Future Research Work Needed in Mechanical-Spring Problems

BY M. F. SAYRE[14]

IN 1924, the A.S.M.E. Research Committee on Mechanical Springs was organized. It had before it a large task, namely, that of establishing a foundation of technical information which would serve as the basis for improving the empirical methods of spring design which in essence were all that were available at that time. For 22 years previously, from 1902 to 1924, not one paper had been published in the Transactions of this Society, dealing closely enough with springs, to justify its inclusion in the index under that title. One paper was published in 1924, that by J. K. Wood, which helped in giving the impetus to the formation of the committee. For the 17 years since then, there are 65 papers in the index dealing with spring properties or spring design, most of them reporting research results of real importance.

There is a law of diminishing returns in research, which states that most fruitful results are likely to be obtained in a new unbroken field, and that after much work has been done the rewards of future work are likely to be less. This fact suggests that now may be a good time to survey what has been accomplished by the Committee on Mechanical Springs in its 17 years of existence, and what further need there is for its existence.

During these 17 years, major emphasis, possibly to too great a degree, has been directed to the design and use of helical extension or compression springs, in no less than 23 papers. In one direction, starting from the old-time simple formula $PR = S_sJ/r$, these studies have introduced complexity, first in the form of the curvature correction formula, as brought over from German papers, simplified and experimentally proved by Wahl, then in the equations by Sayre and de Forest, showing deviation from uniform rate of elongation with load, and more recently in Keysor's excellent work which shows the impossibility of assuming the existence in compression springs of a centrally applied loading and a uniform rate of elongation per coil. The fatigue tests sponsored by Edgerton and by Zimmerli have aided materially in interpreting the rather confusing results given in the papers just mentioned, but much more work remains to be done. A complete list of topics covered in other papers on helical springs during this period would be too long to give here. Table 3 summarizes the record of publication of papers on mechanical springs.

							66

There have been five papers on disk springs, ring springs, and various other special types during this time. On the other hand, spiral springs have been the subject of but one paper and that is also true of the entire field of flexural springs, including leaf springs, surprising as it may seem. These have of course been touched upon to some extent in the seven papers which deal with the general topic of spring design, but these represent rather summations of existing knowledge than extensions of the field.

Five papers deal with fundamental properties of metallic materials for springs; and these have given us a fairly good background of knowledge of some but not all of the quirks which affect stress distribution in springs and their resulting behavior. The current paper, presented by D. J. McAdam, Jr.,[15] is another very important contribution to this field. Six papers deal with vibration problems as influenced by springs and seven with other spring uses.

Research Work Necessary

This leads up to the question of the type of research work which yet remains to be done. The writer can claim no right to speak with authority and so will only attempt to give suggestions which may serve as a foundation on which others may build a more satisfactory set of conclusions. With this limitation in mind, the following set of suggestions is offered:

1 In the present state of the art, an attempt to compute the so-called "true" maximum stress in a helical spring, particularly a compression helical spring, calls for use first of the Keysor formula, then of the Wahl formula, coupled with correction formulas to take into account the effect of combined stresses. Then, if we wish to be accurate, a correction must be made to allow for the effect of the initial stresses introduced by "surging" the spring. This combination is much too complex for ordinary use. Furthermore, we have as yet no truly satisfactory evidence as to what relation, if any, this so-called "true" stress may bear to the probable service life of the spring. Further studies, probably in the form of fatigue tests, are needed to develop this relationship.

2 In compression helical springs Keysor has developed equations indicating marked advantages from the use of certain specific angular relationships between the positions of point of first contact between coils at the two ends of a compression spring. Experimental results have also been given which leave this advantage apparently uncertain. In short springs the stress increments suggested by Keysor are great enough to suggest further study with a view to finding means of capitalizing on these theoretical advantages.

3 Spiral springs seem to have had but little study given to them. Their importance has of course been reduced in recent years by the substitution of electric motors in place of power springs in many applications. Furthermore, a good deal of research work has been done which has not reached the publications of this Society. Possibly the cure may lie in the form of encouraging future publications which will summarize some of this unpublished research work.

4 Leaf and other flexural springs remain of great importance. At a meeting of the committee a few years ago, a verbal report was given covering important research work carried on privately in this field. The writer expresses the hope that this work will be supplemented by published reports and by further investigation.

5 In recent years, there has been a rapidly increasing use of rubber as a spring material. The extent to which this material has forced its way into attention is in some measure indicated by the fact that since 1936 no less than nine papers have dealt with its properties or its engineering uses, as compared to only one paper in the preceding history of this Society. The properties of rubber are widely different from those of the metallic springs with which we have become familiar in the past, and further

study dealing with its properties and method of application would seem to be desirable.

The results obtained by the committee during its 17 years of existence have been very great. In the writer's opinion, the fields for its work in the near future should be somewhat different from those it has emphasized in the past. It is hoped that its future efforts will be equally fruitful.

Nomographic Charts

Advantages and Disadvantages

By L. C. PESKIN[16]

OF all the possible methods available to engineers for computing design formulas graphically with the greatest saving in labor and the maximum amount of precision, none has the advantages of the nomographic or alignment chart, i.e., (1) The chart uses very few lines, as will be readily seen later, and is thus extremely easy to read. (2) Any interpolation that is involved is made along a simple scale rather than between curves with a very definite gain in accuracy. (3) As compared to other graphical methods, the labor of construction of these charts is comparatively slight. (4) One of the most important advantages to the practical designer is the graphic way in which the chart indicates instantly the change in one of the variables due to changes in the other variables.

The fundamental principle involved in the construction of nomographic or alignment charts consists in the representation of an equation connecting three variables, $f\ (u, v, w) = 0$, by means of three scales along three straight lines (or curves) in such a manner that a straight line cuts the three scales in values of u, v, and w satisfying the equation. This procedure can be extended to take care of more than three variables, and examples of three- and four-variable charts are shown in the figures which follow.

Figs. 4 to 9, inclusive, of this presentation are devoted to the design of helical compression and extension springs. Figs. 4 and 5 permit the stress determination of a complete range of spring sizes and loads. Stress correction for curvature may be determined from Fig. 6, while Figs. 7 and 8 enable the deflections per coil for the same range of spring sizes and loads to be readily obtained. Fig. 9 provides a means for modifying the deflections so as to provide for the design of springs using a variety of materials. Figs. 10 to 15, inclusive, show a set of charts serving the same general design purposes in the case of torsion springs. Finally, Figs. 16 to 19, inclusive, provide the necessary means for designing the very smallest to the largest of flat spiral or motor springs. While not shown, there have been derived simple factors which may be applied to Figs. 4 to 15, so as to make them readily applicable to the design of springs using rectangular wire. We will not go into the detail of constructing these charts, except to state that they were originally laid out with extreme care on cardboard sheets 24 × 36 in. and subsequently reduced by photographing to an $8^1/_2 \times 11$-in. size, in which form they will soon be issued as part of a new piece of spring-design literature which we have been preparing for some time.

So far as the advantages of these charts are concerned, the ease with which they may be read is at once obvious from the illustrations. With respect to accuracy, as long as the charts are not laid out on too small a scale completely satisfactory results are readily obtained by any user. It is more desirable to cover a full range of spring sizes on more than one chart than to sacrifice accuracy by trying to cover all with too condensed a scale. It is also important to note that the nomographic chart is fundamentally no more than a means for computing graphically some given analytical expression. In the design of springs, this expression may be any one of the many formulas available for determining stress deflection, load, etc. Consequently, the chart may, at its best, be expected to duplicate exactly the numerical results obtained by direct calculation from the original formula itself. If

the design formulas are approximate or even in error to begin with, the derived chart can only mirror these same departures in accuracy. Furthermore, the actual springs fabricated according to the design, no matter what procedure is used, will show in practice other deviations from the calculations as a result of unavoidable variations required by manufacturing tolerances. Hence, fair judgment of the accuracy of nomographic charts in spring design is therefore obtained, not alone when results determined thereby are compared to those obtained by direct calculation, but also when all of these results are compared to the actual performance of commercially made springs.

Comparing Springs Made by Three Design Methods

Such a comparison was made and is illustrated in Figs. 20 and 21. Fig. 20 shows a typical extension-spring setup in the laboratory with two precision cathetometers arranged to read individual coil deflections. Fig. 21 is a similar experiment arranged for deflection measurements on a compression spring, and in Fig. 22 the results are plotted for nine different springs. The first eight springs are extension springs measured at two loads. Springs 1, 2, and 3 are duplicates, so far as design is concerned, selected at random from a large lot. Springs 6 and 7 are likewise design duplicates, and No. 9 is a compression spring, measured at three different loads. It will be noted that the three methods of design, logarithms, slide rule, and nomograph, in only one or two cases agree exactly with the measured results. These methods, however, for the most part substantiate each other as to relative accuracy. Logarithms and slide rule follow each other almost precisely, while at one time three observers read the nomographic charts with an average result less than 2 per cent away from the other design methods. As a matter of interest, it will be noted that springs of identical design deviated from one another on actual test over 3 per cent. Also, the springs, as commercially made, deviated in individual cases from the design, no matter what method was used, as much as 5 per cent. Since these results are found in all cases as both plus and minus deviations, it can be stated that on the average a lot of springs manufactured according to any one of the three methods of design illustrated will be in all respects commerically identical.

Constructing Nomographic Charts

In commenting on the labor of constructing these charts, all we can say is that the work is neither difficult nor time-consuming but must be carried out with care on a sufficiently large scale. As to the charts showing graphically the effects of varying the different quantities involved in the design, this is a self-evident fact as will be noticed by the user at once. This has already proved a great boon to designers making trial calculations in a spring design. Finally, by actual experience, we have found it possible to place these charts in the hands of spring users and, with but few explanations, have them obtain entirely satisfactory spring designs.

Frankly, after having spent many long hours in practical spring design making tedious slide-rule calculations, struggling through spring-table interpolations, or finding a way through a maze of

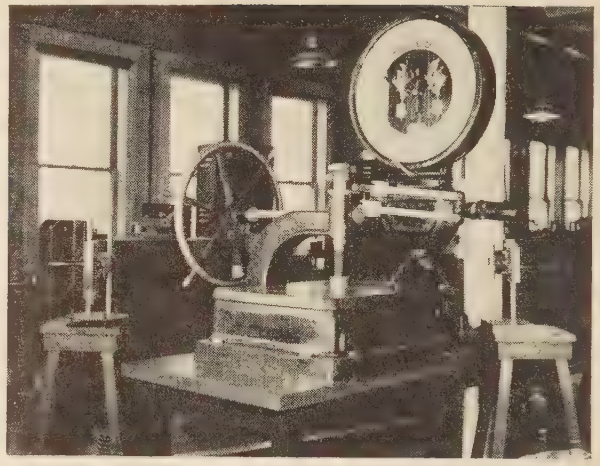

Fig. 21 Compression Spring Arranged for Deflection Measurements

spring curves, the writer finds it difficult to cite a single disadvantage of the nomographic-chart method of design for springs. It may be said that constant use will disfigure these charts but this is also true of any set of spring curves. In the case of the nomographs, we have available not only the very large originals but also the $8^1/_2 \times 11$-in. electroplates with which the charts may be reproduced in any quantity whenever desired.

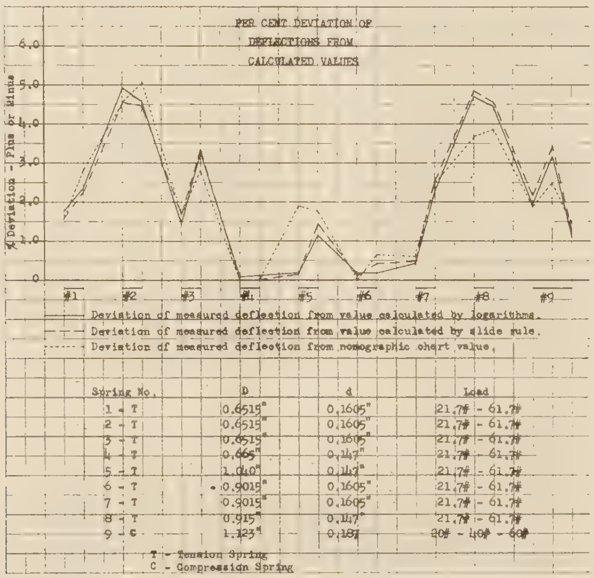

Fig. 22 Percentage Deviation of Deflections in Springs From Calculated Values

High-Performance Fins for Heat Transfer

By R. H. NORRIS[1] and W. A. SPOFFORD[2]

Earlier investigations have determined the forced-convection heat transfer of a single isolated plane or cylinder and of continuous parallel fins. This paper presents test results for groups of small discontinuous fins and pins. These results have been correlated on the basis of Reynolds number in order to show a common quantitative relationship. The heat-transfer coefficients are found to increase in substantially inverse proportion to the square root of the size, or perimeter of the surface element, and can be more than doubled, compared to continuous fins. The relationship between heat transfer and fluid friction is covered quantitatively. Tests of applications show that the data may be rationally applied with satisfactory results.

Introduction

Fins attached to tubes or other base surfaces are much used for transferring heat to or from forced-flow air. Uses include unit heaters, finned coils for air conditioning (evaporators and condensers), hot-air furnaces, "radiators" for liquid-cooled engines, etc.

Most fins for these uses may be called the "continuous" type, i.e., the fin extends in a continuous sheet for more than 1 in., and generally for several inches, as indicated in Fig. 1(*a*).

Much higher performance, i.e., higher heat-transfer coefficients, can be obtained, however, by splitting up a continuous fin into a multiplicity of discontinuous strips, as indicated in Fig. 1(*b*), or by using an array of small pins, as indicated by the cross section shown in Fig. 1(*c*).

To provide a basis for the design of these high-performance fins is the object of this paper. Results of tests of both heat transfer and pressure drop are presented for a considerable variety of these "strip fins" and "pin fins," and a simple, generalized correlation, based on the perimeter of the fin, is obtained.

The tests here reported are concerned primarily with smooth fins having their upstream edges substantially perpendicular to the direction of air flow. Another type of design in commercial use has spikes or strips projecting radially from a round tube. Examples of the latter type of design were also tested by the authors. They too were found to have higher heat-transfer coefficients than continuous fins, but not so high as designs with all the edges perpendicular to the flow (comparing the same size strip or pin for both types).

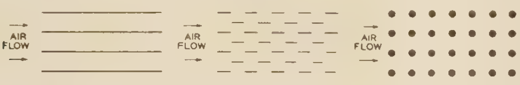

Fig. 1 Types of Heat-Transfer Surfaces
(*a* Continuous fins; *b* strip fins; *c* pin fins.)

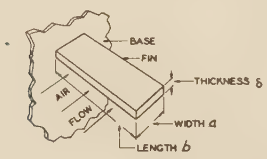

Fig. 2 Fin Nomenclature

Terminology

The terms used in this paper to distinguish certain fin dimensions require definition to prevent ambiguity.

The terms "width" and "thickness" are illustrated in Fig. 2.

The fin "length" is measured from the base of the fin (where it is attached to the tube or other base surface) to the free end or to the mid-point of the fin extending between two walls.

"Depth" is the over-all dimension of the fin assembly, measured in the direction of air flow.

The fin "perimeter," denoted by ψ, is twice the sum of width and thickness for strip fins (see Fig. 2), and is the circumference of a pin fin.

"Short-perimeter" fins is the term used to denote strip fins and pin fins collectively, the perimeter being limited to a fraction of an inch.

Nomenclature

A = surface area of "effective" air-side heat-transfer surface (see Appendix), sq ft
A_c = minimum cross-sectional area open for air flow, sq ft
A_f = surface area of fins alone, on air side, sq ft
A_s, A_w = surface area of steam side (including fins there), and of wall, respectively, sq ft
a = width of strip fin or plane (see Fig. 2), ft
b = length of fin (see Fig. 2), ft
c = specific heat of air, Btu per deg F per lb
f = friction factor, defined by Equations [3] and [3*a*], dimensionless
$G = \rho V$ = mass velocity of air, lb per hr ft²
g = acceleration of gravity = 4.17×10^8 ft per hr²
h, h_s = surface heat-transfer coefficients* for air side, and steam side, respectively, Btu per hr ft² deg F
$j = \left(\frac{h}{cG}\right)\left(\frac{c\mu}{k}\right)^{2/3}$ = heat-transfer factor, dimensionless (for air below 300 F, $j = 3.30h/G$)
k, k_f, k_w = thermal conductivity of air, of fin material, and of wall material, respectively, Btu per hr ft² deg F per ft
Δp_f = pressure drop of air, due to "friction," psf
$R_\psi = \frac{G\psi}{\mu}$ = Reynolds number, based on perimeter ψ, dimensionless
Δt_{12} = temperature change of air from inlet to outlet, deg F
Δt_m = logarithmic-mean temperature difference from surface to air, deg F
U = over-all heat-transfer coefficient, steam-to-air, based on effective area A, Btu/(hr ft² deg F)
V = air velocity (at the free area A_c), ft per hr
δ, δ_w = thickness of fin (see Fig. 2) or wall, respectively, except that for pin fins, δ is radius, ft

Contributed by the Heat Transfer Professional Group and presented at the Annual Meeting, New York, N. Y., December 1–5, 1941, of The American Society of Mechanical Engineers.

* Referred to fin *average* surface temperature, not to temperature of the *base* of the fin. To refer to the latter, use ηh, as in Eq. [6].

η = effectiveness factor of fin (evaluated from Equation [7]), dimensionless

μ = viscosity of air (evaluated at average of air and surface temperatures), lb per hr ft

ψ = fin perimeter [$= 2(a + \delta)$ for strip fins], ft

ρ = density of air, lb per cu ft

Nature of Tests

Smooth copper fins (or pins) joining two parallel steam-heated copper walls, as shown, for example, in Fig. 9, were used to obtain the new test results here reported. The finned samples were placed in a duct through which air flowed, as indicated in Fig. 10.

The use of copper, the small "length" of the fin from the center to the wall (either 0.5 or 1 in.), and the fin thickness (0.01 or 0.02 in.) combined to keep the temperature gradient in the fin small enough so its effect could be calculated by well-established methods (1).[3]

The Appendix gives additional details regarding the tests.

Heat-Transfer Results

Choice of Correlation Basis. The correlation of data by the use of dimensionless groups of variables is a well-established method. In this paper, heat-transfer data will be correlated in terms of the dimensionless groups $[(h/cG)(c\mu/k)^{2/3}]$, which for air simplifies to $0.79h/cG$ or $3.3h/G$. This quantity will be denoted by j, called by Colburn (2) the "heat-transfer factor." One advantage of this dimensionless group is that it does not contain the size of the fin as a factor. Another advantage is that it gives a simple numerical measure of heat transfer for different fluids, e.g., air, hydrogen, or water.

The effect of size of the fin is represented in the dimensionless group known as "Reynolds number," $G\psi/\mu$, expressed in terms of the fin perimeter ψ. The perimeter is used instead of the fin width a, or the fin thickness δ, because, as shown later, it simplifies the correlation of strip fins and pin fins on the same basis. This definition of Reynolds number should be distinguished clearly from the Reynolds number based on diameter in some other applications. For pin fins the Reynolds number based on perimeter is π times as great as that based on diameter.

Single Plane Surface. As a standard of reference, consider heat transfer for a single isolated thin plane parallel to an air stream before considering the more complex case of groups of plane fins. The perimeter ψ here represents twice the width a, in the direction of flow, since the thickness may be considered negligible.

It has long been known (2) that for Reynolds numbers in the low range, corresponding to a laminar boundary layer, both theory (3) and test (4) give heat-transfer data for a flat plate which agree within ± 5 per cent with the straight-line log-log plot denoted as curve *B-B* in Fig. 3. The equation of this line is

$$j = 0.94/\sqrt{R_\psi} \qquad [1]$$

Single Cylinder. Usually heat-transfer data for a single cylinder, diameter D, transverse to an air stream have been correlated in terms of the Reynolds number (2), based on diameter, GD/μ.

Surprisingly close agreement with the data for a plane surface is obtained, however, when the perimeter Reynolds number, $G\psi/\mu$, is used, as shown by curve *C-C* in Fig. 3. There is increasing divergence with increasing Reynolds number, but it does not become large for Reynolds numbers R_ψ, up to 20,000, and higher values are not considered in the fin tests reported in this paper.

Even more surprising is the simplicity of the equation of the straight line *A-A*, in Fig. 3, which can be used as a reasonably close approximation for both a plane and a cylinder, for R_ψ up to 20,000. The equation of this line *A-A* is

$$j = 1/\sqrt{R_\psi} = \sqrt{\frac{\mu}{G\psi}} \qquad [2]$$

These correlations for a plane and a cylinder show that the heat-transfer coefficient can be increased for a given mass velocity G, and given temperature conditions (which determine μ), inversely as the square root of the perimeter ψ. To transfer a reasonable amount of heat, however, many small planes or cylinders would have to be provided, and the effect of adjacent surfaces on the flow and temperature distribution would presumably require consideration.

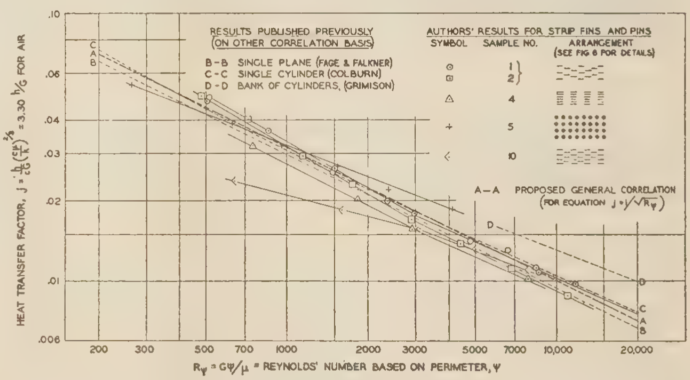

Fig. 3 Dimensionless Heat-Transfer Correlation for Surfaces of Various Shapes, Where Distance, Transverse to Flow, Between Surfaces Is not too Small Relative to the Perimeter; Generally not Less Than 0.1ψ

(For long, closely spaced planes or ducts, j becomes independent of ψ.)

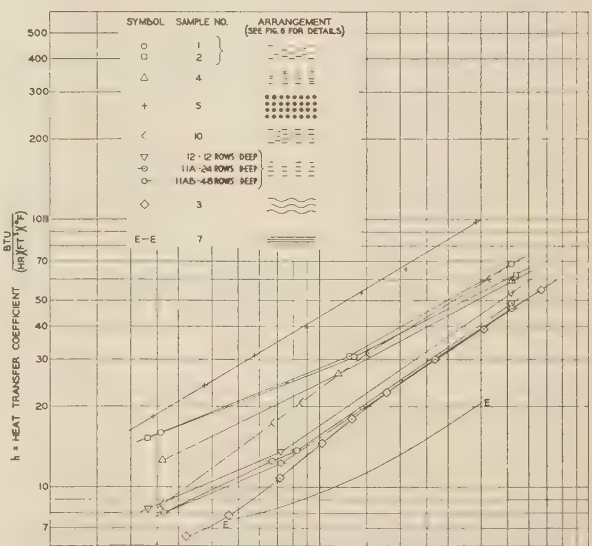

Fig. 4 Heat-Transfer Coefficients for Strip Fins $^1/_8$-In. Wide and 0.04-In-Diam Pins, Compared With Continuous Surfaces for Air at Mean Temperature of 70 F

[3] Numbers in parentheses refer to the Bibliography at the end of the paper.

Accordingly, various arrangements and dimensions of groups of strip fins or pins were tested, with the results to be described.

Results for Strip Fins and Pins. Substantial agreement of results for several designs of strip fin with the basic correlation for a single plane is shown in Fig. 3, where the plotted test results for strip fins are denoted, as indicated in the legend. The results for one design of bank of small round pins are also shown in Fig. 3, which show like agreement, although a tendency to divergence is evident at the upper end of the range of Reynolds number considered, in accordance with the trend shown by line *D-D* for cylinders representative of boiler-tube sizes.

Not all arrangements of strip fins give equally good performance, however. Results for the various designs tested are compared in Fig. 4, and discussed under "General Conclusions."

Results, in Fig. 4, are presented in terms of heat-transfer coefficient as a function of air velocity, instead of in terms of dimensionless variables, in order to facilitate appreciation of the practical significance of the results, but these are restricted to the dimensions specified and to air at the mean temperature of 70 F.

Compared to continuous fins, an increase of over 2-to-1 ratio in the heat-transfer coefficient is obtainable from suitable designs of narrow ($^1/_8$-in-wide) strip fins, as shown by the results tabulated in Fig. 6 and by supplementary data in Table 1.

Air-Pressure-Drop Results

Choice of Correlation Basis. The air-pressure drop observed in a test sample does not by itself have immediately recognizable significance, for it will vary widely with the depth of the sample and the air velocity. There is, moreover, no customary measure of pressure drop per unit of surface area analogous to h, the measure of heat transfer per unit of surface area, and likewise relatively independent of depth of the sample.

TABLE 1 DATA ON SAMPLES TESTED[a]

Sample No.	Description	Ratio, fin-to-wall area	Heat-transfer area used	Ratio, a/δ	Fin-area to wall-area ratio usable for range
1	Strip fins staggered by threes	6.33	$A_f + {}^1/_2A_w$	12.5	4 to 10 with error $< \pm 2$ per cent
2	Same as sample No. 1 except for thickness	6.95	$A_f + {}^1/_2A_w$	25.0	4 to 10 with error $< \pm 2$ per cent
4	Strip fins in line, close spacing	6.19	$A_f + {}^1/_2A_w$	12.5	4 to 10 with error $< \pm 2$ per cent
5	Pin fins	3.18	A_f only	..	2 to 6 with error $< \pm 2$ per cent
10	Strip fins staggered by twos	5.10	$A_f + {}^1/_2A_w$	12.5	3 to 10 with error $< \pm 2.5$ per cent
11A, 11AB	Strip fins in line, wide spacing	3.46	$A_f + {}^1/_2A_w$	12.5	3 to 10 with error $< \pm 2.5$ per cent
12	Strip fins in line, wide spacing	2.98	$A_f + {}^1/_2A_w$	12.5	3 to 10 with error $< \pm 2.5$ per cent

[a] Supplementing sketches in Fig. 6.

There is, however, a dimensionless measure of pressure drop which is relatively independent of depth, and has significant advantages. This is the quantity called the generalized friction factor f, and defined by

$$\Delta p_f = f \cdot \frac{\rho V^2}{2g} \cdot \frac{A}{A_c} = f \frac{G^2}{2\rho g} \frac{A}{A_c} \quad \ldots\ldots [3]$$

This is a generalized form of the well-known Fanning equation for pressure drop of fluids in pipes.

For a single isolated plane or cylinder, drag, not pressure drop, is the measure of friction, so an alternative definition of f is required, namely

$$\text{Drag force, } F_D = f \frac{\rho V^2}{2g} A \ldots\ldots\ldots [3a]$$

For a bank of cylinders, the f thus defined has the same value as the limit approached by the f defined by Equation [3], as the transverse spacing of the cylinders is increased toward infinity.

The ratio of heat transfer to pressure drop, not pressure drop alone, is really the most significant measure of merit of pressure-drop performance.

This ratio is here expressed by $j/(f/2)$, a ratio of the dimensionless measure of heat transfer to one half the dimensionless measure of pressure drop, as this ratio has significance and value which are found to be very convenient and relatively independent of the particular velocity or depth used in the tests.

Sample No.	Type of surface	Arrangement and dimensions (other details in Table I); direction of air flow →	Test results for 1000 ft./min. air: Pressure drop efficiency factor: $j/(f/2)$ (dimensionless)	Test results for 1000 ft./min. air: Heat transfer coefficient h BTU/(hr)(ft.²)(°F)
5	Pin fins (.125" dia. pins; .040" "; .020" ")	3.125 D	.28 .39 .48	27. 43. 56.

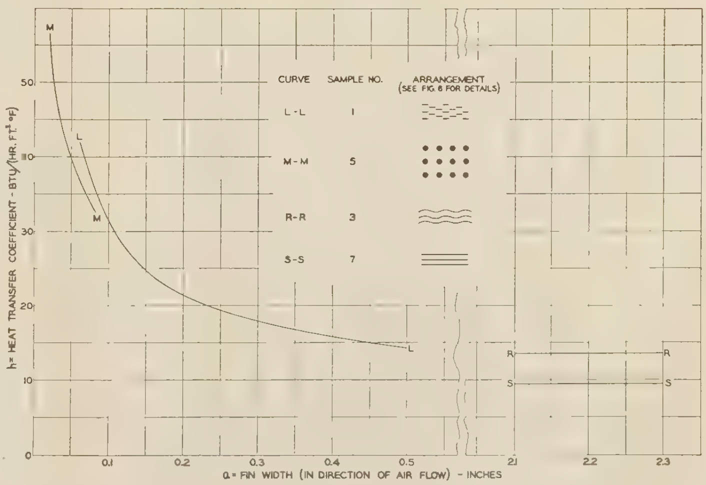

Fig. 5 Effect of Fin Width a on Surface-to-Air Heat-Transfer Coefficients for a Fixed Air Velocity, at Minimum Free Area of 1000 Fpm at 70 F

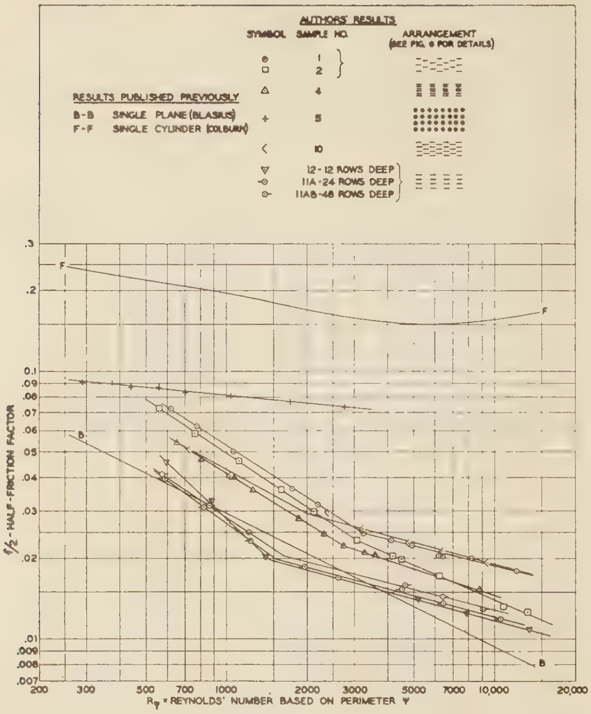

Fig. 7 Half-Friction-Factor Correlation for Strip Fins and Round Pins

Unity may be considered as the ideal upper limit to the ratio $j/(f/2)$, which may accordingly be considered as a sort of pressure-drop efficiency, as explained in a previous paper (5). This significance of $j/(f/2)$ is indicated by the relation

$$\Delta p_f = \frac{\Delta p_0}{j/(f/2)} \qquad [4]$$

where

$$\Delta p_0 = \frac{\rho V^2}{g} \frac{\Delta t_{12}}{\Delta t_m} \left(\frac{c\mu}{k}\right)^{2/3}$$

which may be considered as the minimum theoretically obtainable pressure drop, as explained in reference (5), and Δp_f is the actual friction pressure drop, higher than Δp_0 the more $j/(f/2)$ drops below unity. The test results are therefore presented in the form of $f/2$, and of the ratio $j/(f/2)$, plotted as functions of Reynolds number, as shown in Figs. 7 and 8.

Single Plane. Blasius' theoretical results, as quoted in reference (2), for the friction factor for a single thin smooth plane, parallel to an air stream, for Reynolds numbers up to 20,000, are represented, in the form of $f/2$, by the line B-B in Fig. 7, the equation of which is

$$\frac{f}{2} = 0.94/\sqrt{R_\psi} \qquad [5]$$

This value of $f/2$ is thus the same as the value of j (see Equation [1] and Fig. 3), as pointed out by Colburn (2).

The value of $j/(f/2)$ for this case is therefore unity for R_ψ below 20,000 when f is based on Blasius' theoretical results. No values of f from test, to check Blasius' results, have been found for the values of R_ψ below 20,000 here considered.

Single Cylinder. For a single cylinder, transverse to an air stream, one half the friction factor, as quoted by Colburn (2) from test results in previous literature, is shown by curve F-F in Fig. 7. This curve is much higher than the corresponding heat-transfer curve C-C in Fig. 3. The value of $j/(f/2)$ is therefore much less than unity.

Strip Fins and Pins. The authors' test results for pressure drop of strip fins, and of banks of pins, are shown in Fig. 7. The values of the ratio $j/(f/2)$, obtained from combination of the test results in Figs. 3 and 7, are presented in Fig. 8.

The significance of these results is discussed later, under "General Conclusions—Pressure Drop."

Practical Applications

The data presented permit an economic evaluation of changes in design detail without need for recourse to extensive tests for each new application. As has been shown, the heat-transfer performance may be increased without limit as the fin perimeter is made smaller. (Strictly speaking, only within the range of Reynolds number covered by tests.) This is true, even though some arrangements of fins are superior to others. The object of design is then to select an advantageous arrangement of surface elements made as small as possible consistent with practical design limitations. The design detail is dictated primarily by the method of manufacture, the material used, the strength or ruggedness required, and the conditions of operation.

Extended surfaces on round tubes are typical of construction for which the fin data cannot be applied without some compromise with the more ideal fin arrangements which have been tested. The necessity of having the air circulate around the tube prevents having the air move at uniform velocity at right angles to the fin element and thus prevents the attainment of the same performance reported for strip-fin tests. Even so, the data correlated in this paper have been applied satisfactorily to surfaces on round tubes

Since the trend of the heat-transfer coefficient with velocity, perimeter, and fin arrangement is known, an analysis can be made of the effects on cost and pressure drop of changing tube size and spacing, fin spacing and thickness, etc., in order to establish the most economical design of surface for the particular application. Tests then serve to confirm or rate the performance of the finished design.

The economic advantages of such a short perimeter surface are greater for applications using low air velocities. These surfaces occupy less space, in the direction of air flow, than conventional surfaces. For a given face area, the air pressure drop for a given heat transfer is about the same as for conventional surfaces. As with any surface, the pressure drop can be lowered by an increase in face area with an increase in surface area and cost.

In these surfaces the thermal conductivity of the fin material, which determines the temperature drop along the fin, has an important bearing on the suitability of the design, as an application that is good, when made with high-conductivity copper, may show small advantage over a conventional surface if made with a lower-conductivity metal.

General Conclusions

Heat Transfer

1 An increase of over 2-to-1 ratio in the heat-transfer coefficient is obtained by use of a multiplicity of $^1/_8$-in-wide strip fins, suitably spaced, instead of continuous fins (see Fig. 6).

2 Still greater increase is obtained by yet smaller strip widths, or by pins of the order of 0.040 in. diam or less (see Figs. 5 and 6).

3 The heat-transfer coefficient increases inversely as the square root, approximately, of fin width or fin perimeter, for most of the strip-fin or pin arrangements tested (see Figs. 3 and 5).

4 A single simple curve (curve A-A in Fig. 3) suffices as an

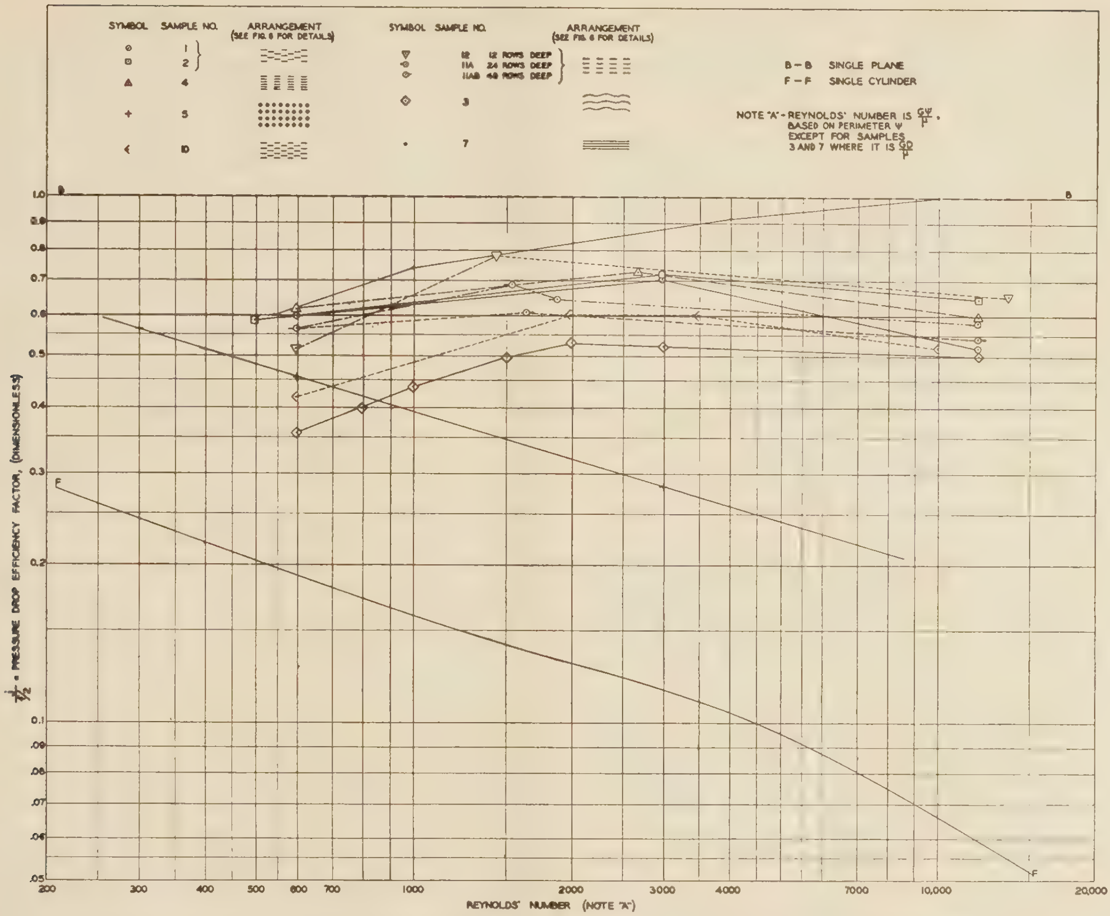

FIG. 8 PRESSURE-DROP EFFICIENCY FACTOR, RELATING HEAT TRANSFER AND PRESSURE DROP, FOR STRIP FINS, ROUND PINS, AND CONTINUOUS SURFACES

approximate correlation of heat transfer for the following variety of surfaces in the range of conditions considered:

(*a*) A single plane (parallel to the air flow).
(*b*) A single cylinder (transverse to the air flow).
(*c*) Strip fins of various designs (except for certain less favorable designs).
(*d*) Pin fins (at least for the one design tested).

5 The generality of this correlation curve permits heat-transfer predictions for strip- or pin-fin designs, differing from those tested both in size and arrangement (for limitations, see Conclusion 8).

6 Fin thickness has but slight effect on the heat-transfer coefficient of strip fins (when this coefficient is based upon the average fin temperature, not the temperature at the base of the fin). Halving the thickness (4 per cent instead of 8 per cent of fin width) decreased the coefficient only 4 to 12 per cent (samples Nos. 1 and 2).

7 The over-all "depth" (in the direction of air flow) of the fin assembly has only a slight effect on the heat-transfer coefficient. A fourfold increase in depth produced a decrease of less than 13 per cent in coefficient (samples 11AB and 12 in Fig. 4).

8 The spacings between strip-fin layers should be kept within a limited range; too great a spacing tends to decrease the heat transfer (compare sample No. 11A with samples Nos. 1, 4, and 10 in Fig. 6). The spacing of the layers should be less than one strip width (i.e., less than in sample No. 11A) and preferably one third of a strip width (as in sample No. 1, Fig. 6).

9 Whether the strips of one layer are in-line or whether they are staggered with respect to the strips of the adjacent layer has

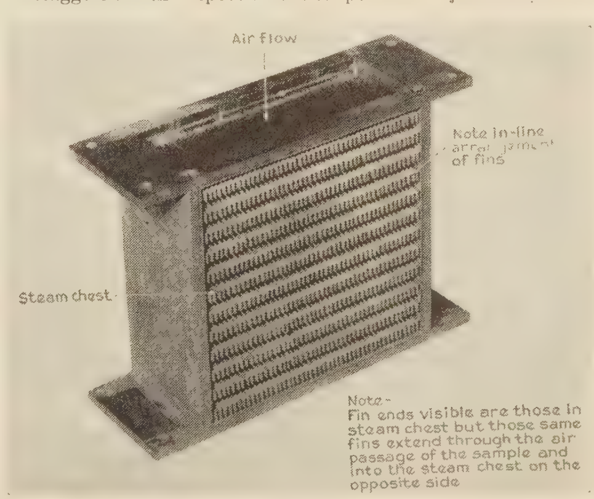

FIG. 9 STRIP-FIN HEAT-EXCHANGER SAMPLE NO. 4
(Steam-chest covers not shown.)

but slight effect on heat transfer (samples Nos. 4 and 10, Fig. 6).

10 The dimensionless correlation of results is substantially independent of the size of the sample chosen for test (e.g., sample No. 12 was made to twice the scale of sample No. 11A; for results, see Fig. 4).

Pressure Drop

Pressure drop is here discussed mostly in terms of the pressure-drop-efficiency factor, $j/(f/2)$, for reasons previously explained.

1 In general, the ratio $j/(f/2)$ for strip fins ranges from 0.5 to 0.7, for the considerable variety of designs tested (see Fig. 8).

2 This range of 0.5 to 0.7 for strip fins is close enough to the 0.7-to-1 range for continuous flat fins (see Fig. 8), so that the difference does not prevent utilization of the great heat-transfer advantages of strip fins (see Figs. 6 and 8).

3 Strip fins seem decidedly superior to corrugated continuous fins, since they give both higher heat-transfer coefficients and a higher $j/(f/2)$ ratio (see Figs. 6 and 8).

4 Smaller thickness helps to increase the $j/(f/2)$ ratio for strip fins. Decreasing the thickness from 8 per cent of strip width to 4 per cent increased $j/(f/2)$ by 1 to 19 per cent (samples Nos. 1 and 2, Fig. 8).

5 The over-all depth (in the direction of air flow) of the fin assembly does not have much effect on the pressure drop of strip fins per unit of depth. A 4-to-1 change in depth changes $f/2$ (a measure of pressure drop per unit of depth) by less than 10 per cent. The effect on $j/(f/2)$ is slightly more than on $f/2$ (Figs. 7 and 8).

6 For pin fins at low Reynolds numbers, the ratio $j/(f/2)$ is surprisingly good (around 0.5), considering the round, unstreamlined cross section (sample No. 5, Fig. 8). Values as low as 0.5 may be quite acceptable in consideration of the very high heat-transfer coefficients obtainable (sample No. 5, Fig. 6).

7 For pin fins, increasing the Reynolds number greatly decreases the ratio $j/(f/2)$, so large pins at high velocities do not appear attractive.

Practical Applications. In practical applications, the designer selects the minimum size of fin element that can be economically fabricated, or that will have sufficient strength in service, or that will satisfy special conditions of operation. As compared to less scientifically designed surfaces, the surface will have less weight and will occupy less space. It will have about the same air-pressure drop for a given heat transfer as a conventional surface, unless the performance gain is to be used to reduce pressure drop rather than to obtain maximum weight reduction.

Appendix

Test Equipment and Procedure

Air System. The air system is shown in Fig. 10.

The air flow was measured by the pressure drop across a square-edged orifice, several sizes being used to cover the different ranges of flow. The orifices were calibrated to $^1/_2$ per cent, using the same duct and vanes. The calibration was made by measured volumetric displacement of a 2200-cu-ft "gas-meter-prover" tank. The coefficients obtained were 1 to 1.9 per cent higher than the corresponding values given by the A.G.A.-A.S.M.E. standard tables. The calibration values, not the standard ones, were used, particularly as they seemed to give slightly less error in the heat balances (which were generally within 2 per cent).

The temperature and barometric pressure were taken into account. The water vapor in the air was considered in selecting the specific-heat value, and also in calculating the air flow from the orifice pressure drop.

A mixing chamber downstream from the test sample provided practically uniform temperature for measurement. This uniformity was confirmed with a movable thermocouple.

The air approaching the test sample was at substantially room temperature, so no insulation was needed there. The test sample and the duct system downstream from it were so well insulated that correction for the heat loss through the insulation was needed only at the lowest air flows, and was then very small.

Steam System. Dry steam, at substantially atmospheric pressure, and a superheat of 6 to 60 F, was supplied to both sides of the test sample. The condensate flowed from the sample through a water-cooled U-shaped trap, thermally insulated, into a beaker, and was weighed at regular intervals.

Scavenging of air from the steam chests was insured by a continual venting process, but check tests without venting (except prior to the test) showed that the amount of noncondensable

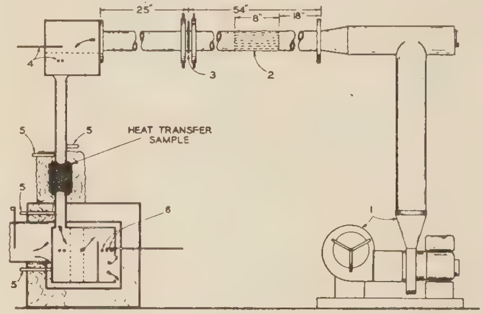

Fig. 10 Arrangement of Equipment for Tests of Heat Transfer

(1 Fans in series; 2 straightening vanes; 3 air-measuring orifice; 4 thermometers and thermocouples in air-inlet mixing box; 5 air-pressure connections; 6 thermometers and thermocouples in air-outlet mixing box.)

carried in by the steam was so small that it would reduce the heat transfer by less than 2 per cent per hr. To provide uniform distribution of steam flow, and thereby facilitate elimination of air, the steam was supplied to a header across the entire 6-in-wide top of the test sample. The presence of the ends of the fins, Fig. 9, or, in certain samples, other restrictions, provided uniformly distributed resistance to steam flow, so that withdrawal of steam from the header at the bottom would cause flow through the entire steam chest.

The rate of withdrawal of vent or "excess" steam was large before each test, and was then reduced to a relatively low value throughout the test to prevent entrainment of liquid water. To permit calculations of the heat obtained from superheat in the entering steam, the excess steam was measured by an orifice and assumed to leave dry at saturation temperature. No noticeable variation of results was obtained by variation of the excess steam flow up to 300 per cent of the amount condensed.

Temperature Measurements. Air temperatures were measured by copper Copnic thermocouples, which were calibrated, together with the potentiometer, to 0.2 deg F. The cold junctions were kept at 32 F. Thermometers, calibrated to 0.05 deg F, were used for check purposes. The accuracy of the outlet-air temperature was aided by the location of the six thermocouples beyond the air-mixing system previously mentioned, Fig. 10.

Steam-saturation temperature was obtained from the steam pressure (atmospheric plus a correction for water in the trap). Temperature of the superheated steam at the inlet was measured by a thermocouple with a long sheath.

Pressure-Drop Measurements. Pressure drop across the test sample was measured by use of draft gages connected to small holes flush with the duct walls, located as shown in Fig. 10. Two independent sets of pressure connections and gages were

used to eliminate danger of undetected leaks. A micromanometer was used when necessary.

From the pressure drop as thus measured, there was deducted the pressure drop of the duct itself, obtained for the same flow by clamping the inlet and outlet ducts together with the test sample removed.

Test Procedure. Each heat-transfer test run consisted of at least four consecutive sets of readings at 10-min intervals, after stable conditions were obtained.

For most pressure-drop tests, isothermal conditions were used, although tests with the sample heated gave substantially the same results after adjustment to the chosen standard conditions of 70 F and 14.7 psi abs.

The number of test runs for heat transfer could be fewer than for pressure drop, because it was found that the results as plotted consisted of two straight lines, the intersection of which could be estimated from the pressure drop.

Calculation of Results. The over-all heat-transfer coefficient U was obtained by dividing the total heat transferred (average of the values from air and from steam) by the "effective" surface area of the air-side surface and by the logarithmic-mean temperature difference between the air and the saturated steam.

The "effective" area was taken as the fin area (both sides of each fin) plus a suitable fraction of the wall area, as specified in Table 1, which also gives the range of ratios of fin to wall area for which use of this fraction of the wall area gives a specified accuracy.

The wall-to-air heat-transfer coefficient (ηh) was calculated by the equation

$$\frac{1}{(\eta h)} = \frac{1}{U} - \frac{1}{h_s}\frac{A}{A_s} - \frac{\delta_w}{k_w}\frac{A}{A_w} \qquad [6]$$

The steam-side coefficient h_s was calculated on the assumption of film condensation, for which consistent results are available (6). The steam-side thermal resistance was, however, only a small fraction of the over-all resistance, being from $^1/_2$ to 3 per cent for all samples except No. 10, where it reached 15 per cent because the steam side in that instance had no fins.

The effectiveness factor η was calculated from the well-known (1) equation

$$\eta = \frac{\tanh b\sqrt{(2h/k_f\delta)}}{b\sqrt{(2h/k_f\delta)}} \qquad [7]$$

Accuracy. Satisfactory accuracy is indicated by the agreement of the heat gain by the air with the heat loss by the steam which was generally within 2 per cent, except at the lowest air flows, where there was a slightly greater discrepancy. The closeness of the plotted results to a smooth curve and the agreement between results for similar samples also indicate good accuracy.

Acknowledgment

The authors gratefully acknowledge the large share of this investigation contributed by Mr. Stanford Neal, who built the test equipment and carried out most of the tests.

Discussion

R. C. Martinelli,[4] M. Tribus,[5] and L. M. K. Boelter.[6] The results given in this paper are very interesting and useful. As pointed out by the authors the trend of the results can be predicted with some success by the approximate relation

$$j = \frac{f}{2} = 0.94\Big/\sqrt{R_\psi}$$

It should be emphasized, as a precaution to those who may apply the test results to larger fins, that all of the authors' data fall within the range of laminar flow along flat plates. In this type of flow, the unit thermal conductance varies inversely with the square root of the fin width a. With larger plates, however, the flow becomes turbulent.

For smooth flat plates, the drag coefficient in the turbulent region may be expressed[7] approximately as

$$\frac{f}{2} = \frac{0.074}{2}\left(\frac{\mu}{V\rho a}\right)^{0.20}$$

As a close approximation $j = f/2$. Substituting physical constants for air at 70 F yields

$$h = 6.06 \times 10^{-3}\left(\frac{V\rho}{a^{0.250}}\right)^{0.80}$$

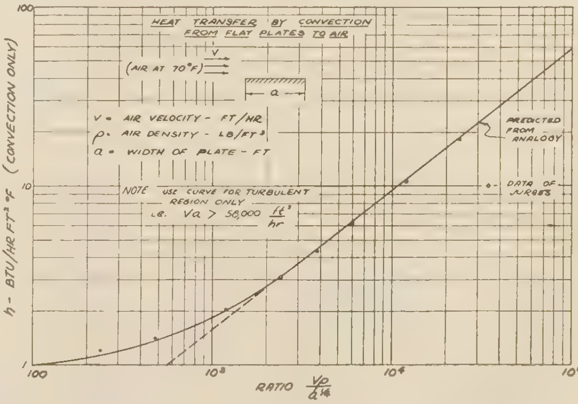

Fig. 11 Heat Transfer by Convection From Flat Plates to Air

where h = unit thermal conductance from plate to air, Btu per hr ft^2 deg F; V = air velocity, fph; ρ = air density, lb per cu ft; and a = width of plate, ft.

A plot of this equation is shown in Fig. 11 of this discussion, together with points obtained from the data of Jurges.[8] At the low magnitudes of the mass velocity G, free convection becomes effective. It is noted that, for large plates in the turbulent region, the unit thermal conductance varies inversely with the $^1/_5$ power of the plate length, as contrasted with the $—^1/_2$ power in the viscous region.

Authors' Closure

The data for a large flat plate provided by Martinelli, Tribus, and Boelter furnishes a particularly convenient correlation for conditions of much practical interest. The rather unusual choice of the variable used for the abscissa in Fig. 11 has considerably simplified the graphical correlation. A less simple but more general correlation of substantially the same data, with j and $f/2$ plotted versus Reynolds number, will be found in reference (2) of the Bibliography of the paper.

The data in Fig. 11 do not necessarily apply, however, to a group of large plates, as distinguished from a single plate. The determination of the effect of different arrangements of the plates in a group, was, in fact, the major object of the authors' investigation, but only for small plates. For these small plates, or strips, the performance can change considerably with some changes in the arrangement, as shown in Fig. 6.

The distinction between laminar and turbulent flow here considered probably applies primarily to the boundary layer on the strips or plates, rather than to the rest of the stream. It seems doubtful that turbulence can be completely absent, for example, in the wake of each strip, for the entire Reynolds number range covered by the authors' tests. The sharp break in some of the curves in Fig. 7 and Fig. 8 may indicate the beginning of turbulence in some part of the stream.

In regard to data for closely spaced large plates, or flat narrow ducts, as represented by sample 7, the test results presented in this paper have been found to confirm, for low Reynolds number, the purely theoretical correlation for laminar flow given in a paper by R. H. Norris and D. D. Streid.[9] In fact, the data for sample 7 in terms of j versus Reynolds number, although purposely not included here, in Fig. 3, will be found in Fig. 5 of that earlier paper.[9]

Combustion of Pulverized Fuel—Mechanism and Rate of Combustion of Low-Density Fractions of Certain Bituminous Coals

By A. A. ORNING,[1] PITTSBURGH, PA.

In the course of the investigation reported in this paper, individual particles of burning coal were studied, using all convenient means of observing the burning process and examining the residues which might be obtained. Using Pittsburgh seam coal and Pocahontas No. 3 seam coal, it was found that the particles were blown into cenospheres before they ignited. The exposures just required to make an impression on the photographic film were used to estimate the temperature history of individual particles. With the available furnace temperatures, less than 1000 C, the degree of combustion depended upon the ability of the particles to maintain themselves above about 1400 C. The degree of combustion increased with increasing furnace temperature in the region where the cenospheres were formed. Photographs of partially burned cenospheres and data on the relation of particle size to burning time were obtained.

THE use of pulverized fuel has developed largely as an engineering art. Furnace conditions, such as gas composition, temperature, radiant flux, dust loading, etc., have been determined (1),[2] but such information tells us very little about what happens to the individual coal particle.

The rate of burning of spheres of electrode carbon under forced-air convection is fairly well known. Mayers (2) has reviewed the earlier work, while Hottel and associates (3, 4, 5) have made important later contributions. However, it is neither safe to extrapolate from comparatively large spheres to dust particles, nor to assume that the burning coal particle resembles a sphere of electrode carbon. Coal particles under certain conditions are known to form cenospheres (6). Although such particles have been found in industrial furnaces, it has not been demonstrated that they are generally involved in the combustion of pulverized fuel.

Griffin, Adams, and Smith (7) have made photographic measurements of the time of incandescence of individual particles in a stream of closely sized coal falling into an electric furnace. For a given coal sample they found that the average time of incandescence, as measured on their photographs, increased with increasing furnace temperature throughout the range explored from 700 to 1000 C. However, they offered no experimental evidence either to establish the relation of incandescence time to burning time, or to show that complete combustion was obtained.

The present investigation was made to study the behavior of individual particles of burning fuel, using all convenient means of observing the burning particles and examining the residues which might be obtained. It has led to several interesting results such as the temperature history of an individual burning particle, and has also indicated that the previously reported negative temperature coefficient (7) may be explained on the basis of incomplete combustion. Ideally, a furnace should have been used which could reach temperatures even above those found in industrial furnaces, but the amount of exploratory work required made it advisable to set a limit at about 1000 C, until the results obtained indicated the type of equipment best suited to the higher-temperature region.

Any carbonaceous substance capable of being pulverized is a conceivable pulverized fuel, but the immediate interest has centered on the bituminous coals. A Pittsburgh seam coal was chosen for the preliminary work, while a Pocahontas No. 3 and an Illinois No. 6 coal were available for comparative tests. The work was confined to the low-density and, therefore, relatively low-ash fractions of these coals. The influence of ash should be the subject of a separate investigation.

Apparatus and Procedure

Figs. 1 and 2 show the furnace used. The main heating elements were supported in fused-quartz tubes placed behind silicon-carbide plates which enclosed a slot $^1/_2 \times 4 \times 24$ in. These elements, each made of about 13.5 ft of 14-gage Nichrome-V wire and operated at a maximum of about 150 w, were connected in a series-parallel arrangement suitable for operation at 220 v. Rheostats were placed across various sections of the furnace in order to obtain uniform temperature as indicated by a survey with a chromel-alumel thermocouple. The average temperature was controlled by means of another couple located near one of the heating elements and connected to a potentiometer-recorder controller.

A blower took air from behind the baffle plates in the dust receiver at the bottom of the furnace and returned it to the top of the window channels. Additional air was admitted through the preheater into a chamber in the top of the furnace. Radiation shields, which protected all but a $^3/_4$-in. strip of glass opposite the furnace slot, carried deflector plates which forced the air out of the channels into the furnace. By proper positioning of these plates and by control of the rate of air circulation, it was possible to maintain a fairly uniform downward air velocity, except for a noticeable increase at the bottom, which resulted from forcing nearly all the air to pass through a constricted space between the heater plates. The velocity of the air could be estimated from the photographic traces of burning particles. These particles were so light and small that they had low drift velocities. The velocity indicated by the slopes of their traces on the photographic record is essentially that of the air.

A rotary vibrator caused the coal sample to flow out of a glass funnel, around a spiral, and through a water-cooled tube into the top of the furnace. The intensity of vibration was kept as low as possible in order to avoid segregation and yet maintain a steady rate of flow. In some cases it was necessary to use a sampling tube which allowed only part of the flow from the spiral to pass on into the furnace.

Contributed by the Fuels Division and presented at the Annual Meeting, New York, N. Y., December 1–5, 1941, of The American Society of Mechanical Engineers.

The camera shown in Figs. 3 and 4 consisted of a disk shutter, rotated at 1800 rpm, placed between the lens and the film drum, which rotated at 10.5 rpm. The lens was a 107-mm F 3.7 Kodak Anastigmat Ektar. The film drum shown removed from its box had a $2^1/_2$-in. face which fitted standard 620 roll film. Several types of film were tested and Eastman Kodak Super-XX Panchromatic roll film was decided upon as being the most satisfactory. The drum in its box could be lifted off the camera and taken to the darkroom for loading. A variety of shutter disks was used; the one shown was of metal and had sector openings corresponding to exposure times of 0.0106, 0.0212, 0.0424, 0.0848, 0.170, and 0.68 millisec. Fig. 7 is a portion of a photographic record obtained with this shutter; each line of dots is the interrupted trace of a single burning particle. The longest exposure registered as a slightly elongated dot, while the others were short enough to "stop" the particles. The time of incandescence, in sixtieths of a second, could be determined by counting the heaviest dots, while the density and shape of the dots indicated the intensity and character of the combustion process. In some records the hot furnace walls appeared as a background of light vertical lines. In making these records, a cam on the axle of the film drum acting through a switch and a solenoid opened the lens shutter only during the passage of a desired sector of the film. In general, the records were single exposures showing only what was in the furnace at the one time.

The coal samples were sized between standard screens and separated into float and sink fractions on various mixtures of benzene and carbon tetrachloride. After removing the organic solvents some coals formed a caked mass which it was necessary to break up by rescreening. The treatment produced a fairly homogeneous sample both in chemical and physical character,

as well as in performance in the furnace. Samples of too wide a density range contained particles which ignited at widely separated levels making it difficult to keep them all in the furnace during the incandescence period. Those density ranges which included nearly pure coal except for finely distributed ash were most uniform in behavior.

The proximate analyses of the coals used are given in Table 1. The volatile-matter contents, on an ash-and-moisture-free basis, and the ash contents for the samples as used are given in Table 2. The volatile-matter contents given in Table 2 were determined by a microanalytical procedure which was developed for the purpose of this investigation. This procedure gives about 10 per cent more volatile matter than is given by the standard A.S.T.M. test.

The principal effect of the density separation was to eliminate particles of high ash content. There was no apparent separation of the pure coal material of the Pittsburgh coal except for an observed concentration of fusain in the 1.35 sink fraction. However, the 1.35 float fraction of the Pocahontas coal was brighter in appearance than the sink fraction. It had a higher ratio of volatile matter to fixed carbon and formed a coke button in the determination of volatile matter, which was not obtained with the sink fraction. There was probably some separation into petrographic constituents with this coal.

Mechanism of Ignition and Combustion

There were definite limitations on the types of fuel which could be ignited in the apparatus used. The controlling factor was the furnace temperature, which was limited to 950 C. For instance, when Pittsburgh seam coal was passed through the furnace, occasional particles of fusain in the residues showed no change in size and shape, although some etching occurred which intensified the fusain-like characteristics. Similarly, a sample of 170–200-mesh anthracite could not be uniformly ignited with the furnace set at 950 C. An occasional bright flash was seen and a few particles showed evidence of attack on thin layers of more reactive material.

The influence of temperature on the degree of combustion was most clearly demonstrated by an examination of the residues. Fig. 5 is a series of photographs showing the 60–80-mesh 1.29-float Pittsburgh coal and the residues obtained by passing it through the furnace at various temperatures. All these pictures were taken at the same enlargement, approximately 15 fold.

This coal began to show some melting, taking on a bright pitch-black surface, at 500 C. As the temperature was raised, the kernel sizes increased, and, on examination under the microscope, they were found to be somewhat irregular cenospheres. At temperatures up to 700 C there was no visible sign of ignition, but at 750 C short bright flashes were seen in the furnace, and the residues occasionally had a dull black coat of soot, but there was no attack on the kernels and the bright black surface could be found by brushing off the sooty coat. At 800 C some attack on the kernels occurred leaving lacy structures of bright graphitic sheen. As the temperature was further raised, the amount of attack in-

(Furnace temperatures, top row, left to right, original coal, 520, 600 C; middle row, 700, 750, and 800 C; bottom row, 850, 900, and 950 C.)

creased and the graphitic sheen turned to a dull gray. A point of special interest was the maximum in kernel size at about 750 C. The small cenospheres formed at the higher temperatures were very fragile and highly perforated. Their lacy structures followed the outline of typical cenospheres. Except for the elimination of nodules there was no indication that they had been formed by partial combustion of larger structures. The small nodules which appeared on most kernels were hollow. Their presence indicated that the surface had begun to harden while the interior was still fluid, the nodules being formed from fluid forced out through a point of rupture in the initial surface.

Fig. 6 is a similar series of photographs, showing the residues obtained from the 60–80-mesh 1.35-float Pocahontas coal. These showed characteristic differences from the Pittsburgh coal. At lower temperatures the cenospheres were wrinkled. They were neither so large at moderate temperatures nor so small at higher temperatures. No sooty particles were observed. Corresponding stages of combustion occurred at definitely higher temperatures, although this difference seemed to decrease as the temperature was increased.

Table 3 shows the analyses of residues which were duplicates of part of those shown in Fig. 6. The degree of combustion, the percentage completion of the combustion reaction, was calculated on the basis of ash contents. The volatile matter was not characterized. It may have been largely carbon dioxide and carbon monoxide.

Residues have also been obtained from the Illinois coal. On microscopic examination they were found to be cenospheres which were generally more irregular than those from the Pittsburgh coal. No evidence was found to indicate any fundamental difference in the behavior of the Illinois coal. It did appear to be more easily ignited than the other coals, but further work must be done to obtain quantitative information on its performance.

Microscopic examination of particles subjected to various furnace temperatures revealed delicate shadings of color and details of structure which are barely suggested in the illustrations. The unattacked cenospheres varied from a mat to a bright pitchy black, depending upon the character of the sample. The presence of perforations and lustrous graphitic sheens was a sensitive indicator of attack on the cenospheres. Delicate lacy structures and dull gray colors were signs of advanced stages of combustion. These differences in appearance offered convenient and convincing criteria for judging the degree of combusion. With the lighter fractions of the 60–80-mesh coals it was found that very few particles ignited below 750 C and that furnace temperatures in excess of about 850 C were necessary to obtain uniform ignition, while even 950 C was insufficient to ignite fusain or anthracite. Every sample that ignited at 900 C or lower showed evidence of increased combustion at 950 C.

Since the degree of combustion depended so strongly upon the furnace temperature, it was decided to investigate the character of the incandescence and its relation to the burning time at the highest available furnace temperature, 950 C. Fig. 7 is part of a record of burning 60–80-mesh 1.29-float Pittsburgh coal. The furnace was set at 950 C and the camera at F 3.7. Fig. 8 is part of a similar record for 60–80-mesh 1.35-float Pocahontas coal.

[a] Pocahontas No. 3 seam coal, 60–80 mesh 1.35 float.

The negatives for these records were intensified for the purpose of reproduction but are otherwise typical of many that were obtained. Other than in the apparent difference in radiant indensity, the Pittsburgh coal differed in that almost every particle ignited with a very intense flame which momentarily died out and then reached a second maximum. This effect, which was quite evident on microscopic examination of the original negatives, was better illustrated with coarser mesh sizes.

Figs. 9*a* and 9*b*, an enlargement of another portion of the same record, show a sample of 40–50-mesh 1.29-float Pittsburgh coal, burning in a furnace temperature of 950 C. The shutter disk used for this record had openings giving exposures of 0.021, 0.042, 0.085, and 3.18 millisec. This record is typical of many in which the brilliant portion of the traces had broad dashes which thinned out to a feathery top edge, while the dots took on a typical teardrop shape.

Using the same 40–50-mesh sample at 800 C furnace temperature it was very difficult to obtain satisfactory pictures. With high feed rates, there appeared to be a cooperative effect causing ignition at high levels in the furnace with considerable smoke. With lower feed rates it was difficult to maintain a steady flow of igniting particles. When the coal feed was so adjusted that the rate of flow of igniting particles was about one half the usual rate, the residues collected at four to five times the usual rate. It appeared that only an occasional particle was sufficiently reactive to ignite at or below 800 C. The brilliant portions of the photographic traces were frequently absent and when present were of short duration. Where they did occur there was usually an accidental grouping of two or more ignited particles.

It seemed quite evident that the brilliant portions of the traces were due to the combustion of volatile matter. This conclusion was also reached by Griffin, Adams, and Smith (7). The fact that the incandescence passed through a minimum indicated that combustible matter was still present, but it could not immediately be assumed that the remaining portion of the trace corresponded to the burning of the coke residue. In an attempt to determine the rate of the combustion process during the final portion of the incandescence period, a series of experiments was performed, using 40–50-mesh 1.29-float Pittsburgh coal, in which the particles were forced out of the furnace at various times after the point of ignition and before they had lost incandescence. It was supposed that the rapid cooling as the particle left the furnace would quench the combustion process.

Fig. 10 shows the results of these experiments. The percentage of the original combustible left in the residues, calculated on the basis of ash contents, is plotted against the time after ignition

during which the average particle remained in the furnace. The total period of incandescence was estimated from later tests as 0.6 sec at 950 C and probably somewhat less at the lower temperatures. At 800 C ignition was not uniform. The increased degree of combustion at the higher time was probably due to an increased percentage of ignition as well as the effect of time on the evolution of volatile matter. At the higher temperatures the variations barely exceeded the limits of experimental accuracy.

The particles, after leaving the furnace, were in their latter stages of combustion where the rate might be expected to be comparatively slow. It is also possible that efficient quenching was not obtained. The particle temperatures, as will be shown

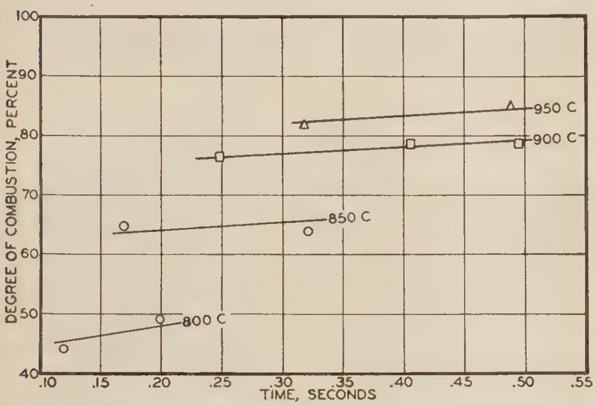

FIG. 10 DEGREE OF COMBUSTION AS FUNCTION OF TIME OF EXPOSURE TO FURNACE TEMPERATURE
(Pittsburgh seam coal, 40–50 mesh 1.29 float.)

later, were about 1500 C. Since radiation is proportional to the difference of the fourth powers of the absolute temperatures, substituting 25 C for the furnace temperature of 950 C would increase the rate of radiation by 29 per cent. Thermal conduction to surrounding gases, being controlled to a first order of approximation by the temperature difference, would be increased by 168 per cent. Wohlenberg and Wise (8), considering a theoretical furnace with angle factors to cold and refractory walls of 0.576 and 0.424, respectively, found that 71.1 per cent of the heat lost by the pulverized-coal flame was conducted directly to the surrounding gases. However, they were considering a coal pulverized 70 per cent through 200 mesh. Since the rate of conduction from a sphere contains the reciprocal radius as a factor, which is not involved in radiation, the portion of the heat lost by thermal conduction from the 40–50-mesh coal was probably less than that from their pulverized coal by a factor of four or five. Considering the differences in the two furnaces, it appeared reasonable to assume that substituting room temperature for 950 C would increase the rate of heat loss by 50 to 125 per cent, depending upon the mesh size in the range from 40 to 200 mesh. Since no criterion was available to determine the rate of heat loss required to cause quenching, the only conclusion that it was possible to draw from these experiments was that, although the degree of combustion depended strongly upon the furnace temperature, it was not significantly affected by forcing the particles out into colder surroundings before they had lost incandescence.

A study of the temperature history of individual particles was much more fruitful in interpreting the final portions of the photographic traces. It was assumed that the exposure just required to make an impression on the film depended only upon the amount of radiant energy available within the spectral-sensitivity range of the film. It was also assumed that the burning coal particle emitted true black-body radiation. According to Planck's law, the amount of energy in black-body radiation, dE, within the wave-length range $d\lambda$, is

$$dE = \frac{\sigma d\lambda}{\lambda^5(e^{c/\lambda T} - 1)}$$

where σ is the Stefan-Boltzmann radiation constant, T is the absolute temperature, and c is a constant depending upon the units of temperature and wave length used. By integrating over those wave lengths to which the film was sensitive, multiplying by the exposure time t, and dividing by the square of the relative lens aperture f, the following expression was obtained for the amount of energy reaching the film which was useful in forming an image

$$E' = \sigma t/f^2 \int_0^\lambda \frac{d\lambda}{\lambda^5(e^{c/\lambda T} - 1)}$$

The lower limit was taken as zero since the spectral sensitivity extended into the ultraviolet where the energy in black-body radia-

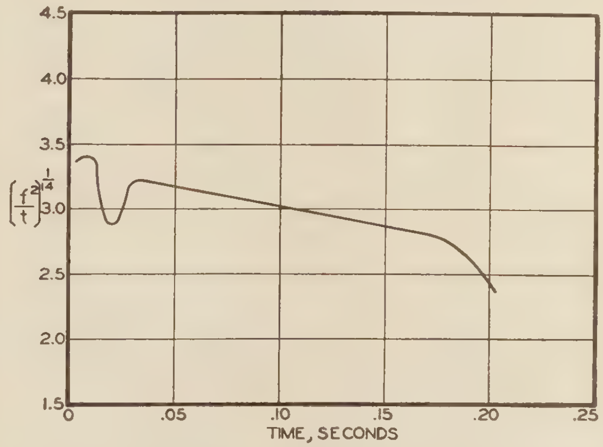

FIG. 11 TEMPERATURE HISTORY OF A BURNING PARTICLE
(Pittsburgh seam coal, 60–80 mesh 1.29 float. Temperature in arbitrary units estimated from relative lens aperture f, and exposure time in seconds t, just required to make an impression on the film.)

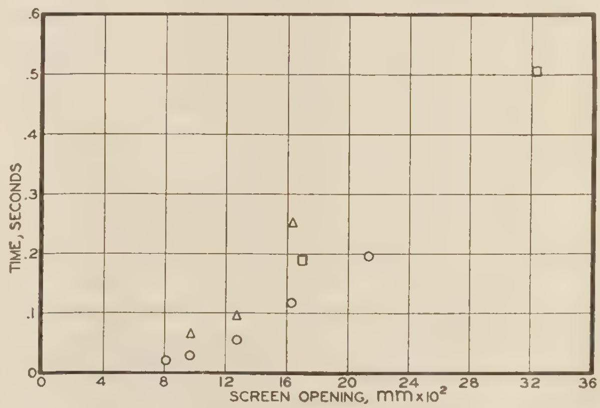

FIG. 12 BURNING TIME AS FUNCTION OF MEAN SCREEN OPENING
(○ 1.29-float Pittsburgh seam coal; △ 1.35-float Pocahontas seam coal; □ Kanawha gas coal, as reported by Griffin, Adams, and Smith, ref. 7.)

tion, except for extremely high temperatures, becomes comparatively negligible. The upper limit was taken as 6500 Angstroms for super-XX film, which had a comparatively flat sensitivity curve extending from this point into the ultraviolet. If the integral had been taken from zero to infinity it would have

led to the familiar result that the rate of radiation was proportional to the fourth power of the absolute temperature. The partial integral could not be solved explicitly for T. However, numerical values for the integral were available (9). By plotting these values against T on a logarithmic scale, it was found that, within limits of accuracy sufficient for the purpose and in the neighborhood of 1500 C, the partial integral was proportional to the fourteenth power of the absolute temperature. By substituting this approximation for the integral and absorbing the constants of proportionality in an arbitrary unit of temperature, the foregoing expression became

$$T' = (f^2/t)^{1/14}$$

This permitted an estimation of the temperature history in terms of relative lens aperture and the exposure time in seconds.

In order to apply the latter equation it was necessary to find lens apertures at which pictures could be obtained with dots, corresponding to different exposure times, disappearing at various points along the traces. In general it was not possible to determine these points with a very high degree of accuracy, but a study of a number of pictures for 60–80-mesh 1.29-float Pittsburgh coal at 950 C furnace temperature led to the composite curve given in Fig. 11. This procedure for determining particle temperatures should be calibrated against sources of known temperature. Preliminary calibrations, involving pictures of the filament of a pyrometer bulb, placed at the same distance from the camera as the burning coal without any optical system between the camera and the bulb, led to an estimate of 1800 C and 1500 C as corresponding, respectively, to the first maximum and minimum of Fig. 11.

It is now possible to give a fairly complete interpretation of the photographic traces. When the coal particle entered the furnace, it was blown into a cenosphere by the escaping volatile matter. If there was sufficient volatile matter and the furnace temperature was high a brilliant flame of burning gas resulted. Since this flame consumed all the oxygen in the vicinity of the particle the temperature of the residue fell after the flame disappeared, until oxygen could again reach the particle. Whether or not the volatile matter ignited, the attack on the residue raised its temperature to a maximum, and then as the process continued, the temperature gradually fell. The residue was in the form of a cenosphere which was being etched and pitted by the combustion process. Thin wall sections, especially the nodules, disappeared or at least they were so fragile that it was impossible to collect the residues and observe any ash structures in the holes that were left. Except for the possible falling away of the nodules, the cenospheres could be considered as burning at constant radius. Since the inner surfaces were visible through the holes, the effective radiation area was at most decreasing very slowly. However, the oxygen, which was being consumed as rapidly as it reached the surface, and which was largely depleted before it could diffuse through the holes to the inner surfaces, was consumed on an effective area which was decreasing more rapidly than the radiation area. Since these areas controlled the rate of heat release by combustion and the rate of heat loss, the temperature had to fall in order to keep the process in balance. Finally the temperature began to fall at a very rapid rate, although the residues were still largely combustible. Starting with coal of about 2 per cent ash, the residues contained from 20 to 30 per cent ash at the highest furnace temperatures obtainable in the present apparatus.

Tu, Davis, and Hottel (3) found that the rate of burning of a sphere of electrode carbon, burning in air under forced convection, increased rapidly with increasing surface temperature up to about 1000 C, while above this temperature the rate increased very slowly. Parker and Hottel (4) found that above 1100 C the concentration of oxygen at the carbon surface approached zero, while at lower temperatures it rose rapidly to the normal concentration in the air. Their interpretation was that at low temperatures the rate of the surface-reaction was the controlling factor, while at high temperatures the oxygen was being consumed as rapidly as it could diffuse to the surface. Since surface-reaction rates generally have high temperature coefficients while those of diffusion processes are comparatively low, this explained their results. In applying their conclusions to the burning cenospheres it was necessary to consider that the cenospheres, being formed at temperatures probably on the order of 1800 C, were less reactive than the electrode carbon. This meant that as the temperature gradually fell, a point estimated at about 1400 C was finally reached where the rate of the surface reaction became a controlling factor and the high temperature coefficient of this reaction caused the final rapid fall in temperature.

The study of the mechanism of combustion has led to three important results as follows:

(*a*) During all of the incandescence period, except for a small part at the end, the rate of combustion was controlled by the rate of transport of oxygen to the surface. Since the cenosphere was burning at nearly constant radius, the effective surface could not have been decreasing rapidly, and the rate of combustion must have had the same order of magnitude, except for the very last portion of the incandescence period.

(*b*) The degree of combustion was not significantly reduced by forcing the particle out of the furnace while it was still incandescent, a major fraction of the normal incandescence period being spent in surroundings at room temperature.

(*c*) The degree of combustion increased with increasing furnace temperature.

These results indicated that the cenospheres burned at a rate which was independent of changes in the temperatures of their surroundings during the combustion period, until the rate suddenly decreased at a degree of combustion which depended strongly upon the temperature at which the process began. It was also shown, as illustrated in Figs. 5 and 6, that the residues were in the form of cenospheres even though the temperature was too low to cause ignition, while the size and shape of the cenospheres depended upon the temperature at which they were formed. The most plausible conclusion seems to be that the conditions ahead of the point of ignition, under which the cenospheres were formed, were the controlling factors.

Relation of Particle Size to Burning Time

Before making a study of the relation of particle size to burning time it was necessary to decide on a suitable definition of burning time. Obviously the period of incandescence, as determined by the photographic records, could not be used because it was found that this period depended upon the film and the lens aperture used. It was also necessary to consider that slow combustion processes occur even at room temperature. The study of particle temperatures indicated that the rate of combustion was decreasing slowly, until the surface reaction became a controlling factor causing the final rapid fall in temperature. During this final period the rate of combustion was probably so low that it would be of no importance in changing the degree of combustion attainable in the times available in any practical furnace. For these reasons, the time of combustion was defined as the time from the point of ignition to the beginning of the final rapid fall in temperature. Experimentally this time was determined by counting the dashes along a given trace until a point was reached at which two or more dots disappeared within a single timing cycle, $^1/_{60}$ sec. Since the ratio of exposure times for successive dots in each cycle was two to one, this meant that at this point more than a twofold increase in exposure time was required to compensate for the temperature fall within $^1/_{60}$ sec.

A series of experiments was made at 950 C to determine the relation of burning time to particle size. Fig. 12 shows the time in seconds plotted against the mean screen opening for each size fraction (60–80, 80–100, 100–140, 140–170, 170–200). These are provisional values subject to further confirmation. It must be emphasized that these were burning times at constant furnace temperature and not at constant degree of combustion. This was probably not a serious limitation because the degree of burning of the 60–80-mesh Pittsburgh coal was estimated from ash contents of the residues as approximately 94 per cent, while the finer sizes with which it was impossible to collect residues must have reached even higher degrees of combustion. The Pocahontas

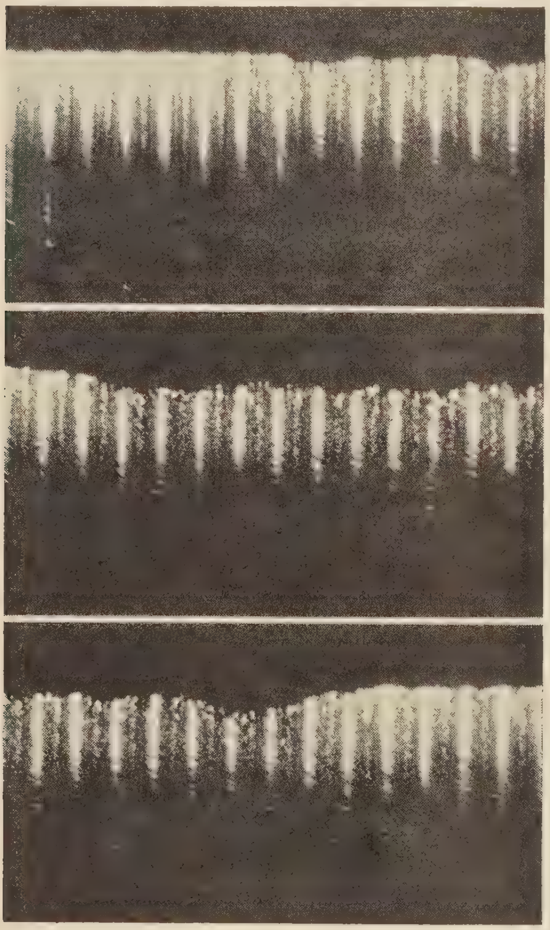

Fig. 13 Flame of Pittsburgh Seam Coal
(Minus 200-mesh coal at 950 C furnace temperature.)

coal showed the longer burning times although residues were collected even for the 140–170-mesh size which indicated a much lower degree of combustion than for the Pittsburgh coal. The two values shown for Kanawha gas coal are those reported by Griffin, Adams, and Smith (7). They used a recording paper for most of their work, but did get some data on panchromatic film. These materials being slow, as compared to Eastman super-XX roll film, it is possible that their traces may have died out before the particles entered the final period of rapidly falling temperature. On the other hand, if their traces had died out during the period of slowly falling temperature, the paper and the film, which had different speeds, should have indicated distinctly different times of incandescence. Since they reported almost no difference, their traces must have died out at or shortly after the beginning of the final rapid fall in temperature. This means that they were measuring approximately what has been defined previously as the burning time.

The burning times were obtained with rates of coal feed such that nearly infinite air supply could be assumed. With higher rates of feed, the burning time increases. This is clearly indicated in Fig. 13, which shows the flame of minus 200-mesh Pittsburgh coal at a furnace temperature of 950 C. Where the cloud was most dense, the incandescence time increased, but it was not possible to evaluate the density, except that in this case the formation of smoke indicated, at least in a part of the flame, that there was an actual deficiency of air. The increased burning time was probably due to the decreased excess-air supply, but it is possible that, at least in part, it was due to an increased degree of combustion with higher cloud densities. Aside from its influence on burning time, the cloud density had another very important effect. As the density was increased, the flame became steadier and occurred at a higher level in the furnace. The formation of well-defined and steady flame fronts depended critically upon the cloud density and was most easily obtained with the finer-mesh sizes of the higher-volatile coals. There appeared to be a co-operative effect causing a continuous-gas-phase flame front in the volatile matter which was driven out before ignition occurred.

General Considerations

In the present investigation, the available furnace temperatures were not, in general, sufficient to obtain complete combustion. Rapid combustion depended upon the ability of the individual particle to maintain itself considerably above the temperature of its surroundings. Whether the temperature required varied with particle size was not determined. However, an examination of the records which were obtained showed that the finer particles burned at approximately the same temperature as the 60–80-mesh sample, which was used in the quantitative studies, except that the onset of rapidly falling temperature was more sharply defined. Since the temperature required, above about 1400 C, was the same order as that found in industrial furnaces, it appeared probable that incomplete combustion would only occur with those particles that still contained combustible when they passed out of the high-temperature regions of the furnace. The experimental results have indicated that such particles would be able to maintain their temperature sufficiently above their surroundings to sustain active combustion, until a degree of combustion was reached which was determined by the character of the particle itself and only to a minor degree by its surroundings.

Furnace temperature was the variable subject to control but was not the variable which could be compared with conditions in a flame front. The important factor was probably the temperature history of the individual particle before ignition occurred. With the coals investigated it was shown that increasing furnace temperature, and therefore increasing rates of rise of particle temperature, influenced the size and form of the cenospheres. It has also been shown that the yield of volatile matter increases with the rate of rise of temperature (10, 11). It would seem reasonable to suppose that the tremendous rates of rise available in the flame front might have considerable effect on the yield of volatile matter. Since the degree of combustion and probably the percentage conversion to highly combustible volatile products both increased with increasing furnace temperature, it appears desirable that the rate of rise of particle temperature should be high. However, no evidence has been obtained to indicate how far it might be practical to go in this direction.

The appearance of the flame depended upon the cloud density. At low densities ignition occurred at random levels in the

furnace but, as the density was increased, a point was reached where a definite flame front appeared. This effect was probably due to propagation of a continuous gas flame in the volatile matter which was driven out before ignition occurred.

Any air in excess of that required in the region where volatile matter is burned would have to be consumed in the comparatively slow combustion of the residues. The amount of such excess air would have an effect on the temperature attained in this region, which in turn is most directly responsible for the rate of heating of the coal particle. These results indicated that the desirability of high rates of heating of the coal particle, as well as flame stability, are fundamental reasons for not admitting all the air required for combustion with the coal.

Information on the relation of burning time to particle size was also obtained. The numerical results must be interpreted with care. They were obtained at constant furnace temperature and not at constant degree of combustion. They must be corrected for the influence of limited excess air. This information is probably of greater value for comparison of different coals than it is for interpretation of furnace conditions.

Probably the most important result of the investigation has been that it has focused attention upon those changes in the coal particle which occurred before ignition. The indicated desirability of a limited primary-air supply, as a means of obtaining flame stability as well as high rates of heating the unignited coal, must be considered in relation to the fuel used. Delayed admission of secondary air requires considerable power for thorough mixing. It generally involves more expensive equipment. Such extra costs may not be justified except for fuels which are more difficult to ignite and burn.

Summary and Conclusions

1 The mechanism and time of burning of individual particles of coal have been determined using all convenient means of observing the burning coal particles and examining any residues that were obtained.

2 The investigation was limited to low ash fractions of Pittsburgh, Pocahontas No. 3, and Illinois No. 6 seam coals, but included particle sizes ranging from 40 to 200 mesh.

3 The residues obtained at various furnace temperatures showed nonuniform ignition at temperatures below about 850 C and an increasing degree of combustion with increasing temperature throughout the range explored up to 950 C.

4 The coal particles were blown into cenospheres by escaping volatile matter. The conditions under which this process occurred were found to be the controlling factors in the performance of the coals investigated. It is probable that the temperature, and therefore the rate of temperature rise, in the region just ahead of the zone of ignition should be maintained as high as possible.

5 Contrary to the assumption which has frequently been made in theoretical calculations, the coke residues were in the form of cenospheres which burned essentially at constant radius.

6 Probably the most important result of this investigation has been a demonstration of the fact that the changes, which occur before the particle of coal ignites, exert considerable influence upon the subsequent combustion process.

Discussion

Henry Kreisinger.[3] The paper gives the results of an interesting laboratory investigation of combustion of pulverized coal and deserves a careful study and analysis. The furnace conditions under which the experiments were conducted should be carefully compared with the conditions existing in a commercial pulverized-coal furnace before any general conclusions can be reached.

In the paper the furnace temperature has not been defined. It is assumed to be the temperature of the two silicon-carbide plates which form the inner sides of the experimental furnace. Pulverized-coal particles were dropped into the space between these two plates and fell through the furnace. Air was circulated through the furnace in the same direction as the falling pulverized-coal particles. The paper does not state how hot this air was while flowing through the furnace, but it probably never reached the temperature of the two plates. The particles of coal falling through the furnace were heated mainly by radiation. The heating drove the gas from the particles and, when this gas reached certain concentration and temperature, it ignited.

The rate of heating depended upon the temperature of the plates and the size of the particles. The smaller particles had greater surface compared to their mass and were heated more quickly than large particles. When the temperature of the plates was low, the rate of heating of the coal particles was low, the gas was evolved from the coal particles slowly, and the particles formed almost perfect cenospheres. With high temperature of the plates, the coal particles were heated rapidly, and the gas was evolved faster, in most cases breaking the surface while cenospheres were being formed. This procedure in the formation of the cenospheres seems to be indicated by Fig. 5 of the paper, which shows the residue from Pittsburgh coal and furnace temperature, varying from 520 to 950 C. According to Fig. 5, the most perfect cenospheres were obtained with temperature of 700 to 750 C. With the lowest temperature, the coal particles did not get hot enough to form cenospheres; with high temperature the surface of the coal particle was broken before cenospheres were formed.

When the coal particles ignited, their temperature reached 1400 to 1500 C, which is several hundred degrees higher than the furnace temperature. The elevation of the temperature was the result of the heat generated by the combustion of the gas. The combustion took place at or near the surface of the particle, and the heat was contained in the small amount of combustible

[3] Engineer in Charge of Research and Development, Combustion Engineering Company, Inc., New York, N. Y. Mem. A.S.M.E.

and the oxygen which had combined. The heat from the products of combustion was then transmitted to the surrounding gas and to the silicon-carbide plates. The temperature of 1400 to 1500 C corresponds to the temperature obtained in a commercial furnace in the ignition zone. The particles of pulverized coal entering a commercial furnace are heated mostly by radiation from the coal already ignited, which is at a temperature of about 1500 C. Because of this very much higher temperature in a commercial furnace, the coal particles entering the furnace are heated quickly. Therefore, it is questionable whether under such rapid heating any cenospheres are formed.

Pulverized coal, as burned in commercial furnaces, contains a large percentage of superfines which heat and evolve gas very quickly. It is these superfines which start the ignition. With such rapid heating, it is likely that the evolution of the gas from the coal particles is so fast that it breaks the surface before any cenospheres can be formed. This is true of the average conditions under which pulverized coal is burned. If any cenospheres are formed, it is the large particles of certain coals which may go through the cenosphere stage when burned under unfavorable conditions.

The fineness of pulverized coal, burned in commercial furnaces, is about 70 per cent through a 200-mesh and 90 per cent through a 100-mesh screen. Large particles remaining on an 80-mesh screen, which include the size on which most of the experiments were made, may amount to 5 per cent. Inasmuch as this small amount of large particles is surrounded by a large amount of fine and superfine particles which ignite readily, these large particles are heated quickly by the heat generated by the combustion of the fine particles. Therefore, the large particles behave differently in commercial furnaces from what they did in the experimental furnace where they were burned by themselves without the influence of the heat from combustion of the fine particles. It is doubtful that satisfactory results could be obtained in a commercial furnace with pulverized coal from which all coal passing through an 80-mesh screen was removed.

When the experimental furnace was operated at the low temperatures, the heating of the particles was so slow that some of them passed out of the furnace before they ignited. If allowed to fall freely, they would stay in the furnace about $^1/_3$ sec. If the air moved faster than the falling particles, there was a drift and the coal particles stayed in the furnace less than $^1/_3$ sec.

In the experimental furnace, the furnace temperature controlled the rate of heating of the coal particles and the evolution of combustible gas, thereby controlling the ignition. With high furnace temperature, the ignition conditions were reached soon after the particles entered the furnace. Most of the time that the particles stayed in the furnace was available for combustion. At low furnace temperature, the heating of the coal particles was slow, and much of the time that the particles stayed in the furnace was used to bring them to ignition condition, and very little time was left for combustion. Some of the particles did not ignite, and therefore did not burn at all. When ignition occurred, the combustion proceeded at the temperature of the coal particles, which was always much higher than the furnace temperature.

The coal particles and the air in the furnace moved in the same direction with very little or no relative velocity between them. The products of combustion, after ignition had been established, formed an envelope around the coal particles and moved with them, thus preventing access of free oxygen to the surface of the coal particles, or to the combustible gas evolving from them. As a result of the formation and retention of this envelope of inert gas, the combustion quickly decreased and stopped, not because of drop of temperature, but because of lack of oxygen. The results would be different if the air moved in the opposite direction to the falling particles. The ignited particles would be continually moving out of the envelope of inert products of combustion and meeting free oxygen. Combustion would occur as fast as combustible made contact with free oxygen and the temperature at or near the surface of the particles would be maintained considerably above the furnace walls. In commercial furnaces, we often observe particles of burning coal puffed out through the observation doors continue to burn at bright red heat for 1 or 2 sec in the boiler room in spite of the low atmospheric temperature, because they meet plenty of free oxygen to support combustion.

Authors' Closure

It is gratifying to find that a laboratory investigation is sufficiently interesting to merit careful study and analysis in relation to conditions existing in a commercial pulverized-coal furnace. It is necessary, however, to examine carefully any conclusions that are made and to determine whether or not they are based on experimental evidence.

The aim of the investigation was to replace the uncontrolled surroundings of an individual particle burning in a flame by the controllable surroundings of an electric furnace, so that the variables could be individually studied. The temperature effect was studied to the limit of the present equipment. There was no indication that higher furnace temperatures would cause any changes except the continued decrease in cenosphere size and increase in degree of combustion.

Mr. Kreisinger's assumption as to the furnace temperature is incorrect. The furnace temperature was determined by an unprotected chromel-alumel thermocouple temporarily inserted into the air space between the heater plates. A temperature difference between the air and the heater plates may have existed, but the air temperature was not necessarily the lower. The air entering the top of the furnace was passed through a preheater minimizing such differences. The indicated temperature was a good approximation to that which brought about the ignition of the coal particles.

The supposition, that ignition occurs as soon as the gas being driven out of the particle has reached a sufficient concentration and temperature, has no foundation in the present experimental investigation nor has any experimental evidence for it been found in the literature. The identification of the brilliant streaks at the beginning of the photographic traces as the burning of volatile matter does not identify the ignition process. The ignition of the volatile matter may be brought about by previous localized heating of the particle surface due to oxidation reactions. Ignition of the volatile matter was not found to be essential to burning of the residue. At the lower furnace temperatures especially, many photographic traces were found without the initial brilliant traces. Experimental investigations on the ignition processes in solid-injection Diesel engines have indicated that combustion reactions at the surface of large oil drops, rather than the ignition of previously vaporized small oil droplets, were responsible for the initial pressure rise.[4]

There is need for a similar direct experimental investigation of the ignition processes in pulverized-coal flames.

Mr. Kreisinger's interpretation of Fig. 5 is not correct. With all the coals examined and at all furnace temperatures, including the highest, the residues were cenospheres. It is true that escaping volatile matter probably caused some breakage but, even under the microscope, evidence of breakage was obscured by the effects of combustion.

Undoubtedly the presence of unburned cenospheres in the resi-

[4] "Neuere Anschauungen über den Zündvorgang im Dieselmotor," by K. Zinner, *Zeitschrift des Vereins deutscher Ingenieure*, vol. 83, 1939, pp. 1073–1079.

dues from commercial furnaces is correlated with unfavorable furnace conditions. However, the absence of cenospheres in the residues, under more favorable conditions, does not indicate that cenospheres were not involved in the combustion process. An ash skeleton, containing a small percentage of carbon and at a temperature above its fusion point, could not be expected to retain the form of the carbonaceous particle from which it originated.

The relative velocity between particles and air was controlled by the acceleration of gravity and by inertia effects in regions of changing gas velocity. Any attempt to obtain higher relative velocities was considered impractical for experimental reasons. Further, it is improbable that appreciably higher relative velocities occur in commercial pulverized-coal furnaces. A large dense object when thrown into an air stream maintains its relative velocity for a considerable time. Small particles show this tendency to a comparatively negligible degree. The inertia effect, being controlled by the mass and hence the cube of a linear dimension, decreases much more rapidly than the flow resistance. The latter varies as the projected area at high velocities while in the region of Stokes' law, which probably applies in the present case, it varies as a linear dimension. Except in regions where opposing gas streams impinge, the added accelerating forces are probably small as compared to gravity. High relative velocities produced in such regions are quickly destroyed. In order to maintain such velocities throughout the burning period, strong and continuous accelerating forces, such as those found in cyclone separators, would have to be employed.

The slopes of the lines in Figs. 7, 8, and 9 are measures of the particle velocities. The particle velocity was the sum of the air velocity and the relative velocity between air and particle. The upward convexity in Figs. 7 and 8 indicates that one or both of these velocities were decreasing as the particles moved through the furnace. The downward convexity in Fig. 9 indicates the converse. The relative velocities may be estimated on the basis of the rate of fall of free particles in stagnant air. Since the particles were cenospheres of low apparent density and lost weight due to combustion with little decrease in projected area, the relative velocities were probably a small fraction of the total velocity and decreased strongly as combustion proceeded. The slight curvature indicates slow changes in velocity and correspondingly small inertia contributions to the relative velocity.

Depreciation Estimates in Appraisals of Manufacturing Equipment

By P. T. NORTON, JR.,[1] and E. L. GRANT[2]

A replacement-cost appraisal should answer the question: "What could one afford to pay for this asset in comparison with the most economical new one?" The depreciation deduction from the cost of the most economical new asset should measure the value inferiority of the existing old asset. Depreciation estimated in this way may be very high even for comparatively new assets. General recognition of this in the manufacturing industries might well lead not only to a new concept of appraisals but also to a revision of depreciation-accounting policies and methods. The purpose of this paper is to outline briefly the theory which should govern measurements of value inferiority in appraisals, in other words measurements of appraisal depreciation.

CONVENTIONAL practice in commercial appraisals may result in misleading valuations because of the failure of the appraiser to understand clearly the theory which ought to govern appraisal depreciation. This may be illustrated by an example.

Shortly after the first World War, a manufacturing plant was appraised by a well-known appraisal organization as a basis for a loan. The major part of this plant consisted of several well-built brick buildings which had been constructed some years before. These were appraised on the basis of cost of reproduction less depreciation. The high cost of brick construction at this postwar date was naturally reflected in the reproduction-cost estimates. Because these buildings were so well built, the appraisers estimated a long life for them; hence straight-line depreciation deduction was but a small percentage of their reproduction cost.

On the basis of this high appraisal, the manufacturing company secured a substantial loan. Within a few years the company was unable to meet the interest and principal payments on this loan and went into receivership.

An important element in this company's failure was the high cost of materials handling. This high cost was due largely to the fact that electric overhead traveling cranes could not be used in these brick buildings. The lower-cost steel-frame mill-type buildings used by some competitors permitted this more economical method of handling materials. This fact had been given no consideration in the conventional "reproduction-cost less straight-line-depreciation" appraisal.

Appraisal Depreciation Should Measure Value Inferiority

Many such incidents could be cited where conventional appraisals have been misleading. The interpretation of a reproduction-cost-less-depreciation appraisal requires a clear understanding of the limited inferences which may be drawn from any appraisal based on replacement cost. It also requires an understanding of the theory which should govern the depreciation deduction from replacement cost. The clearest and most complete explanation of these matters which has come to the attention of the authors is by J. C. Bonbright.[3] Professor Bonbright summarizes his analysis as follows:

"A sharp distinction must be drawn between replacement cost in the sense of the cost of acquiring a substantially identical type of property, and replacement cost in the sense of the cost of constructing or buying the most desirable substitute. The former is never a measure of value unless it happens to approximate the latter. But even the cost of a different type of substitute cannot be used directly as a measure of value. Account must be taken of the likelihood that in some respects the substitute would be superior to the present property, while in other respects it would be inferior."

The most economical new substitute asset may have many advantages over an existing old asset, such as longer life expectancy, lower annual disbursements for operation and maintenance, increased receipts from sale of product or service. The depreciation deduction from the cost of the hypothetical new substitute asset should be a measure in money terms of all of these disadvantages of the existing old asset. Seldom, if ever, is the conventional depreciation deduction, based on the age of the old asset in combination with some formula (usually either straight-line or sinking-fund), a satisfactory measure of this value inferiority.

Four Examples of Measurement in Appraisal Depreciation

Before discussing the kind of forecasts which ideally should be made in order to measure this value inferiority, it will be helpful to consider four representative examples expressed in money terms. In all of these examples, the central question is how much could be paid for the existing old asset in order to realize annual costs exactly equal to those obtainable from the most economical new asset which could replace the service. Because equal services are assumed, the question of differences in annual receipts does not enter into any of these four examples. For the sake of simplicity, zero salvage values are assumed at all times in all four examples.

Example 1. The hypothetical new asset to be used as the valuation base is identical with the existing old asset. This implies that there have been no improvements in design and no changes in service requirements. The only difference is that the existing old asset has a shorter remaining life expectancy.

An old asset being appraised has a remaining life expectancy of 10 years. The identical new asset to be used as the valuation base has a first cost of $1000 and a life expectancy of 20 years. There are no other differences. The minimum prospective rate of return considered sufficient to justify such an investment is 7 per cent. In other words, this enterprise will not make such an investment unless an economy study indicates that the investment will be recovered plus at least 7 per cent interest. This means that all annual cost calculations should involve an interest rate of 7 per cent.

[3] "Valuation of Property," by J. C. Bonbright, McGraw-Hill Book Company, Inc., New York, N. Y., 1937; especially chapters 9 and 10.

Let X = the appraised value of the old asset which will give annual costs equal to those of the new asset.

The annual cost of capital recovery of P dollars in n years with interest rate i is P multiplied by the capital-recovery factor $\frac{i\,(1+i)^n}{(1+i)^n-1}$. The derivation of this formula may be found in texts either on engineering economy or on the mathematics of finance.

As all other annual disbursements are the same, equal annual costs may be obtained by merely equating the annual capital-recovery costs for the two assets as follows:

$$X\,\frac{0.07\,(1.07)^{10}}{(1.07)^{10}-1} = \$1000\,\frac{0.07\,(1.07)^{20}}{(1.07)^{20}-1}$$

$$0.14238\,X = (0.09439)\,\$1000$$

$$X = \$663$$

The value inferiority of the old asset with the 10-year life expectancy to the new asset with the 20-year life expectancy is \$337, the difference between \$1000 and \$663. In other words, the appraisal depreciation is \$337.

Example 2. The hypothetical new asset is superior to the existing old asset not only in longer life expectancy but also in a uniform annual saving in disbursements for all purposes. This prospective saving might come from various causes, such as improved design or the better adaptation of the new asset to the present service.

An old asset being appraised has a remaining life expectancy of 10 years and prospective disbursements for all purposes of \$500 per year during this remaining life. The most economical new asset to perform the same service has a first cost of \$1000, a life expectancy of 20 years, and prospective disbursements for all purposes of \$450 per year during its life. Interest is at 7 per cent as before.

Let X = the appraised value of the old asset which will give annual costs equal to those of the new asset. Then

$$0.14238\,X + \$500 = 0.09439\,(\$1000) + \$450$$

$$X = \$312$$

Here the value inferiority or appraisal depreciation is \$688.

Example 3. As in example 1, the hypothetical new asset is identical with the existing old asset; there have been no improvements in the art or changes in service requirements. However, unlike example 1, the termination of the life of assets of this type occurs because of a progressive and steady increase in the cost of operation and maintenance. The old asset has two disadvantages as compared to the hypothetical new one, shorter life expectancy and higher annual disbursements for operation and maintenance.

A certain type of asset has a first cost of \$1000. Annual disbursements for all purposes are \$500 in the first year of its life, \$508 in the second year, \$516 in the third year, and increase by \$8 each year thereafter. A 10-year-old asset of this type is to be appraised at a figure which will give an equivalent uniform annual cost for its remaining life equal to the equivalent uniform annual cost over the life of a new asset. Interest is at 7 per cent.

Where disbursements vary from year to year, an equivalent uniform annual disbursement for any period may be determined by first finding the sum of the present worths of the respective annual disbursements during the period, and then multiplying this sum by the capital-recovery factor for the period. The present worth of each disbursement is obtained by multiplying the disbursement by the present-worth factor $\frac{1}{(1+i)^n}$. The sum of the present worths of annual disbursements for this asset for a 20-year period is as follows:

$$\$500\,(0.9346) + \$508\,(0.8734) + \$516\,(0.8163) + \$524\,(0.7629) + \$532\,(0.7130) + \$540\,(0.6663) + \$548\,(0.6227) + \$556\,(0.5820) + \$564\,(0.5439) + \$572\,(0.5083) + \$580\,(0.4751) + \$588\,(0.4440) + \$596\,(0.4150) + \$604\,(0.3878) + \$612\,(0.3624) + \$620\,(0.3387) + \$628\,(0.3166) + \$636\,(0.2959) + \$644\,(0.2765) + \$652\,(0.2584) = \$5917$$

The equivalent uniform annual disbursement is \$5917 (0.09439) = \$558.5. This, added to the annual capital-recovery cost of \$1000 (0.09439), gives an equivalent uniform annual cost of \$652.9 over a 20-year life. As the annual disbursement was \$652 in the twentieth year and will be \$660 in the twenty-first year, it is evident that the economic life of such an asset is 20 years.

A 10-year-old asset therefore has a remaining economic life of 10 years. The sum of the present worths (at age 10) of the annual disbursements during the final 10 years of its economic life is as follows:

$$\$580\,(0.9346) + \$588\,(0.8734) + \$596\,(0.8163) + \$604\,(0.7629) + \$612\,(0.7130) + \$620\,(0.6663) + \$628\,(0.6227) + \$636\,(0.5820) + \$644\,(0.5439) + \$652\,(0.5083) = \$4295$$

The equivalent uniform annual disbursement during this final 10 years is \$4295 (0.14238) = \$611.5.

Let X = the appraised value of the 10-year-old asset which will give annual costs equal to those of a new asset. Then

$$0.14238\,X + \$611.5 = 0.09439\,(\$1000) + \$558.5$$

$$X = \$291$$

Here the value inferiority or appraisal depreciation is \$709.

Example 4. In this example the hypothetical new asset has the advantages described in examples 2 and 3. Both the old and new assets are subject to progressive and steady increases in the cost of operation and maintenance. However, the hypothetical new asset has an improved design, and its annual disbursements start at a lower level than would be possible with a new asset of the old design. Thus the old asset has disadvantages of shorter life expectancy, higher operation and maintenance costs, and obsolescence. These combine to create its value inferiority or appraisal depreciation.

The 10-year-old asset in this example is the same as the one described in example 3. The improved new asset in this example has a first cost of \$1000, and annual disbursements of \$450 in the first year of its life, \$458 in the second year, \$466 in the third year, and increasing \$8 each year thereafter.

If it is assumed that there will be no further improvements in design or changes in prices or service requirements, it may readily be shown that the economic life of the improved new asset will be 20 years, and that the equivalent uniform annual disbursements will be \$50 less than the \$558.5 calculated in example 3, or \$508.5. This, added to the annual capital-recovery cost of \$94.4, gives an equivalent uniform annual cost for the 20-year economic life of \$602.9.

The existing old asset requires annual disbursements next year of \$580, followed by annual disbursements of \$588, \$596, and \$604. It is evident that the remaining economic life of the old asset is only 3 years, as the disbursements of \$604 in the fourth year are higher than the expected equivalent uniform annual cost of \$602.9 over the anticipated life of the most economical new asset. The sum of the present worths of the annual disbursements, during this 3 years of life remaining, is \$580 (0.9346) + \$588 (0.8734) + \$596 (0.8163) = \$1542. The equivalent uniform annual disbursement is \$1542 multiplied by the 3-year capital-recovery factor, 0.38105. This product is \$587.6.

Let X = the appraised value of the old asset which will give annual costs equal to those of the improved new asset. Then

$$0.38105\,X + \$587.6 = 0.09439\,(\$1000) + \$508.5$$

$$X = \$40$$

Here the value inferiority or appraisal depreciation comes to $960.

Discussion of Examples

These four examples may seem somewhat theoretical in that they make use of more specific forecasts of future events than one usually can make with assurance. However, the point which they emphasize is a severely practical one. This point is that the question which a replacement-cost appraisal should answer is "what is the greatest amount one could afford to pay for an existing old asset in comparison with the most economical present method of performing its service?" The answer to this question may not be the appropriate value of the asset in an appraisal, but it usually should place an upper limit on any appraised "value." Moreover it should have its bearing on other important matters such as the choice of a depreciation-accounting policy and the determination of taxable income for income-tax purposes. Some of the implications of these four examples will, therefore, be explored further.

Few actual situations will be found like example 1, in which the only difference between the old and new asset was future life expectancy. This example implies that retirements are imperative at the end of a fixed number of years, rather than that they depend upon someone's decision that it is economical to make them because of obsolescence, inadequacy, increasing cost of operation and maintenance, or some combination of these causes. An example is a railroad crosstie which has no appreciable maintenance cost up to the time when it is retired because of wear or decay.

It is evident that, for the special type of situation considered in example 1, an asset with 10 years of prospective service is worth considerably more than one half as much as an asset with 20 years of prospective service. Because of the time value of money, service for 10 years starting now is worth more today than 10 years of similar service starting 10 years hence. It may readily be shown that the $337 appraisal depreciation found in example 1 is the depreciation obtainable by the so-called sinking-fund method for an age of 10 years and a total life of 20 years with interest at 7 per cent.

It will be recognized that most actual situations contain in some measure the reasons for value inferiority illustrated in examples 2, 3, and 4. In all such cases the appraisal depreciation will be greater than that given by the sinking-fund method. Although the magnitude of the appraisal depreciation in any individual case naturally depends upon the facts of that case, the authors believe that many situations in industry will be similar to examples 2, 3, and 4, in that appraisal depreciation will be much greater than would be estimated by the conventional straight-line method.

Data Needed for Replacement-Cost Appraisals

The facts and estimates required for a sound appraisal based on replacement cost are as follows:

1 The expected service to be performed. Because replacement-cost appraisals should be based on the cost of replacing a service, they have little meaning unless related to some specific service. The appraised value of an old asset for one service will differ from its appraised value for another service. In the appraisal of machinery, care must be taken not to base the appraisal on full rated capacity when this is greater than the expected service.

2 The most economical new asset to perform this service. This requires an engineering economy study to compare the various alternative ways of getting this service performed.

3 The remaining life expectancy of the old asset.

4 The life expectancy of the substitute new asset.

5 The minimum attractive return or interest rate to be used in the comparison.

6 The prospective difference in annual disbursements (and whenever applicable, in annual receipts) between the existing old asset and the most economical new asset.

Some Paradoxes

Many paradoxes arise in the application of this equal-annual-cost viewpoint to replacement-cost appraisals, for instance:

1 Often the appraised value of a plant as a whole should be less than the sum of the appraised values of its parts. The substitution of an entire new plant of radically different design may indicate many economies not possible in contemplating the most economical replacement asset for each part of the plant without any general change in the plant design or arrangement.

2 The more rapid the prospective future obsolescence, the more valuable may be the present obsolescent asset. Prospective improvements in design of new assets or prospective changes in service requirements may reduce the appraisal depreciation of existing old assets. For instance, in example 4 the prospect of further design improvements would reduce the expected life of the new asset below 20 years. This in turn would increase the equivalent uniform annual costs during the life of the new asset and would therefore increase the appraised value of the old asset.

3 In some cases, as time goes on, the appraisal depreciation of an old asset may become less as compared to a specific new one. If engineering ingenuity permits its better adaptation to the present service, the value of an old asset may increase with time even without price-level changes. For instance, developments in materials handling by lift trucks in the last 20 years served to decrease the value inferiority of the brick buildings to the mill-type steel-frame buildings in the factory previously described.

4 Appraisal depreciation may be negative, in other words, the appraised value of an old asset may be greater than the cost of the most economical substitute asset. For instance, if the most economical substitute is a new 18-in. pipe line, the lower pumping costs of an old 24-in. pipe line might give it a value superiority to the new pipe line.

5 Appraised values may be negative. The value inferiority of the old asset may be greater than the cost of the most economical substitute asset; for instance, in example 2, if the annual disbursements for the new substitute asset were $400 (instead of $450), the appraised value of the old asset would be negative. This simply means that it would pay to make an immediate replacement.

6 The less the contemplated service, the greater may be the appraised value. Although the most extreme instance of this seems to arise when appraising a plant used merely for stand-by purposes, it should be emphasized that the most economical plant for stand-by service may be quite different from that for regular operation.

Comments on Objections to Equal-Annual-Cost Appraisals

Objections of two sorts have been raised to replacement-cost appraisals made on the equal-annual-cost basis described:

1 Because it is the existing asset which is to be appraised, some objectors maintain that a different substitute asset should not be used as the basis of valuation. This objection is apt to be made by those who advocate "reproduction-cost" appraisals, based on the assumed replacement of the existing old asset with an identical new asset.

However, if replacement with a different substitute asset would be more economical, the cost of reproducing identically an existing old asset has no bearing on its value. This objection is therefore without merit.

2 Because there may be differences of opinion as to the most economical new asset to replace a service and as to the advantages of this new asset over an existing old one, it is even more difficult to reach agreement on appraised values in equal-annual-cost replacement appraisals than in the usual reproduction-cost appraisals with conventional depreciation deductions. There is no doubt that this difficulty of securing evidence is a very real one; value judgments which depend upon forecasts of future events are inevitably matters upon which opinions will differ. However, this difficulty in applying a method which is sound, although complicated, certainly does not justify the use of another complicated method (such as the conventional reproduction-cost method) which is fundamentally unsound.

Whenever it is likely that any complicated method of valuation may involve expensive and long-drawn-out litigation, practical considerations may dictate the use of a simple method. In such cases, definiteness may be more important than soundness of principle.

Examples and Limitations of Predetermined Depreciation Rates

Nearly 2000 years ago, Vitruvius[4] wrote as follows:

"No walls made of rubble and finished with delicate beauty—no such walls can escape ruin as time goes on. Hence, when arbitrators are chosen to set a valuation on party walls, they do not value them at what they cost to build, but look up the written contract in each case, and then, after deducting from the cost one eightieth for each year that the wall has been standing, decide that the remainder is the sum to be paid. Thus they in effect pronounce that such walls cannot last more than eighty years."

Vitruvius' use of a predetermined base (cost) and a predetermined depreciation deduction at any time finds a modern counterpart in a proposal made in the autumn of 1940, that a defense plant financed with government funds might be purchased from the government by the private operator at cost less a 5 per cent annual depreciation on buildings and a 12 per cent annual depreciation on heavy machinery. The following excerpt from a letter[5] to the editor of a business publication gives the viewpoint of a production man at the time of this proposal:

"Take the case of the typical plant manager—as of five years from now. By paying 'only' 75 cents on the dollar for buildings and 'only' 40 cents on the dollar for machinery, he then gets an equipped plant 'only' five years old. But what a five years! It's been a day-and-night operation—much of it seven days a week. Maintenance has been some problem because of the breakneck production pace. Inexperienced operators have taken their toll of the machine tools.

"And how about that 1945 dollar? Won't it buy a lot more than the 1940-1941 dollar did when it bought this stuff? Won't my 75 cents of 1945 pay for a new plant, built on 1945's labor and material market, instead of a five-year-old plant built on the bull market of 1940-1941?

"And isn't XYZ Machine Company offering me in 1945 some brand new milling machines for $4000 each, whereas, I paid (for the government) $5750 apiece for twenty almost identical ones five years ago in 1940? Let's see—40 per cent of $5750 amounts to $2300. For $2300 I can get one of these five-year-old machines that's kinda wheezy but will work okay as long as Jim Smith is around to run it (Jim knows its eccentricities). On the other hand, for $4000 I can get a new machine—it's faster and has all the latest attachments, and any good operator can handle it without difficulty. Put yourself in my place—What would you do?"

As this quotation shows, the question of the cost of replacing a service is always relevant in judgments regarding values which are made by a prospective purchaser of old assets.

Relationship of Appraisal Depreciation to Other Depreciation Concepts

"Depreciation" is a word with several meanings. This paper has discussed "appraisal" depreciation. To show the relationship of this paper to other depreciation problems, it is necessary to recognize three fundamentally different depreciation concepts:[6]

1 The appraisal concept of depreciation. As has been pointed out, this should mean the value inferiority at some particular date (the date of the appraisal) of one asset, the existing old one being appraised, to another asset, a hypothetical new one used as the basis of valuation. This concept implies two assets and the measurement of their values at one date.

2 The popular concept of depreciation is decrease in value. This involves subtracting from the value of an asset at an earlier date the value of the same asset at a later date. "Values" may be determined by appraisal, by market price, or in any other appropriate way. This concept involves one asset and the measurement of its value at two dates.

A common practice in the manufacturing industries illustrates a use of the popular concept of depreciation. Frequently, a manufacturer will refuse to install new machinery unless an engineering-economy study indicates that it will "pay for itself in 3 years" (or some other short time from 1 to 5 years). This requirement usually means that the manufacturer thinks it probable that machinery acquired now will have a very low value 3 years hence, as compared to the most economical machinery likely to be available then for meeting the service requirements which may exist at that time. That is, the manufacturer (perhaps unconsciously) applies the appraisal-depreciation viewpoint, outlined in this paper, to the valuation 3 years hence of the proposed machinery; he then applies the viewpoint of popular depreciation in his forecast that the decrease in value during the next 3 years of machinery purchased now will be nearly 100 per cent of his investment in it. This forecast is made despite his expectation that the final retirement of the machinery from his service may not take place for 10, 15, or 20 years.

3 The accounting concept of depreciation is the writing off or amortization of cost on the books of account. It should be emphasized that this relates to cost and does not relate to value at all. The definition of depreciation as "loss in value" which is so common in accounting literature is a misleading description of the actual practice of accountants.

The practical question in depreciation accounting is how rapidly cost should be written off. Occasional appraisals would help management answer this question. Such appraisals should be based on the principles outlined in this paper. However, appraisals could not be used as the sole basis of depreciation accounting, which for practical reasons must be based on some systematic procedure.

For many years, the manufacturing industries wrote off most machinery at a rate of 10 per cent per year. This arbitrary rate gave no consideration either to realized service lives or to the common experience that before a machine is many years old its value is quite low compared to the most economical substitute. Recently the U. S. Bureau of Internal Revenue has effected drastic reductions in depreciation allowances made on income-tax returns. The purpose has been to bring depreciation rates, for tax purposes, into line with available evidence that realized lives of most machines are more than 10 years. In many cases

[4] "Vitruvius, the Ten Books on Architecture," trans. by M. H. Morgan, Harvard University Press, Cambridge, Mass., 1914, Book II, chap. 8, par. 8.

[5] *Business Week*, Oct. 26, 1940, page 67.

[6] Adapted from a classification in "Valuation of Property,"[3] p. 183.

these reduced depreciation rates have also been adopted for corporate-accounting purposes.

It is the belief of the authors that a continued trend in corporate accounting toward lower depreciation rates is undesirable both for individual corporations and for the nation. Depreciation charges in corporate accounting have many indirect effects on the economic system through their influence on such matters as dividend policy, pricing policy, taxes, security issues, maintenance of stand-by plant, and the selection and replacement of machinery. Although space limitations prevent a discussion in this paper of the various consequences of inadequate depreciation charges, the authors believe that a more desirable development than the one now taking place would be toward high depreciation rates in the early years of the life of machinery followed by lower rates in subsequent years.

The primary purpose of this paper has been to emphasize the concept that appraisal depreciation should be a measurement of value inferiority. A second purpose—possibly more important in the long run—has been indicated in the last few paragraphs; it is to suggest that if a number of manufacturing concerns could be persuaded to make such value-inferiority studies of machines of various ages, this might serve as a basis for a critical review and possible modification of depreciation-accounting policies and methods. As the facts on which such studies would be made are essentially engineering facts, the lead in any such development must be taken by engineers.

Discussion

Harry A. Bullis.[7] The approach to the determination of values proposed by the authors, whereby the value assigned to properties is based on the most economical substitute, provides an apparently sound basis of valuation which should assist management from two viewpoints:

1 From the point of view of deciding upon the desirability of replacement of existing assets.

2 Possibly from the point of view of valuation for purposes of refinancing, or of purchase or sale of all or a substantial part of the properties and business of a company.

This theory provides a useful tool to management, but one which should be used carefully. Valuation obviously is an intangible process. Most of the factors upon which it depends lie in the minds of men and their judgment of the relative desirability of goods. Concepts of value depend largely upon the purposes for which the values are being determined. For example, the term "fair cash value," as used by insurance companies, has come to mean the cost to reproduce a particular asset in its condition at the time of loss. The element of cost to replace with the most economical new asset of a substantially different character has been, in the past, only a minor consideration in the settlement of insurance losses. Nevertheless, the theory of valuation, developed in the paper, is a real contribution to the science of valuation and, used restrictively for certain purposes, provides an index from which there will flow important managerial decisions relative to property replacements.

A few general observations are offered, not with the idea of criticism, but from the point of view of indicating the possible limitations:

1 Most appraisals are used for insurance purposes. The extreme flexibility of the proposed system presents a problem, in that the available types of insurance coverage are not designed with this approach in mind and are not sufficiently flexible. The benefits of this particular approach could probably be most fully realized only for properties which are 100 per cent self-insured.

2 It seems probable that the adoption of this policy would tend to decrease the value of outside appraisals for most manufacturing concerns. The "equal-annual-cost" theory depends largely upon engineering knowledge, research, and management opinion in arriving at values. Presumably, the best information and the best judgment in this field exist within the particular organization. It seems safe to say that there are few, if any, established appraisal companies which would be qualified to exercise this type of judgment except in a limited number of manufacturing fields, of which the utility field is probably outstanding.

3 The theory as presented tends to ignore the possible existence of an actual market for assets which might be at a substantially higher level than a low value arrived at from the equal-annual-cost approach. In the specific illustration given of the brick building which led to the bankruptcy of a company, because it was impossible to use therein a particular type of mechanical handling system, the value of this property presumably prior to the company's collapse would be zero. Yet it is entirely possible that this building would have a relatively high market value for some other manufacturing operation.

4 Along this same line, the theory seems to place little or no emphasis on the rather generally accepted idea of fixed property values. Values are approached from the point of view of earning power only. This may be entirely sound in studying specific replacements, but is it not possible that it might lead to an unfortunate situation if a company's earnings were abnormally low or even nonexistent because of improper management? Are we justified in reaching the conclusion that property values are actually decreased by poor management? This leads to a rather difficult consideration of the differences between real property values and earning values.

5 The application of this approach requires the combination under one centralized authority of several phases of business activity. These would be operations, engineering, research, cost accounting, and what might be termed management judgment in forecasting future trends. To wrap these all up in one package and arrive at a specific answer is a large degree of concentration, but it is realized that this is the information that management must have to make the most intelligent decisions.

These observations seem to be mostly in the nature of objections or difficulties which might be encountered in using this theory. It should be emphasized again that the approach seems to be basically sound and is very interesting. In general, it seems that it can be used with real value in connection with the conventional type of appraisal and with ample consideration of possible outside market values rather than as a replacement of either of these two accepted approaches.

E. C. Clarke.[8] The purpose of this paper has been to emphasize the concept that appraisal depreciation should be a measurement of value inferiority. There can be no exceptions taken to this purpose. The basic concept of progress in our system of free enterprise is one of more goods at lower costs. The attainment of this progress requires the systematic obsolescence of both materials and processes; hence the systematic obsolescence of manufacturing equipment and the replacement of that which has been made obsolete. Cash is necessary for each replacement, and it is important that capital invested in facilities be recaptured in the selling price of the products of the facilities during the life of the facilities. In the cycle, appraisals of values are needed frequently and factually.

[7] Executive Vice-President of General Mills, Inc., Minneapolis, Minn.

[8] President, Chambersburg Engineering Company, Chambersburg, Pa. Mem. A.S.M.E.

The cycle of obsolescence is a shortening one, as the conclusions of our research laboratories are brought into practical uses. Thus, example 1 of the paper, the replacement of an asset with an identical one, is the exception rather than the rule, and additional emphasis is placed upon the importance of the stated purpose.

However, in the writer's opinion, the second purpose stated, i.e., that manufacturing concerns be persuaded to make more realistic appraisals of their assets, seems the more important one by far. This purpose would be strengthened were it to include provision for reversal by the Department of Internal Revenue of its policy of depressing depreciation allowances for tax purposes. Germany rebuilt her factories by a governmental relief from taxes, if new equipment were installed, and by this artificial means built productive facilities which exceeded those of her then potential enemies. One can agree with the results attained by Germany, although the method violated every sound theory of depreciation. If we are to compete in the postwar world, both management and government must realize that obsolescence is with us always and requires quick recognition of actualities of value in use, for cost purposes and for tax purposes. The quick are strong.

Hence, the writer must disagree with the concluding sentence of the paper, implying that the problem is one for engineers. Actually, it is one reflected in sales, distribution, costs, and all phases of demand and production and, hence, becomes a responsibility of management. Mayhap, the best conclusion might be that the subject of depreciation of one's assets is a painful one which requires a cold-eyed, realistic manager to see that the engineers face it without favor to their brain children of yesteryear, and that the comptrollers get more enthusiasm for lowered costs than for book values; in other words, better plans for tomorrow with less emphasis on today's valuation; or, less credence to the score of depreciation written in advance of realization.

The authors are to be congratulated on cementing a principle particularly applicable to evaluations, and it is hoped that they will continue their fruitful studies into broader fields.

A. R. Colbert.[9] The authors emphasize that the value of an existing plant unit is the amount which could be paid for it in order to realize total annual costs, including operating expenses, depreciation, and return, equal to those obtainable from the most economical new unit which could replace the service. The difference between the value found for the existing asset and the cost of the new is called appraisal depreciation or value inferiority of the old unit, as compared with the new.

It should be noted that the appraisal depreciation found by the authors' method is not the deduction to be made from the cost of the old asset, but rather the deduction to be made from the cost of the new hypothetical asset to bring it to the value of the existing asset. The difference between the value so found and the cost of the old asset (assuming the cost represented value at the date acquired) would represent the total decline in value of the old asset between the date acquired and the date of the appraisal.

Unquestionably, the cost, new, and the annual costs of new equipment have an important effect upon the value of old equipment. The conclusion of the authors that the maximum value attributable to the old is that amount which would permit total annual costs to be no higher than if the most economical substitute were purchased seems sound, for the value of an existing asset can be no greater than the worth of what it will live to do.

The proposed method of estimating value would be particularly helpful in determining the most economical time to make replacements of property or in comparing the over-all costs of new equipment best suited for the desired function. Also, it may be useful for general appraisal purposes in some instances, particularly competitive commercial industries. However, considerable difficulty lies in the application of the valuation formula, especially where circumstances are those illustrated in examples 3 and 4. This becomes more apparent when the authors' formula is restated, as shown hereafter, in a manner to emphasize the extent to which estimates of the future are involved.

It can be shown mathematically that the following is equivalent to the equal-annual-cost formula, suggested by the authors:

The value of existing equipment equals a, the cost, new, of the substitute equipment, plus b, the present worth of operating expenses of the substitute equipment during its entire life, minus c, the present worth of operating expenses of the existing equipment during the remainder of its life, minus d, the present worth of operating expenses of the substitute equipment if installed at the end of the life of existing equipment for a period thereafter equal to the difference between the life of the substitute equipment and the remaining life of the existing equipment, minus e, the present worth of the cost, new, of the substitute equipment if installed at the end of the life of the existing equipment, plus f, the present worth of the value of the substitute equipment if installed at the end of the life of the existing equipment at a date in the future corresponding with the end of the life of the substitute equipment if it were installed now.

The formula in this form, although giving results identical with the equal-annual-cost application proposed by the authors, is not recommended for actual use, as it becomes quite involved. It illustrates, however, the extent to which estimates of the future are involved in the valuation method proposed; and, as stated in the paper, the difficulty of securing evidence regarding the future is a very real one. In fact, in many instances, the necessary estimates of future conditions might well be so uncertain as to detract substantially from the reliability of value determinations by the method suggested. However, the uncertainty of estimates of the future is present, in greater or lesser degree, in all valuations of physical property, and a method, which attempts to measure the worth of what a piece of equipment will live to do, has much to commend it, as compared with appraisal methods which ignore this important element of value.

It is interesting to note that the authors' method of measuring the value of old equipment indicates that the depreciation may be greater than the conventional straight-line method (refer to examples 2, 3, and 4). Perhaps this condition prompts the authors to favor higher depreciation rates in the early years of life of machinery, followed by lower rates in subsequent years.

The wisdom of such a procedure is questionable. Since income-tax rates are on the upgrade, additional taxes would be incurred in the future if high depreciation were taken now, followed by lower charges at a later date. Also, equipment is often installed which does not operate at capacity for some years, and the higher depreciation in the early years might be quite burdensome during a period of low earnings. Further, even if depreciation reserves higher than under the straight-line method are believed desirable, a company may retain part of its earnings in surplus and thus accomplish all of the financial benefits which a higher reserve would, although it must be admitted that, as long as a large surplus were shown, pressure for higher dividends might be brought.

On the other hand, low charges for depreciation initially followed by higher charges in later years (as is the case with the sinking-fund or compound-interest methods, considering both the annuity and the interest component) involve the danger inherent in postponing charges to the later years of life of property (the uncertain part of life estimates) when operating costs are

[9] Chief, Accounts and Finance Department, Public Service Commission of Wisconsin, Madison, Wis.

probably higher. As between these two extremes, it is the writer's belief that the straight-line method is the most satisfactory method of accounting for depreciation in most instances.

W. D. Ennis.[10] Depreciation is too often and too seriously underestimated, and it is more than time to acknowledge the fact. Old tabulated life expectancies were too generally based on expected wear and tear alone. Obsolescence was recognized but dodged. Many of the tabulated expectancies, long in general use, are admittedly ridiculous in the light of later experience. Yet the Federal Bureau of Internal Revenue continues to assume and emphasize improbably long lives, for reasons which are obvious enough, but in defiance of engineering judgment.

Inadequate depreciation estimates are dangerous to the permanence of the enterprise, and misleading to investors.

The authors' thesis is (briefly) that, in an appraisal, the criterion of value is the cost of duplicating, not the plant, but the service rendered by the plant. Other engineers have sensed this and have in effect paralleled the Norton-Grant analysis. Some of the "paradoxes," the concept of negative value, for example, have been recognized before. The present authors now clear the atmosphere by suggesting, as a result from their thesis, that reproduction cost (as well as actual or historical cost) of the actual plant thus becomes a matter merely of academic interest. The value of the plant may depend, not on its characteristics, but on those of another plant capable of doing the same (or better) work. This is notable.

The "capital-recovery factor" is of course the annuity i, n, realized from a purchase price of 1.

H. B. Fernald.[11] The writer concurs in the conclusions of this paper that "a continued trend in corporate accounting toward lower depreciation rates is undesirable," and that "a more desirable development than the one now taking place would be toward high depreciation rates in the early life of the machinery followed by lower rates is subsequent years." There is less concern with the theoretical question of what one could afford to pay for a present asset in comparison with the most economical new one or with questions of "value inferiority" than with the question of how much should be charged against costs each year to write off the cost of machinery ratably over its probable useful life, and the question of when machinery now in use should be replaced by new machinery.

The formula developed and the discussion given with the various examples seem appropriate, but the writer is not ready to condemn as of no value, or as never appropriate, the old-style appraisals based on reproduction cost. Probably they are more certain as to their factual basis than appraisals based on "value inferiority," as proposed in this paper, since that involves the appraiser's estimate of probable future operating costs and usefulness of one machine as compared with another, which may rapidly change from month to month, or day to day. However, there can be no question that replacement-cost appraisals do not serve to indicate how much should be written off each year in order that the cost of plant and equipment be recovered ratably out of operating profits during the useful life, nor do they answer the question whether existing plant and equipment should be displaced in favor of new. Such formulas as those here proposed undoubtedly are more indicative of what should be written off and when equipment should be replaced.

More important than the actual formulas are the various factors to which attention is here drawn; such as, the usefulness of present compared with other available equipment, relative costs of operation and of output, etc. The full and continual recognition of these factors is probably more important than the exact formulas by which their results may be expressed. The great problem of depreciation is obsolescence, due to changes in competitive conditions, in demands for product, in materials to be handled, in cost of materials or labor, in taxes and government controls, and the progress of the art as to machinery and materials; as this paper recognizes.

After many years of accounting practice, the writer is satisfied that the "straight-line" method of depreciation, which seems to be the generally accepted accounting basis (particularly under the impetus of income-tax regulations) is far from a satisfactory guide. Even if a machine might have a life of 20 years, it is doubtful whether its actual useful value in operations will be as great in the nineteenth and twentieth years as in the first and second years. Yet that is the assumption, if we write off 5 per cent depreciation each year. Generally, it probably would be better if we charged a relatively high rate of depreciation on the declining balance (cost less depreciation to date). An alternative would be to start with a relatively short estimated life and consequent high annual depreciation rate; then when, if, and as it appeared the machine would have a longer life, thereafter apply a reduced rate. Either of these plans would give depreciation charges more nearly in accord with the factual situation.

Of one thing the writer is sure, which is that the desirability of replacement or substitution is never to be determined by the amount at which plant and equipment are carried in the books. If we can look ahead and see that in the long run new equipment will pay for itself and leave us more dollars in hand than we would have from continuing the old machinery, there should be no hesitancy in making the change. The real question is the ultimate dollar result, and that should not be sacrificed because of any disinclination to write off the balance carried on the books for old machinery.

Of course, we should try to have our depreciation charges such that the equipment will have been fully depreciated when it becomes obsolete, but changes may come so swiftly they cannot be foreseen. That should be recognized so no one will feel that a charge-off of obsolete equipment is any reflection either on management or on accountants. Rather, if it is done in good faith, it is meritorious; certainly better than to retain machinery which ought to be replaced.

Whether or not in reaching the appropriate conclusions, we use the particular formulas here set forth, the writer feels that this paper is a material contribution to the thought on this subject.

M. R. Scharff[12] and F. J. Leerburger.[13] The literature on the subject of depreciation is so voluminous and the discussions and arguments so extensive that it sometimes seems that little room remains for further contributions. It is heartening, therefore, to have the authors demonstrate so clear an understanding of the proper places of theory and practice in the solution of appraisal problems; and to have them bring the discussion back to the economic field, where it belongs, by relating value to the present worth of prospective return of and return on capital.

The writers have been particularly interested in the consideration of these problems as related to the public-utility industry, where their difficulty has been increased by the precedents established by the courts under the fair-value rule, based on conflicting legal, engineering, and accounting interpretations of

Smyth vs. Ames,[14] and Knoxville vs. Knoxville Water Company.[15] It is their view, however, that the principles, suggested by the authors for the appraisal of manufacturing equipment on the basis of the present worth of the returns it will produce at competitive prices for its product, are equally valuable as a guide to the solution of the problem in the public-utility field.

The one criticism the writers would make of this paper is that the authors are too modest, and advance their sound proposals with too many reservations and qualifications. For example, they suggest that, "whenever it is likely that any complicated method of valuation may involve expensive and long-drawn-out litigation, practical considerations may dictate the use of a simple method. In such cases, definiteness may be more important than soundness of principle." This seems to be an unnecessary abandonment of the engineering point of view. A simple and direct method, if sound in principle, is, of course, always to be preferred to a complex one. Nevertheless, engineers properly reject analytical procedures, no matter how simple, when they fail to take cognizance of the facts. Apart from engineering considerations, it may also be stated that, for many businesses, including the public-utility industry, soundness of principle is far more important than simplicity.

With respect to the reference to long-drawn-out litigation, the highest court of the land has repeatedly shown a clear preference for presentation of facts bearing on loss in value in contrast to simple and direct mathematical calculations with no known relation to the facts. Public-utility rate regulation is generally considered as aiming to simulate competition. Loss in value caused by competitive forces is admittedly not usually capable of direct and simple measurement. However, utilization of economic theory as a guide to judgment, in estimating accrued and annual depreciation, has at least the advantage that it aims at the actual objective and not in the direction corresponding with an unrelated mathematical formula.

The paper points out the distinction between recorded book costs and value new, as well as between accounting for depreciation and loss in value or accrued actual depreciation. That such distinctions are customarily recognized, is clear enough; but they are not necessary distinctions. The writers suggest that there would be advantage in a reconciliation of ideas, in order to relate in a consistent manner, recorded book costs and recorded depreciation with value and loss in value. The fact that depreciation accounting is to be recorded in terms of book cost does not seem to be a sufficient argument to reject a recording of the facts of depreciation in favor of some systematic but unrealistic amortization program. It is true that much inertia must be overcome in order to direct depreciation accounting toward the recording of complex economic facts after so many years have been devoted to rule-of-thumb and oversimplified approximations. Governmental regulatory agencies are by their rules and decisions forcing a reconsideration of depreciation accounting and have indicated a preference for recorded book costs and estimates of actual depreciation in terms of these book costs. Again, the authors appear to have placed too many qualifications and limitations on their excellent paper, because, in the present state of knowledge, they have presented at least as good a guide as could be found to begin the study of how to make depreciation-accounting techniques reveal the realities of economic loss in value. Accounting, for most aspects of business activity, attempts to approximate facts, and it is only in the accounting for accrued and annual depreciation that oversimplified rules of practice, recognized as being divergent from the facts, have been accepted.

[14] 171 U.S., 361.

[15] 212 U.S., 1.

G. O. May.[16] The proposition which the authors of the paper advance seems to the writer to have a certain theoretical validity, and some, though only a limited, significance. The writer has regarded it as a legitimate and effective counterproposition to the crude replacement-cost theory of value, and so used it in an article,[17] in commenting on the majority decision in the Indianapolis Water Company case. In that case the Court had said:

"There is to be ascertained the value of the plant used to give the service and not the estimated cost of a different plant. Save under exceptional circumstances, the Court is not required to enter upon a comparison of the merits of different systems."

However, the objection to the crude form of the replacement-cost theory of value can be stated in more general terms; that it begs the whole question whether property is worth replacing as and where it is.

The authors suggest that the appraisers have failed to understand their point. It seems doubtful whether this is so. The position may rather be that the appraisers regard it as having less general application than the authors believe it to possess It would seem to be directly relevant to the case of determining the postemergency value of emergency facilities. But the fact cannot be too strongly emphasized that it could not properly be applied to each item in the valuation of a normally constructed plant of average or more than average efficiency. In an imperfect world, an attempt to measure depreciation by reference to a constantly moving standard of perfection would be to ignore the way in which plants are constructed and to present a practically insoluble task of measuring the annual charge against operations. It would be open to the criticism which Mr. Justice Brandeis made of the "spot reproduction cost basis." It would not, it is believed, produce economically desirable results.

As a practicable procedure, the method of computation, which the authors propose, suffers from the defect that the results which it produces depend largely upon assumptions made as to the appropriate rate of return and the life expectancies of the existing units and of the potentially replacing units. Moreover, the elements of the problem are far more numerous and complex than the authors' examples suggest. For instance, the existing units are already installed; substitution of new units would entail cost for dismantlement and installation, and possibly a loss of production during the period of change.

The authors are perhaps correct in saying that in accounting, depreciation is not a value concept, though it might perhaps be argued that accountants merely take liberties with the word "value" and that every other profession does the same. The more one studies the problem the more convinced one becomes of the wisdom of accountants in declining to range over the uncertain ground that lies where the boundaries of law, engineering, economics, and finance meet in pursuit of that will-of-the-wisp. They prudently take their stand on the relatively firm ground of cost.

It is believed that the authors are correct in suggesting that present tax allowances for depreciation are inadequate. It is also agreed, that there is much to be said for writing off depreciation more liberally in the earlier than in the later days of use. However, since the authors apparently hold that interest or return on investment should enter into the computation of depreciation, they should recognize that the straight-line method does produce a higher charge in the earlier years. This point is clear from their own first example. Reference may be made to a defense of straight-line depreciation[18] suggested a few years ago.

[16] New York, N. Y.

[17] "Further Thoughts on Depreciation and the Rate Base," by G. O. May, *Quarterly Journal of Economics*, vol. 44, 1930, pp. 687–697.

[18] "A Defense of the Straight-Line Method," by Oliver May, *Journal of Accountancy*, vol 60, 1935, p. 282.

The treatment of depreciation seems to be one of those cases to which the authors refer, in which "practical considerations may dictate the use of a simpler method." Among the advantages of the straight-line method of depreciation is the fact that it is simpler, and that no one can be deceived into believing that it is scientifically precise or anything but a crude approximation. There is danger as well as absurdity in applying meticulous mathematical processes to assumptions which have no surer foundation than our highly precarious knowledge of the future and our subjective concepts on such questions as to what constitutes a reasonable rate of return in a given set of circumstances. Such processing cannot convert the raw material of guesswork into a finished product of statistics of a higher order of significance.

Dundas Peacock.[19] What is the purpose of the depreciation reserve provided upon the books of a company by charges against current operations? Is it intended that the reserve shall reflect the change in value of the assets through wear and tear, obsolescence, market value, etc., or is it a means of absorbing the cost of the asset as part of the cost of production during the period of the useful life of the asset?

The authors have pointed out that "the accounting concept of depreciation is the writing off or amortization of cost on the books of account......... and does not relate to value at all." This is entirely true, for, obviously it would be impossible to evaluate the worth of existing assets annually or periodically and to attempt to reflect on the books of account the changes in value which have taken place, which values are dependent upon the condition and usefulness of the assets and changing economic conditions. Consequently, it follows that the depreciation-accounting policies are intended to result in the absorption of the cost of assets in operating costs during the useful life of the assets.

It does not seem logical, therefore, for the authors to suggest that appraisal depreciation should serve "as a basis for a critical review and possible modification of depreciation-accounting policies and methods." The theory of appraisal depreciation, as expounded in the paper, is intended to indicate the economic worth of an old asset, which worth could change rapidly, depending upon many factors, not least of which is prevailing or anticipated economic conditions. The accountant, realizing the impracticability of attempting to reflect such rapidly changing values on the balance sheet of a company, confines himself to showing the cost of the assets and the portion of the cost which has been recovered through charges against operations.

We may therefore assume that the authors' theories are worthy of consideration only for:

1 Determining the real value (as opposed to the book value) of the assets of a company upon sale of those assets to a willing buyer.

2 Determining the relationship of real value of the assets of a company to the book value.

3 Determining the desirability of continued use of an old asset or the replacement with a new asset.

The exception taken by the authors to the use of depreciated replacement values in commercial appraisals, when it is extremely doubtful if identical replacements would ever be made, is sound. However, to attempt to evaluate each of the assets of any company, other than a very small company, in accordance with their appraisal-depreciation theories, would be so lengthy as to be almost impractical. Furthermore, the sum total of the appraised values so determined would not represent the true worth of the assets, since allowance would have to be made for the cost of revisal of production methods which would undoubtedly be made if the hypothetical substitute assets, which formed the bases for the multitude of calculations, were actually acquired.

No appraisals of the value of the assets of any large or moderate-sized concern can ever be other than an estimate of doubtful worth, and should be looked upon, not as a guarantee of value, but as a starting point for determining the possible value.

It would seem, however, that the appraisal concept of depreciation is a sound policy to follow to determine the desirability of continuing to use old assets or groups of assets, or to replace those assets with new or more efficient assets.

M. E. Peloubet.[20] This paper points out several basic considerations in depreciation and appraisals which are frequently lost sight of. It has often been said that facts are stubborn things. It is also true that unless they are properly understood and interpreted, they are useless things. As this paper points out so clearly, the mere reproduction cost of an identical building or facility, no matter how carefully proved and documented, is of no use in determining a fair sales price or value to the enterprise. Accountants quite properly do not attempt to deal in values, but the determination of values is the most important part of the appraiser's work. It is, perhaps, true that the determination of value or loss of value involves certain assumptions, but if these assumptions lead to an approximation of what the property is really worth to the company, they are of far more value than so-called facts which, while perfectly true as isolated statements, have no bearing on the present or future operations of the company.

The dependence on proper engineering data of any reasonably correct determination of depreciation or loss of value is well covered. One of the difficulties under which public accountants frequently have to labor is the assumption that, because the accountant is able to make proper entries and to set up proper accounts for depreciation, he must necessarily be able to determine a correct rate. Occasionally, this is possible by some more or less rule-of-thumb method derived from experience and observation but, in the long run, questions such as the life expectancy of new property, remaining life of the old, the additional amount of depreciation caused by accelerated production, and other questions of this sort, are ones which may well be raised by the accountant but which must be answered, if the answers are to be satisfactory, by the engineer. In saying that they must be answered by the engineer, it is also meant that they must be answered by the appraiser, as appraisal is essentially an engineering function.

There is a great deal in the paper which could well be expanded in rather more detail and with somewhat fuller examples. The conception of a negative appraised value is an interesting one and, although it seems paradoxical, should be of much assistance to management in working out replacement programs. The proposal that depreciation rates should be arranged so that greater amounts would be written off in the earlier years of the life of the property than in the later years is an interesting one. It is, of course, well known that this is the British practice, carried out by the use of the diminishing-balance method. It is also probable that in some cases the use of a method of depreciation based on production would have somewhat the same result.

It is certainly true that, as a rule, more of the value, if not the physical life of a machine, is exhausted in the first few years of its life than in the later years.

The paper is interesting, well thought out, and the writer is in hearty agreement with the principles developed in it. His only real criticism is that it covers rather too much ground in a very concentrated way and probably would be more valuable if it were expanded and more examples given.

[20] Pogson, Peloubet & Company, New York, N. Y.

Walter Rautenstrauch.[21] The authors have suggested several important matters which need to be taken into account for estimating the "value" of the machinery of manufacture and industrial equipment.

The procedure proposed in this paper for determining value depreciation on the basis of annual costs equal to those of a new machine or equipment is a much closer approximation to the fact of value in a competitive economy than is the method for determining present depreciated worth.[22]

The reliability of any method of value determination, as the authors recognize, depends upon the probable error of estimate. The authors point out, quite properly, that the results of calculations of "present depreciated worth" frequently have no relation to the value of an asset as a unit of competitive enterprise. No competent industrial engineer would advise an investment banker to loan money against the value of the building of a manufacturer without inquiring into the probability of success of the manufacturer's business. The first example cited in this paper is a good illustration of what happens when values are determined by formulas which do not provide for the significant variables. The paper also suggests that a piece of industrial property, whether buildings or machinery, cannot have its value correctly determined as an item by itself. These values are always relative. For example, a gasoline-condensing plant, connected to a natural-gas pipe line may have a very high value so long as the natural gas is flowing. When the gas well is exhausted, even though the plant may be only 1 year old, its value may decline 100 per cent. If the machinery of a manufacturing plant is not well balanced in relation to the processing needs of the business then, quite obviously, the total value of the property is not the sum of the values of the individual machines and buildings. This raises the question of procedure in determining the value of groups of assets, or the problem of determining the value of the "relationship" of assets to each other. This problem is implied by the authors in their statement under the heading, "Data needed for Replacement-Cost Appraisals" that "In the appraisal of machinery, care must be taken not to base the appraisal on full rated capacity when this is greater than the expected service." How is the probable average annual load factor on each machine to be estimated? If a group of machines are integrated into a production line, it is not difficult to determine the hourly output of the line and compare it with the maximum capacity of each machine. However, production lines are changed and new layouts are constantly being made, perhaps several times a year, for the manufacture of new models and new styles. How can we estimate the probable average annual load factor on any machine for the period of its life expectancy? Obviously, this problem is more easily solved in the case of plants of the process industries than of the mechanical manufacturing industries.

In fact, the relative values of some plants of the process industries may be compared when their outputs may be measured in terms of production rates of the same unit products. Sugar refineries are a good example, since their capacities may be measured in pounds of daily melting capacity. A study of six cane-sugar refineries shows that their approximate original investment costs divided by their daily melting capacities varied from a maximum of \$3.75 to a minimum of \$1.74 per lb daily melt capacity. The plant with the maximum investment cost per unit capacity cost \$6,000,000 to build, the other cost \$4,350,000. Assuming, two such plants were built in the same year and that their total annual costs except depreciation are the same (which of course is not likely to be the case, but is assumed for simplicity) and assuming that each has the same life expectancy, then, according to the equal-annual-cost method of appraisal it appears that the value of the \$6,000,000 plant should be written down to approximately \$3,840,000. But in the case of an automobile manufacturing plant, no unit of output, such as an automobile, is found and, hence, no comparison is possible as was made for the sugar refineries. When appraisals are made for the purpose of establishing a basis for a loan, the banker is interested in the probability of the value of the assets underlying the mortgage, for the period of the loan. If this should be a 10-year period, it is perfectly obvious that many factors must be taken into account other than the present depreciated worth of the physical assets as of a given date. The writer's experience indicates that sole reliance on values of physical assets made by any one of the several commonly used appraisal methods is largely a reliance on pure fiction. The real value of the property lies in the combination of the values of the physical assets, management, markets, and reserve margins of a business.

It is realized that this raises problems outside of the limits of presentation which the authors have set for themselves. It is hoped that the authors' suggestion to manufacturing concerns to make such value-inferiority studies of machines as this paper proposes will be carried out, for we need data from studies of this kind.

The writer suggests, that a symposium be held on the problem of methods for determining the comparative economic worths of entire industrial plants.

[21] Professor, Department of Industrial Engineering, Columbia University, New York, N. Y. Mem. A.S.M.E.

[22] Replacement of the identical machine at current prices less straight-line depreciation from date of purchase.

L. S. Ready.[23] The writer's particular interest in depreciation estimates has largely had to do with appraisals of public-utility properties in rate and condemnation proceedings. This new treatise is helpful in such matters as well as in appraisals of manufacturing plants.

There is a very strong tendency in appraising public-utility properties, in connection with purchases and sales, and in condemnation proceedings, to estimate (1) the reproduction cost, new, of the units of property actually in existence and (2) the accrued depreciation thereon, either by general inspection or by the use of estimated lives and expectancies, disregarding all causes of removal which in the normal run of operations may be considered accidental, or not in any way a function of time.

In determining accrued depreciation, many appraisers ignore or refuse to give thought to the cost of constructing a modern up-to-date facility or system and, consequently, fail to take into account improvements in the art and in the design. The disregard of this important element invariably results in an estimate of the accrued depreciation which is lower than the actual loss in value. A recent example was the appraisal of a building more than 40 years of age, which was initially constructed for use as a steam-electric plant and later made over for use as a substation building. The accrued depreciation was determined at 5 per cent of the cost to reproduce the building new at the present time. Such a procedure ignores advances and changes in the design of substations during the last 40 years.

One additional point, not mentioned specifically in the paper, but of importance in determining accrued depreciation or "value inferiority," is the maintenance condition of old equipment, as compared with new, as of the time of appraisal. Although maintenance is not an item to be reckoned with under depreciation accounting, the condition of maintenance must be taken into account in appraising a property which is not new. As a simple example, the painting of a building which may be required once in 5 years, though charged to operating expenses, must be definitely considered in determining the depreciated value of the building at a given time. If the periodic painting is only due but

[23] Consulting Engineer, San Francisco, Calif.

not done, its cost should be a deduction from the depreciated value of the property determined on a strictly age-and-life basis, while if it has just been finished, no deduction or modification of the depreciation of the structure as a whole would be necessary. Likewise, periodic maintenance of equipment must also be given weight when determining its depreciated value.

Authors' Closure

The discussion has been very helpful in supplementing the points made in the original paper. The authors take this opportunity to thank the discussers for their participation. Because so many topics have been mentioned in more than one discussion, this closure is arranged by topics. It falls naturally into three main headings:

1 Depreciation estimates in actual appraisals.

2 Relationship of the concept of appraisal depreciation to depreciation accounting.

3 Relationship of the concept of appraisal depreciation to managerial decisions.

Actual Appraisals

Mr. Bullis suggests that the general acceptance of the viewpoint of this paper would tend to decrease the usefulness of outside appraisals. Although this might be a temporary result, the authors believe that in the long run, the usefulness of outside appraisals would be increased. Professional appraisers would become skilled in utilizing information secured from management by means of techniques which could be applied best by specialists in the appraisal field.

Several discussers have commented on the authors' point that there are difficulties in making value judgments which depend upon forecasts of future events. The influence of such forecasts upon appraised value is emphasized by Mr. Colbert's restatement of the equal-annual-cost method in terms of present worth. Mr. May correctly points out that "meticulous mathematical processes" can give results no better than the forecasts on which they are based. Mr. Peacock expresses doubt of the practicability of making such forecasts except in the case of small companies. In apparent contrast is the view emphasized by Messrs. Scharff and Leerburger that "soundness of principle is far more important than simplicity."

Complexities of two kinds may enter into any valuation process. One kind is the complexity involved in making the necessary forecasts and cost estimates; the other is the complexity involved in converting these forecasts into value. Basically, the complexity of forecasts emphasized by several discussers enters into any valuation; valuation methods which appear to be simple really involve implied forecasts even though the appraiser may not be conscious of making such forecasts. The forecasts and estimates required by the equal-annual-cost method are no more complex than those made by engineers of large industrial companies in connection with proposals for new plants or new processes. It should be emphasized that once the forecasts and estimates are made, the calculations of value required by the equal-annual-cost method are relatively simple. Moreover, the question of complexity should not be confused with the related question of definiteness. Some complex methods may be definite; other simpler methods may be indefinite.

Professor Rautenstrauch refers to a particular difficulty, that of forecasting future load factor when making equal-annual-cost appraisals. Clearly this is a difficult estimate to make. However, it is a necessary one for many other purposes, such as calculation of unit costs.

Messrs. Scharff, Leerburger, and Ready point out that the equal-annual-cost viewpoint of depreciation proposed for manufacturing industries is equally sound in public-utility appraisals. Apart from the many problems introduced by regulation, the differences between public utilities and manufacturing industries in this respect are less a matter of principle than of difference between the typical situations. The large value-inferiority of individual assets a few years old to new substitute assets, so common in manufacturing industries, seems less likely to exist in public utilities. An offsetting consideration is that the equal-annual-cost viewpoint in public utilities usually should be applied to combinations of assets rather than to individual assets; because of the piecemeal growth of most public utilities, the most economical substitute combination of assets to perform a service may differ even more from the present combination than in manufacturing industries.

Mr. Bullis suggests that the equal-annual-cost approach tends to ignore actual market values. Bonbright[24] as the very basis of his two-volume treatise on valuation, recognizes "two distinct though related major concepts of property value, the one referring to sale price, the other referring to value to a specific owner or group of owners." The equal-annual-cost viewpoint of depreciation obviously relates to the concept of "value to the owner," placing an upper limit on this value for some specific use. If the market price of an asset is higher than "value to the owner" for a specific purpose, the owner should either sell the asset at this price, or adapt it to another use which is associated with a higher value to him.

Mr. May points out that the equal-annual-cost method will be appropriate in postwar valuations of wartime facilities. Certainly the value of such facilities to their owners after the war cannot possibly be greater than a value calculated by this method. Many factors will combine to create low values for war plants at the close of the war, even if they can be adapted for postwar use. Different types of possible substitute plants may require consideration in making postwar appraisals. One type will be the new plant which might be built with the benefit of the newest methods and the careful economy studies which were not practicable in hastily constructed war plants. Another type of substitute will be the plant that might be constructed at low first cost using second-hand machinery from war plants that are dismantled.

As Mr. Bullis points out, equal-annual-cost appraisals could hardly be used for fire-insurance purposes under present insurance practices. This is evidently one of those situations in which definiteness is essential. However, in selecting the most economical type of insurance coverage, it often is desirable for management to estimate "value to the owner" as well as the "fair cash value," which latter will probably be applied by the insurance company in the event of a loss. Where industrial fire insurance is written with a co-insurance clause, the insured will not be completely covered for a partial loss unless the amount of the policy is a specified percentage of this "fair cash value." Where obsolescence or other causes make "value to the owner" substantially less than "fair cash value," it may be economical to carry less insurance, paying the higher premium rate which is required when there is no co-insurance clause.

Accounting Aspect

It is on the question of the relationship between appraisal depreciation and depreciation accounting that the issue is most sharply drawn among the discussers. Mr. Peacock states that it is illogical to suggest that appraisal depreciation should serve "as a basis for a critical review and possible modification of depreciation accounting policies and methods." Mr. May commends accountants for not ranging "over the uncertain ground" of value determination. Messrs. Colbert and May commend the conventional use of straight-line depreciation based on average

[24] See reference 3, particularly pp. 14 to 16.

life. In contrast, Messrs. [illegible] and Leerburger favor a consistent relationship between "recorded book costs and recorded depreciation" on the one hand, and "value and loss in value" on the other.

The authors are in agreement with the position expressed by Mr. Fernald that "the full and continual recognition" of such factors as "the usefulness of present as compared with other available equipment" and "relative costs of operation and of output" is essential in judging how rapidly cost of fixed assets should be written off. When Mr. May states that accountants "prudently take their stand on the relatively firm ground of cost" and Mr. Peacock states that "the accountant. . . . confines himself to showing the cost of the assets and the portion of the cost which has been recovered through charges against operations," they are, the authors believe, begging the question of how rapidly cost ought to be written off, all things considered.

If past decrease in "value to the owner" of fixed assets has been substantially greater than the portion of their cost which has been written off in the accounts as depreciation, it is evident that the enterprise has not been as profitable to its owners as the accounts have indicated. Similarly in situations in which prospective decrease in "value to the owner" in the early years of life of assets is much greater than will be written off under conventional depreciation accounting, it is evident that profit figures based on such accounting will be, during this period, an overstatement of the profitableness of the enterprise to its owners. As already pointed out, this is particularly true with respect to much of our war industry. It was given recognition in 1940 in the sixty-month amortization provision of the income-tax law. This provision was justified because of the probability that after a few years, the value of war plants to their owners would be very low, even though their physical lives might continue for many years thereafter.

The authors agree with Mr. Fernald that the recognition of such matters in depreciation accounting is the important thing, more important than the specific depreciation formulas by which they are recognized. This viewpoint is also clearly brought out by Mr. Peloubet.

The important and controversial question of depreciation allowances for income-tax purposes is intimately related to depreciation accounting. Comments on this question are made by Messrs. Clarke, Colbert, Ennis, Fernald, and May.

No tax system is ever completely free of inequities. The most important problem is not so much the possible inequity in a tax policy, as the effect of that policy on the social and economic system. In this instance, this relates to the effect of depreciation tax policy on the investment of private capital in [illegible].

Depreciation allowances on federal tax returns have long been a subject of controversy between taxpayers and the Bureau of Internal Revenue. However when corporate tax rates were at 13.75 per cent or thereabouts the fact that future depreciation allowances might seem inadequate did not deter new plant investments.

Today, March, 1942, with a present top effective rate of 72.1 per cent, and with the Treasury Department's proposal that this be increased to 88.75 per cent, the situation is very different. Under these circumstances, inadequate depreciation allowances may result in taxes higher than 100 per cent of true profits. Obviously, even the fear that this may happen will discourage new capital investment. It did in fact delay necessary expansion of defense plants during the critical summer of 1940 before the passage of the sixty-month-amortization provision.

This has a direct bearing on Mr. Colbert's statement that taxes are on the upgrade, and on his suggestion that high present depreciation allowances might result eventually in greater total taxes. His point was certainly valid a few years ago, but seems so no longer.

Professor Ennis refers to "improbably long lives" used by the Bureau of Internal Revenue in setting depreciation rates. Under orthodox straight-line depreciation accounting, the question of whether depreciation rates are consistent with past life experience is a matter of fact to be determined by statistical studies of past physical-property mortality. Unfortunately few manufacturing companies have plant ledger records adequate for such studies. Where such records exist, they may be used to support depreciation rates used in tax returns.

In all fairness to the Bureau of Internal Revenue, it should be pointed out that the Bureau's policies are consistent with the orthodox accounting view of basing straight-line depreciation on expected average lives. Several discussers agree with the authors that it might be well to have higher depreciation rates in the early years of life of much manufacturing equipment. However, the most elaborate statistical documentation of life estimates would not produce this result if combined with orthodox accounting methods. A necessary prerequisite to any change in tax policy is a considerable acceptance of the view that "value to the owner" may decrease more rapidly in the early years of life and that depreciation accounting should be consistent with this [illegible].

[illegible]

Messrs. Bullis, Colbert, Fernald, and Peacock suggest that measurements of value-inferiority of old assets to proposed new substitute assets might be used to determine whether proposed replacements are economical. Although this can be done, the methods of calculation outlined in this paper were not intended as a solution for this problem. Both authors have written elsewhere explaining simpler methods for such replacement-economy studies.

One type of managerial decision already discussed is the decision regarding plant expansion when the prospect of high income-tax rates is associated with what management believes to be inadequate depreciation allowances for tax purposes. The reference by Mr. Clarke to postwar problems suggests that the period immediately following the war may be a critical one. It seems probable that a high rate of private capital investment in this period will be necessary to avoid a severe depression. It will be extremely unfortunate if at that time depreciation tax policy acts as a deterrent to this needed capital investment.

On Some of the Essentials of Control-Chart Analysis

By E. G. OLDS,[1] PITTSBURGH, PA.

In this paper the author indicates the possibility of a new approach to control-chart technique in connection with manufacturing processes. The advantages of quality control of product are widely recognized, and the principles pioneered by Walter A. Shewhart in 1924 have since that time been the object of intensive investigation. Primarily, the present paper is concerned with control with respect to a given standard. By analyzing hypothetical examples, illustrated graphically, the basis of the control-chart method is clarified. However, in exemplifying the control-chart technique, the author indicates a method of reversing the usual procedure, by creating uncontrolled conditions, and then noting whether the tests made locate the "assignable causes" which have been introduced in the experiments. The investigation is carried out with the aid of H. C. Tippett's tables of "Random Sampling Numbers."

IT IS generally recognized that any measurable quality characteristic varies from item to item in a manufacturing process. For example the measured tensile strength of steel bars changes from bar to bar. The desirability of reducing such variability to an economic minimum has long been recognized and the general problem has been and still is the subject of a great amount of investigation. Thus it seems unnecessary to record here the manifest advantages of a manufacturing process so controlled that uniformity in quality can be guaranteed.

The control-chart technique as pioneered by Walter A. Shewhart in 1924, and developed by him and many others over the period of the last 17 years, is now so well known as to need no detailed explanation. It has been the subject of a multitude of books and articles published both here and abroad. Within the year, the field of application has been reviewed by an Emergency Technical Committee[2] appointed by the American Standards Association upon request of the War Department. The findings of this committee have been published.[3]

Two uses of the control chart are given in a publication of the American Society for Testing Materials, namely, control with respect to a given standard and control when no standard is given. This paper is concerned with a discussion of some of the questions involved in the first of these two uses.[4]

Control With Respect to a Given Standard

To make reasonably sure that our process remains in a state of control at the given standard, we take samples of items produced and examine the variation in their measured characteristics with the aid of statistical tests. We use tests to check on hypotheses. In this case our hypothesis could be that our process was in a state of control at the given standard with respect to a given quality characteristic at the time when the samples were taken.[5] Should the test, when applied to a set of measurements of individual items, indicate that variation could well be attributed to chance, then the conclusion would be drawn that the test gave no evidence to cast doubt on the truth of the hypothesis. But should the test indicate the presence of variation not attributable to chance, then the truth of the hypothesis would be in question and in practice the necessity for investigation of trouble indicated.

To clarify the foregoing statements without introducing too many technicalities let us consider the following hypothetical example:

Sixty per cent of the items from a manufacturing process have been receiving an A-1 grade. Forty per cent have been marked defective[6] and subjected to poorer classification.[6] A series of 50 samples each consisting of 20 items is drawn at random, and the percentage of defectives in each sample is computed. Does this set of results undermine the hypothesis that the process is controlled at the 60 per cent level of effectiveness?

An appropriate test[7] is the following:

If the per cent defective in one or more of the samples is greater than 73 or less than 7, reject the hypothesis, otherwise, accept the hypothesis.

Omitting a detailed exposition of the mathematical assumptions underlying this test, it is sufficient to state that, if the product is controlled at the standard level of quality assumed, and if a random sample of 20 items is drawn, then the probability that the percentage of defectives will fall between 7 and 73 is greater than 0.997. The occurrence of a value outside these limits is taken as an indication of the presence of an assignable cause of variability.

From a process producing 40 per cent of defectives, it is possible to get by chance a sample with no defectives or with as many as 100 per cent of defectives. Therefore, in common with all other tests of significance, this test may lead to the rejection of a true hypothesis.[8] Also, the test might lead to the acceptance of a false hypothesis, as will be exemplified later.

[5] In correspondence, W. A. Shewhart has suggested that the reader be duly forewarned of the difference between the formal statistical hypothesis and the control hypothesis. For a discussion of this distinction refer to "Statistical Method From the Viewpoint of Quality Control," by W. A. Shewhart and W. E. Deming, Graduate School of U. S. Dept. of Agriculture, Washington, D. C., 1939, chap. 1, in part, pp. 39–43.

[6] In using this high percentage, there is no implication that such would be tolerated in practice. Because it avoids certain technicalities, this percentage is convenient to use as an illustration of the principles involved.

[7] The limits have been set at $p \pm 3\sqrt{\frac{p(1-p)}{n}}$, where $p = 0.40$ and $n = 20$.

[8] "On the Use and Interpretation of Certain Test Criteria for Purposes of Statistical Inference," by J. Neyman and E. S. Pearson, *Biometrika*, vol. 28A, 1928, pp. 175–240.

TABLE 1 TEST DATA FOR CONTROL OF A QUALITY LEVEL

(a) Number and percentage of defectives in random samples of 20 from a population 40 per cent defective

[Data from Table 1 (a).]

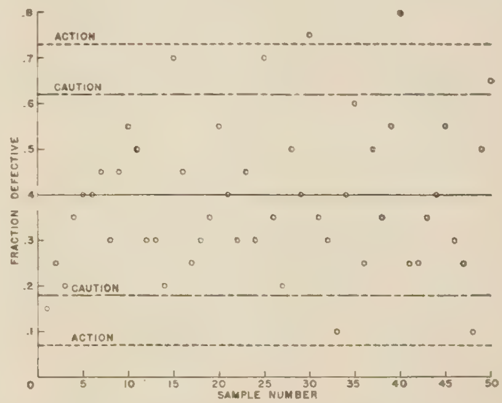

Fig. 2 Test for Control at a Quality Level of 40 Per Cent Defective. Samples of 20
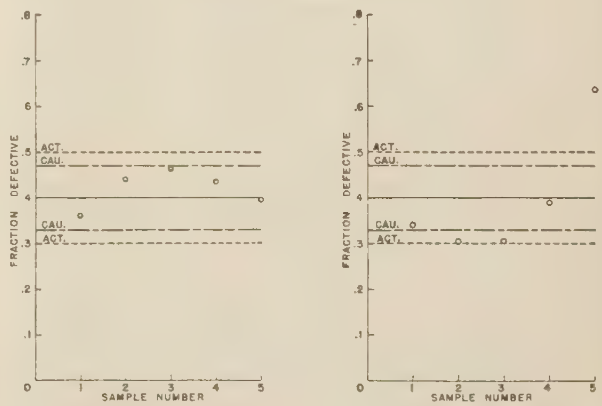
[Data from Table 1 (b).]

Table 1(a) presents the data for one series of samples from the specified process and Fig. 1 exhibits the graphical application of the test. It should be noted that since no points fall outside the action lines the test gives us no cause to reject the hypothesis that the process is controlled at the given level.

Table 1(b) presents a second series of data to be tested, and Fig. 2 shows the test. Here we are forced to reject the hypothesis that the process is controlled at the given level. The rejection of the hypothesis is due to samples 30 and 40. We are forced to the consideration of one of two alternative hypotheses; either (1) the process is under control but at a different level, or (2) assignable causes of variation are present in the process.

The concept of "assignable" causes seems to have been introduced by W. A. Shewhart,[9] and has been developed by him in various books and articles. From an engineering point of view, assignable causes are those causes of variability which can be



(a) Data from Table 1(a) (b) Data from Table 1(b)

Fig. 3 Tests for Control at a Quality Level of 40 Per Cent Defective. Samples of 200, Formed by Rational Subgrouping

found and eliminated. Mathematically they might be defined as those causes whose effect on any individual item depends upon the position of the item in time or space and, therefore, prevent accurate prediction of the characteristics of items when the knowledge of the dependence and positions of individuals is absent. Another definition might be that assignable causes are those which tend to introduce heterogeneity. In any case, the

general effect of the presence of such causes is the prevention of the prediction of the behavior of quality characteristics in random samples.

The method proposed by Shewhart for the investigation of assignable causes is that of "rational subgrouping."[10] In Fig. 2 we note that points 30 and 40 are outside of the action lines. Taking this as evidence of lack of control, it is now the engineer's job to locate and eliminate the assignable causes whose presence is indicated. If there is available a careful description of the conditions under which each sample was taken, the engineer may note that some unusual condition, such as excessive humidity, was common to both of the bad samples. Combining engineering judgment with the statistical evidence, he may adopt the tentative hypothesis that excessive humidity is an assignable cause. Before taking long and expensive measures to eliminate excessive humidity, he is likely to desire further evidence. This may be obtained by dividing the data into subgroups on the basis of the suspected property.

Since the samples have been recorded in the order taken, and since the numbers corresponding to suspected samples are multiples of 5, it seems rational to combine the 10 samples whose numbers are multiples of 5 (i.e., 5, 10, 15, . . ., 50) into a single sample of size 200. To balance this, four other combinations are made, using the 1st, 6th, etc., the 2nd, 7th, etc., the 3rd, 8th, etc., and the 4th, 9th, etc. In other words, large sample 1 consists of the small samples whose order numbers are $5K + 1$, large sample 2 of those whose numbers are of the form $5K + 2$, etc.

The control chart for the new test is given in Fig. 3(*b*). Since the numbers in the samples are larger, the action lines are closer together. The fact that the fifth point falls outside the action lines gives support to the theory that every fifth sample came from a population significantly different from the population which produced the others.

Figs. 1 and 2 contain a second pair of lines which the author has chosen to call "caution lines." The position of these lines[11] is so chosen that the probability of finding a sample point outside is less than 0.05, when the process is controlled at the 40 per cent level. The appearance of a point between an upper caution line and an upper action line, or between the corresponding lower lines, is a signal that trouble may be approaching. It does not mean necessarily that investigation should start. If this were the case, we should be looking for trouble in 5 per cent of the controlled situations. Occasionally this might be desirable, but usually it seems to be uneconomical.[12]

In the case under consideration, sample points 15, 25, and 50 fall above the upper caution line. Also, points 10, 20, 35, and 45 fall above the mean. It is the combination of these facts which suggests grouping the multiples of 5.

CREATING UNCONTROLLED CONDITIONS

In exemplifying the control-chart technique, it has been customary to take a manufacturing process, apply a test for control, state what assignable causes were found and eliminated, and then apply the test again in order to show that control has been achieved. Examples of this sort are of the greatest value, and it is to be fervently hoped that many more of them will find their way into print. The author, however, has found considerable interest in endeavoring to reverse the process, and the remainder of this paper will be concerned with the results of a few simple experiments in creating uncontrolled conditions. Rather than moving into control, we shall see how to get out of control, and then note whether or not our tests locate the assignable causes we have introduced into the situation.

[10] Reference (9), "Economic Control of Manufactured Product," p. 299.

[11] The lines are set at $p \pm 2\sqrt{\frac{p(1-p)}{n}}$, where $p = 0.40$ and $n = 20$.

[12] L. E. Simon, in "An Engineers' Manual of Statistical Methods," John Wiley & Sons, Inc., New York, N. Y., 1941, has suggested the use of two sets of control lines, together with supplementary tests designed to appraise the significance of the number of points falling outside either set. His control lines, however, are differently located.

The table of "Random Sampling Numbers,"[13] prepared by L. H. C. Tippett, contains 41,600 four-digit numbers obtained by taking 40,000 digits "at random"[14] from census reports and combining them by fours. On each page, the numbers are arranged in 8 columns of blocks of 5, 10 blocks to a column.

Using this table it is possible to set up many kinds of distributions and draw long series of samples without excessive labor. For example, if one wishes the number of heads resulting from 10 tosses of a coin, he need only turn at random to some page of the table, read the first digits of each of 10 numbers in a column, let the digits 0 to 4, inclusive, represent heads, and count their number. If we were to use the first digits of the numbers of Fig. 4, we could count 6 heads (corresponding to 1, 0, 4, 2, 4, and 0).

A satisfactory model of a controlled process may be obtained by regarding certain digits as representing defective items. Then we have a model of control at the level of 40 per cent defective. Considering each block as a sample of 20, it is quick and easy to draw 50 samples. The data of Table 1(*a*) were obtained by this method.

To obtain data like that of Table 1(*b*) we may proceed as follows: For samples 1, 2, 3, 4; 6, 7, 8, 9; 11, 12, 13, 14; . . ., let the digits 0, 1, 2, and the 3's in the first two columns of each block represent defectives. For samples 5, 10, 15, . . ., let the digits 0, 1, 2, 3 represent good items. Then the probability for a defective item is 0.35 for the one set of samples and 0.60 for the other set. For the total set the expected percentage of defects is still 40. We now have a model of an uncontrolled process which we can compare with the model of a process controlled at the same expected value.

As shown in Fig. 2, our test rejects the hypothesis of control at the 40 per cent level. It is interesting to note that the probability that a single sample point of the 35 per cent set will fall outside is 0.005, and the probability for one or more of the 40 points is 0.18. For the 60 per cent set we have a probability of 0.12 for a single point and 0.72 for one or more of the 10 points. For the 50 points, the probability for one or more points outside the action lines is 0.77, so that the chances are greater than 3 to 1 that the presence of assignable causes of variability will be suspected.

The rational subgrouping of the data of Table 1(*b*) has been explained and the result exhibited graphically in Fig. 3(*b*). The result of similar subgrouping for the data of Table 1 is exhibited in Fig. 3(*a*). As expected, no lack of control is indicated. Of course, for this controlled situation we should not expect any kind of subgrouping to indicate the presence of assignable causes of variability.

One method of subgrouping the data of Table 1(*b*) strengthens our belief in the presence of assignable causes. How about other methods? It is fairly clear that, if the hypothetical basis for rational subgrouping is false, the new set of samples will be expected to behave like a set formed at random and may give an indication of control.

As a first illustration of the foregoing statement, let us form 5 samples of 200 by combining the samples 1–10, 11–20, 21–30, 31–40, and 41–50 of Table 1(*b*). The result for this is shown in Fig. 5(*b*). The result for a similar treatment of the data of Table 1(*a*) is shown in Fig. 5(*a*).

As a second illustration, let us consider 5 samples formed at random as follows: Write down one half of each of the even two-digit numbers in pairs of columns of Fig. 4, starting with the first column, omitting duplications, and continuing until 40 numbers are obtained.[15] The first 10 of these indicate which samples to combine into the first sample of 200. The next 10 indicate the parts of the second large sample, and the third and fourth sets of 10 give the third and fourth samples. The remaining small samples are combined for the fifth sample of 200. Figs. 6(*a*) and 6(*b*) show the results of applying this procedure to the data of Tables 1(*a*) and 1(*b*), respectively.

[13] "Tracts for Computers," No. XV, Cambridge University Press, London, 1927.

[14] The question of the "randomness" of these numbers is discussed in the following papers: "Randomness and Random Sampling Numbers," by M. J. Kendall and B. Babington-Smith; *Journal*, Royal Statistical Society, vol. 101, 1938, pp. 147–166; "Second Paper on Random Sampling Numbers," by M. J. Kendall and B. Babington-Smith, Supplement to *Journal*, Royal Statistical Society, vol. 6, no. 1, 1939, pp. 51–61; "A Test of Tippett's Random Sampling Numbers," by G. U. Yule, *Journal*, Royal Statistical Society, vol. 101, 1938, pp. 167–172. For a discussion of the general concept of "randomness," see W. A. Shewhart and W. E. Deming, reference (5), pp. 12–17.

Measuring Quality Characteristics

Up to this point we have been focusing our attention on the control-chart technique for fraction defective. Much of the time, however, we are not content with sorting items into just two categories, good and bad, but we are rightly concerned with actual measurements of the quality characteristic under consideration.

The situation as regards control immediately becomes quite complex because of the variety of functional forms useful in describing controlled characteristics and the number of constants contained in these forms. Even the notation becomes complicated.

Let us assume that the measurement of a quality characteristic is denoted by the continuous variable x. Further assume that, for an infinite collection of items, the percentage of the items with quality between $x = \alpha$ and $x = \beta$ is given by the relation

$$P(\alpha \leqq x \leqq \beta) = \int_{\alpha}^{\beta} f(x)dx$$

It follows then, that

$$P(-\infty < x < \infty) = \int_{-\infty}^{\infty} f(x)dx = 1$$

Further let $\bar{x} = \int_{-\infty}^{\infty} xf(x)dx$ give the mean or average value of x, and let $u_n = \int_{-\infty}^{\infty} (x - \bar{x})^n f(x)dx$ give the nth moment about $\bar{x}$.

In particular, we shall call the second moment μ_2 the variance, and the square root of μ_2 the standard deviation. We denote the standard deviation by σ and mention that it is a measure of the dispersion of the individual measurements from the mean.

In case $f(x)$ is of the form

$$\frac{1}{\theta_2\sqrt{2\pi}} e^{-\frac{(x-\theta_1)^2}{2\theta_2^2}}$$

we call it "normal." It is well known and easily verified that $\bar{x} = \theta_1$, and $\sigma = \theta_2$ for this function. Also the transformation

$$t = \frac{x - \theta_1}{\theta_2}$$

reduces the function of x to the t function $\frac{1}{\sqrt{2\pi}} e^{-t^2/2}$. The integral of this latter function for the limits 0 to t, or $-\infty$ to t, is available in many handbooks and sets of tables.

Judging from both written and oral testimony many of the frequency distributions met in engineering practice are approxi-

[15] The numbers are: 2, 24, 20, 32, 38, 45, 26, 29, 44, 25—17, 16, 30, 49, 46, 5, 12, 1, 15, 47—27, 14, 22, 13, 6, 18, 35, 28, 4, 40—41, 31, 3, 23, 33, 37, 19, 48, 9, 10.

mately normal.[16] While the condition seems by no means to be necessary, the sufficient condition for a controlled process is the condition that it behave as though its items were normally distributed.

The method of setting up a working model for a normal distribution, and, therefore, for a controlled process, will now be described.

Working Model for a Controlled Process

Tippett's table[17] provides careful instructions for the construction of a finite frequency distribution whose difference from a normal distribution is due, in the main, to its finiteness. Using his general method but not his result, we set up the numerical correspondence given in Table 2. This finite distribution is approximately normal. It has a mean of 10 and a standard deviation of 2.5. From our knowledge of the Tippett numbers we have reason to believe that the 41,600 numbers will serve as a satisfactory model of a normal distribution, provided the numbers are renamed, as indicated in Table 2.

TABLE 2 TRANSFORMATION FROM A RECTANGULAR DISTRIBUTION TO A NORMAL DISTRIBUTION WITH A MEAN OF 10 AND A STANDARD DEVIATION OF 2.5

The integers	Correspond to	Relative frequencies
0000	0	0.0001
0001–0002	1	0.0002

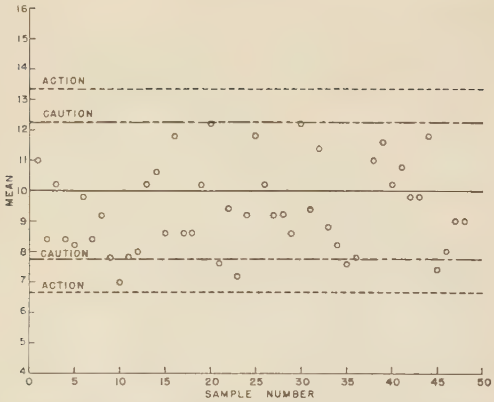

Fig. 9 Means of Samples of 5 From a Process With Trouble Introduced

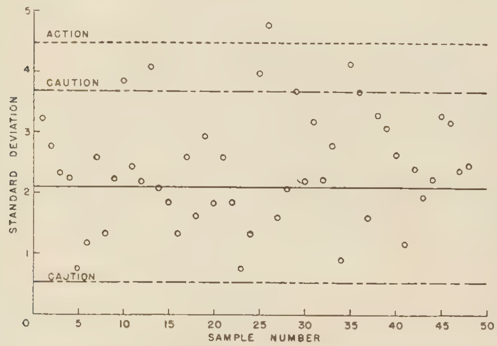

Fig. 10 Standard Deviations of Samples of 5 From a Process With Trouble Introduced

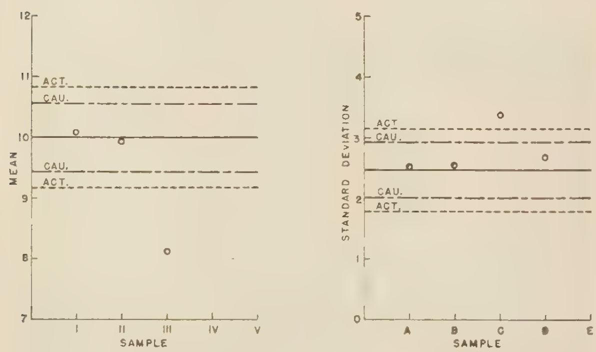

(a) As suggested by Fig. 9 (b) As suggested by Fig. 10

Fig. 11 Rational Subgrouping

normally distributed population. If we take the upper left-hand block and transform the numbers

1373 becomes 7
0490 becomes 6
4852 becomes 10
2358 becomes 8
4088 becomes 9

If we replace integration by summation in our formulas for the mean and standard deviation and compute these statistical quantities for our sample, we find that $\bar{x} = 8.0$ and $\sigma = 1.4$.

While we might test single items, it is better practice to test small groups of items. Both the mean and standard deviation will be considered.

The hypothesis to be tested is that the process is controlled at a mean of 10 and a standard deviation of 2.5. If the hypothesis is true then (with certain approximations):

1 The probability is greater than 0.997 that the mean of a sample of 5 items will fall between 6.65 and 13.35.[18]

2 The probability is greater than 0.997 that the standard deviation of a sample of 5 items will be less than 4.47.[19] Failure to satisfy either condition clouds the hypothesis.

Suppose we have an item in mass production by three 8-hr shifts, with four different lots of material being used, one lot for each three shifts. Furthermore, let us suppose that samples of 5 items are taken at 2-hr intervals. Using Tippett's table,[13] as explained, we can set up a model for a controlled process and draw an experimental set of samples. Such a set of samples is given in Table 3, together with their means and standard deviations.

Figs. 7 and 8 give the control charts for the means and the standard deviations of these samples, respectively. As expected, both tests are passed so no lack of control is indicated.

As in the case of fraction defective, let us see what happens when the process goes out of control. Fig. 9 shows the situation when the samples for the third shift come from a model with a mean reduced 20 per cent, but the standard deviation is unchanged. Our test fails to indicate the presence of assignable causes, although we now find three points between the two lower control lines. If, however, we were to group our data into rational subgroups on the basis of shifts, we would get the condition pictured in Fig. 11(*a*). Here the point for the third shift is far outside the action lines.

Now let us look at the effect of an increase in the variability of material C. If the mean is unchanged but the standard deviation is increased 20 per cent, we have the situation shown in Fig. 10. The one sample point outside the action lines gives an indication of lack of control, and the presence of several points between the two upper control lines lends support. When we group on the basis of material and draw Fig. 11(*b*), the change in variability of material C becomes very apparent.[20]

Conclusions

The elimination of assignable causes is a problem for the engineer. The principal service of the statistician is in the application of tests designed to reveal the existence of such causes and, in many cases, to give some clue as to their general character. In addition to the tests outlined in this paper, there are many others which rest on sound assumptions and have important applications. In particular, it should be noted that the entire group of tests, which must be used before control has been established and the standard determined, has been omitted. The author has neither the space nor the confidence to give an adequate treatment of this larger problem. However, its omission should not minimize its great importance.[21]

Our principal purpose has been that of setting up models of controlled processes and of showing a few ways of throwing them out of control. As has been indicated, samples can be drawn

---

[18] The limits are set at $\bar{x} \pm \dfrac{3\sigma}{\sqrt{n}}$, where $\bar{x} = 10$, $\sigma = 2.25$, and $n = 5$.

[19] The limits are set at zero and $0.84\,\sigma + \dfrac{3\sigma}{\sqrt{2n}}$, where $\sigma = 2.5$ and $n = 5$. If $0.84\,\sigma - \dfrac{3\sigma}{\sqrt{2n}}$ were greater than zero, it would have been used as the lower limit.

[20] This situation presents an excellent opportunity for the analysis of variance. Discussion of such a method of attack is outside the scope of the present paper.

[21] For a discussion of some of the difficulties see W. A. Shewhart and W. E. Deming, reference (5), chap. 2; and "Determination of Sample Sizes for Setting Tolerance Limits," by S. S. Wilks, *The Annals of Mathematical Statistics*, vol. 12, no. 1, 1941, pp. 91–96.

with ease and their nature quickly analyzed. Sometimes our simple tests failed at first to give a clear indication of the presence of assignable causes. This was to be expected, since from their very nature, statistical tests occasionally reject true hypotheses or fail to reject false ones. One of our great problems is to adjust significance levels so that both types of errors are reduced to an economic minimum.

In each of the cases considered the use of rational subgrouping provided samples which revealed the presence of the trouble introduced. Wherever chance subgrouping was applied, results were obtained which were easily explainable on the basis of chance. This was a matter of good luck, as there was some probability, as previously noted, that the reverse situation might have eventuated.

In conclusion, the hope is expressed that the methods outlined in this paper may prove of some slight help in increasing the general understanding of statistical methods for the control of quality. Although many of our larger companies have been using these methods with beneficial results, some organizations have been hesitant to try them until their engineers could examine the theory more closely and gain more knowledge of its operation. Perhaps this discussion will be of assistance in that direction.

Discussion

G. J. Meyers, Jr.[22] The question was asked in connection with this paper why statistics were used to show things which would have in any case become observable in the course of the normal use of common sense. This question seemed to the writer to be quite in order, since it is one being asked many places by manufacturing people who are being told about statistical methods of quality control. The reason behind the question is that, in describing statistical methods, it is often necessary to use conditions which are sufficiently extreme to enable the average person to see the gain made by the use of statistics. In actual use, statistical methods are applied to borderline cases where the answers are not as obvious as in those cases which are only used as examples of statistical methods.

Statistical methods serve as landmarks which point to further improvement beyond that deemed obtainable by experienced manufacturing men. Hence, after all obvious correctives have been exhausted and all normal logic indicates no further gain is to be made, statistical methods still point toward a reasonable chance for yet further gains; thereby giving the man who is doing trouble shooting sufficient courage of his convictions to cause him to continue to the ultimate gain, in spite of expressed opinion on all sides that no such gain exists.

Author's Closure

Mr. Meyers reports that the question was asked why statistics were used to show things which would have in any case become observable in the course of the normal use of common sense. In so far as I understand the question, I quite agree with the answer he has suggested. However, a certain amount of clarification of the question and amplification of the answer seems to be in order.

I am not clear as to what is meant by "common sense" or the "normal use" of it. If this is translated as being the ordinary use of good judgment, then I must assert that, in my opinion, any judgment, to be good, must be arrived at by the collection and correct interpretation of pertinent facts. But the science of statistics is concerned with the collection, classification, and interpretation of numerical data. It would seem, then, that good judgment about quantitative matters must be based on statistics of some sort. As to the amount and type of the arithmetical calculations necessary, this seems to depend somewhat on the relation of its cost to the value of increased precision in discrimination between possible decisions.

Let us look at the data given in Table 1 (*b*) of the paper. Without any statistical theory, how can we decide whether or not it came from a controlled process? We are restricted from assuming that the samples in any way represent the lots from which they were taken; we cannot compute any measure of central tendency or dispersion; we cannot even think about any expected number of defects in samples of size twenty. With these aids to jugment ruled out, I doubt that we can reach any decision in which we would have much confidence.

Judging from past experience, I suspect that the real point at issue is not the desirability of the use of some statistical principles and techniques but of the use of such elaborate ones. "If the process has been averaging 8 defects out of 20 pieces, cannot anyone see, without a control chart, that something must be wrong when there are 16 defects in a sample of 20?" is the usual question.

It would seem that the proper rejoinder would be the following interrogations:

1 Just what chain of reasoning leads to the inescapable conclusion that something must be wrong?

2 Would you say that something was wrong if there were 15 defects? How about 14 or 13 or 12? Where would you draw the line, and why?

3 Would 16 defects out of 20, 8 defects out of 10, or 4 out of 5 give you equal assurance that something was wrong? Why or why not?

Anyone who gives careful consideration to these question should begin to perceive that one needs to have some systematic knowledge of the kind of samples different sorts of lots are likely to produce. Having such knowledge, he is likely to agree that the methods of control-chart analysis provide efficient application of it. And, since many industrial organizations have been able to save money and material by the use of these methods, it would seem to be uncommonly bad common sense not to try them.

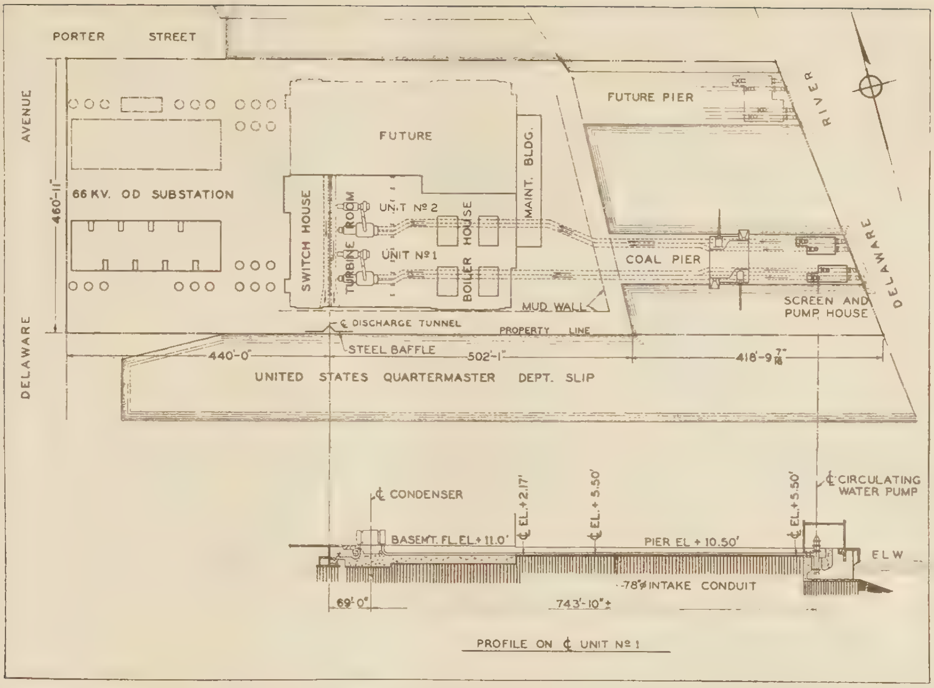

Fig. 1 Plot Plan and Elevation of Southwark Station

Hydraulic-Engineering Problems at Southwark Generating Station

By S. LOGAN KERR[1] and STANLEY MOYER,[2] PHILADELPHIA, PA.

This paper discusses the hydraulic-engineering features of the Philadelphia Electric Company's Southwark Station, the latest addition to its chain of generating stations along the Delaware River. Problems in the design and selection of major equipment centered around (*a*) the location of the intake and discharge passages for condenser circulating water; (*b*) the prevention of recirculation of warm discharge water from condensers; (*c*) operating head on pumps under various river-level conditions; (*d*) size, type, and arrangement of pumps and conduits. A comprehensive model-test program was carried out to solve certain pump, circulating-water-discharge, and condenser problems, the results of which are reported.

THE latest addition to the Philadelphia Electric Company's chain of generating stations along the Delaware River in the Philadelphia area will be Southwark Station located at Delaware Avenue and Porter Street in South Philadelphia. Fig. 1 shows the plot plan of the site and the general arrangement of the major items of equipment, both for the initial development and for the ultimate project.

Contributed by the Power Division and presented at the Annual Meeting, New York, N. Y., December 1–5, 1941, of The American Society of Mechanical Engineers.

Description of Initial Installation

The initial installation will consist of two 168,750-kw 90 per cent power factor units of the cross-compound two-cylinder type. The 3600-rpm, single-flow, high-pressure turbine element drives an 81,250-kva generator. The low-pressure element operates at 1800 rpm double flow and drives a 106,250-kva generator. These ratings are continuous at normal hydrogen pressure. The turbine elements together are capable of developing 187,500 kw. Each low-pressure unit condenser has a total surface of 77,000 sq ft.

Steam is supplied by four 850,000-lb-per-hour, two-drum, open-pass, direct-pulverized-coal-fired, continuous-slag-tap boilers at 925 psi and 900 F total temperature. Each main unit is arranged to be completely independent, a pair of boilers serving a single turbo-generator without cross connection.

Hydraulic-Engineering Features

The design and selection of many of the major items of equipment for this station depended upon a satisfactory solution of certain hydraulic-engineering problems, as follows:

1 The location of the intake and discharge passages for condenser circulating water, and their effect on adjoining structures.

2 The prevention of recirculation of warm discharge water from condensers.

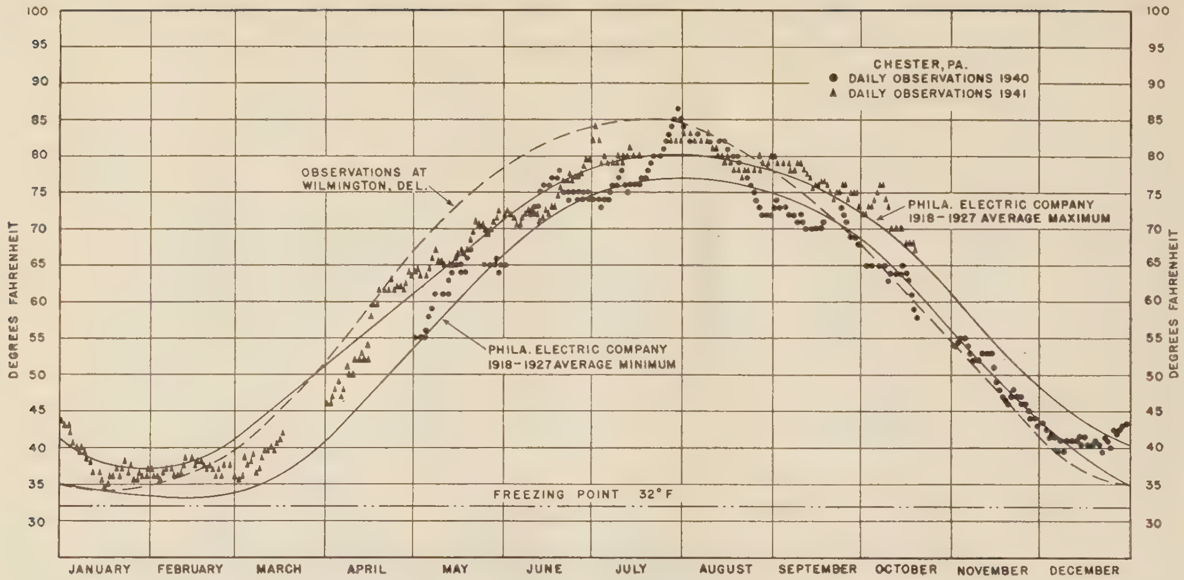

Fig. 2 Delaware River Water Temperatures in the Vicinity of Philadelphia

3 The operating head on the pumps under various river level and flow conditions.

4 The size, type, and arrangement of the pumps and conduits.

Since the site is new and no existing structures other than a marginal wharf are to be used in the station, it was possible to approach the solution of these hydraulic problems without restriction.

Condenser-Water Requirements

The total water requirement for condensing alone was set at 146,000 gpm for each unit. An additional 6000 gpm per machine is needed to supply the hydrogen and turbine-bearing-oil coolers. An allowable water velocity of 8 fps was decided upon, and the maximum river-water temperature for design purposes was taken as 85 F. Fig. 2 shows the temperature records at several locations on the Delaware River over long periods of time.

To guard against a complete shutdown of a turbogenerator because of the failure of a single circulating pump, it has long been the practice of the Philadelphia Electric Company to provide two pumps for each condenser, each pump providing about half of the cooling water required under peak conditions. Such an arrangement allows a substantial portion of rated load to be carried on the turbine with one pump out of service.

Studies were made of the effect of condenser vacuum upon the coal rate. A potential saving of about 0.6 per cent of the coal used would result from an increase in vacuum of $^1/_{10}$ in. At half load this would be about 300 lb of coal per hr, and at full load, about 700 lb per hr.

Location of Intake

The first study of the site as shown on the plot plan, Fig. 1, indicated a number of possible locations for the circulating-water intake from the river, i.e., navigable slips on both sides of the property, frontage on the river along the established bulkhead line, or the piers constructed for coal-handling purposes.

The conventional design, calling for intake and discharge tunnels under the turbine room with the pumps located adjacent to the condensers, would have necessitated a substantial lowering of the substructure. Since the entire station is to be built on piling, depressing the elevation of the top of the piles was considered undesirable.

Both slips have some undesirable features for an intake. The upriver slip would have required bulkheading and backfilling, and extensive dredging would be necessary to provide and maintain a satisfactory depth of intake canal from the river. The water here is contaminated by inflow from several city sewers, making it a still less favorable location.

The plan of development called for the installation of two units on the downriver or south side of the site; hence if the pumping station were located on the north side of the site, it would be separated at some distance from the initial development and would have required considerable additional construction work not otherwise needed for the first two units.

The downriver slip in the adjacent dock is in constant use for loading and unloading ocean-going ships. An intake located in this area might at times be blocked or restricted by vessels tied up at the marginal wharf. The yard area between buildings and the downriver edge of the wharf is to be used for railroad tracks over which emergency rail deliveries of coal will be handled. Interference with this layout by an intake structure was considered undesirable.

With four units installed ultimately, an outlet tunnel carried through the structure could be arranged to discharge into either the upriver or downriver slip. This plan had many advantages and eliminated either slip as an intake channel.

If the intake were located at the bulkhead line, interference with flow would be experienced from the piers and from barges moored at the coal-handling equipment.

After a review of these conditions, another alternative was considered, namely, locating the intake on the end of the coal piers which extend out from the bulkhead line some 450 ft into the river to the established pierhead line adjoining the ship channel on the Pennsylvania side of the river. The ship channel maintained by the government is now 35 ft deep and is being developed to a depth of 37 ft as a part of the improvements to the Port of Philadelphia.

A usual design would call for long submerged intake conduits leading to the circulating pumps located close to the condenser. Extreme low water at the site is about $9^1/_2$ ft below mean high water, and about 15.35 ft below flood. To provide ample submergence for such intake tunnels would require laying of sub-

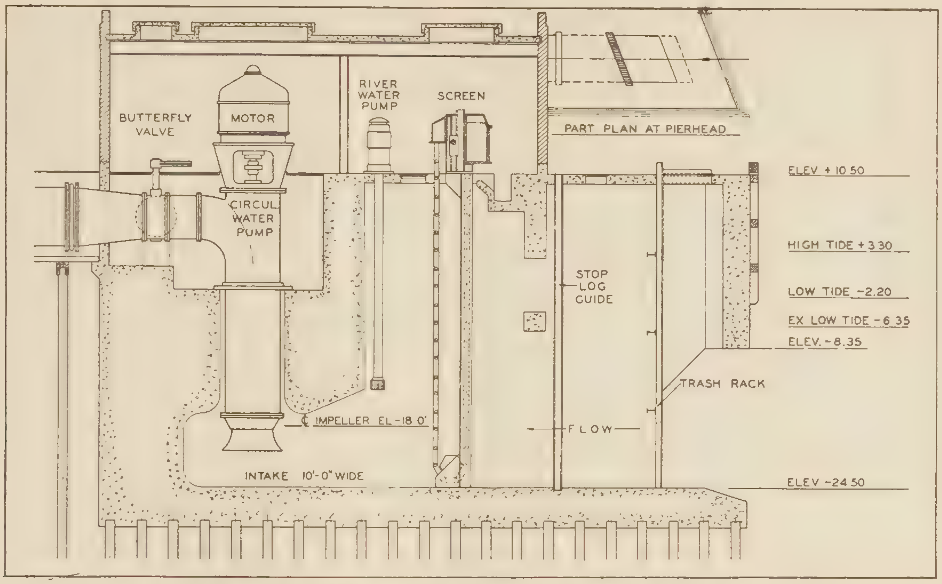

Fig. 3 Arrangement of Intake and Pumping Units

aqueous pipe or construction of a cast-in-place conduit inside a long and costly sheet-pile cofferdam. Subaqueous pipe was ruled out early in the design stages because of the closely spaced pile construction necessary for supporting the pier itself.

The cost of a cofferdam in which to construct cast-in-place conduits appeared so high that an alternate method was sought. After a careful study of pumping heads, reliability of long pressure conduits, and the co-ordination of pump and condenser operation, a scheme was developed locating pumps at the pierhead connected to the condensers through pressure conduits 650 ft in length. Estimated construction costs were so greatly in favor of the latter design, with operating cost and reliability so little affected, that it was immediately adopted. The conduits are to be placed on the relieving platforms of the pier and wharves under the coal-handling machinery and tracks. In the yard and below the floor of the boilerhouse and turbine hall, the conduits are carried on pile-supported cradles. General excavation in the building area was not substantially increased and much subaqueous work was eliminated.

Two coal piers, shown in Fig. 1, are required in the ultimate development, although only one pier is planned for the initial project. With a pair of pumps for each generating unit, two such installations could be placed at the end of each pier and thus conform to the general plan of development. A general arrangement of the pumps and intake passages is shown in Fig. 3.

The intake racks are arranged so that they present a uniform, smooth face, parallel to the pierhead line. At Southwark Station, the pierhead line and the bulkhead line are at an angle to the center line of the piers. This construction requires the rack bars to be skewed, making the clear face of the intake structure parallel to the channel of the river where the high-velocity tidal currents should assist in keeping the racks free from trash.

The concrete deck of the pier is carried out beyond the intake and forms a skimmer wall to fend off floating debris and ice. The construction is rugged and provides sufficient strength to withstand forces exerted by mooring barges and other vessels. Mechanical rack-raking and cleaning devices are provided to remove trash from the racks. Disposal channels are provided where this refuse can be discharged or removed. A vertical traveling intake screen 8 ft wide and 35 ft deep is provided ahead of each pump.

Vertical-shaft high-speed-type pumps are placed in separate intake channels. Each pump is connected to an individual discharge conduit, and an automatic check valve of the butterfly type is located between the pump-discharge flange and a taper section leading to the pressure conduit.

It was possible to segregate each pair of pumps serving one condenser in a separate pump house and intake structure. No cross connection of the pump-discharge lines occurs except at the condenser-inlet water box where two separate circular connections are made. Rubber expansion joints are included at both ends of each conduit.

Outlet Channels

Returning the circulating water to the river introduced additional problems due to conditions peculiar to the Southwark site. The marginal wharf and the bulkhead on the downriver portion of the site are on Philadelphia Electric Company property, but are owned by the United States Government and constitute an easement on the Southwark site.

The discharge of 300,000 gpm or more into this navigable slip had to be carefully studied. The effect on the existing marginal wharf on the Southwark site, upon docking and unloading of ocean-going vessels in the slip, upon the existing Quartermaster pier structures, and upon the silting of the slip between the Southwark wharf and the Quartermaster pier, all had to be considered.

Two series of model tests, described later, were undertaken, the first to establish the means of dissipating the energy in the discharge water; the second to extend such studies to the detailed design features, to the problem of distributing the discharge in the adjoining slip, avoiding heavy local currents, and to the effect of this discharge upon the existing silting problem in the slip.

Recirculation Studies

A further study was required of the possible recirculation of warm condenser-discharge water back into the intake on the ends of the piers. The structures on the shore side of the bulkhead line are of solid construction, with the exception of the marginal wharf on either side of the Quartermaster slip. This portion is of open piling construction, but only 40 ft inshore from the edge of

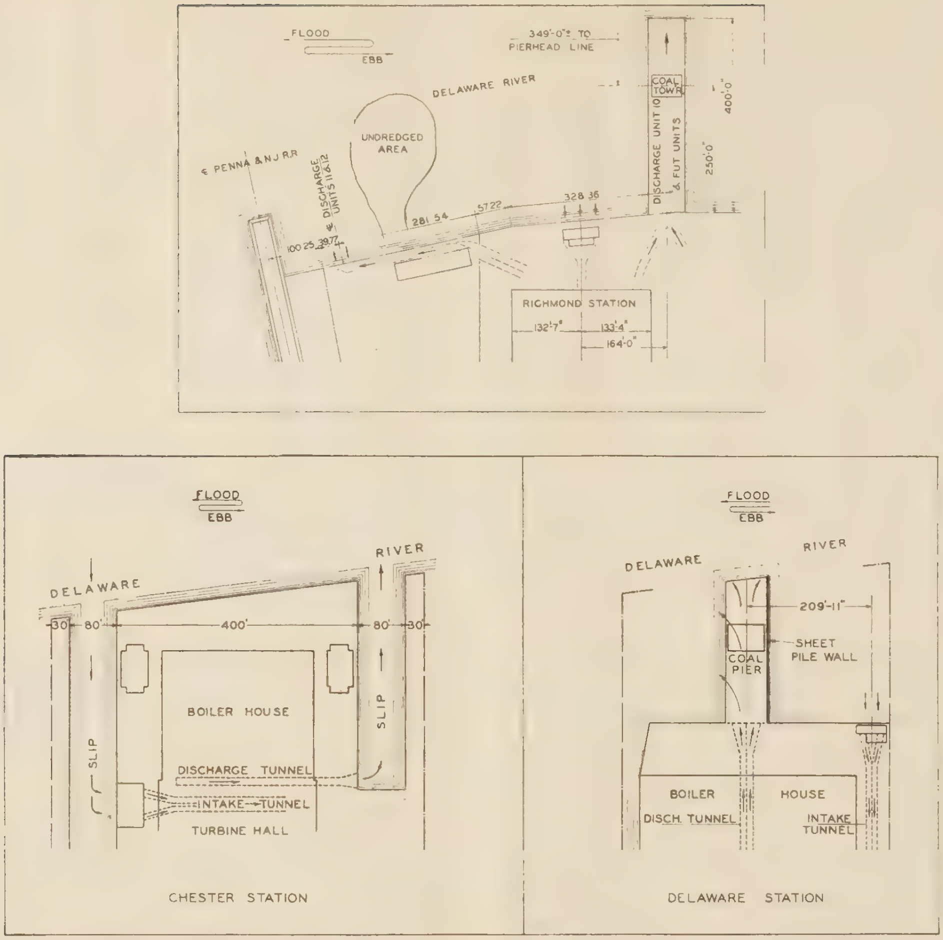

Fig. 4 General Arrangement of Circulating-Water Systems at Richmond, Delaware, and Chester Stations

the wharf. The rest of the property is filled land cut off from any river flow. Riverward of the bulkhead line, the new coal piers and the Quartermaster pier are of open construction, as required by the United States Engineer Office, to reduce the silting effect and avoid local high velocities adjacent to the pierhead.

Referring to the circulating-water conditions at the Richmond, Delaware, and Chester Stations, each has a different physical arrangement of the intake and discharge works, Fig. 4. Operating records of the three stations were studied in relation to total output, condenser vacuum, river-water temperature, and tide conditions. At Richmond Station there is evidence of some recirculation, and the condenser-inlet water on downriver tides showed an increase of several degrees above the mean river-water temperature. There is a corresponding decrease in condenser vacuum, and while there is no impairment in station capacity, it is evident that some slight reduction in economy takes place during certain tide conditions.

At Delaware Station, the discharge is carried under the coal pier. The downriver side of this pier has been bulkheaded off with steel sheet piling to prevent recirculation of warm water back into the intake located on the bulkhead downriver from the discharge tunnel. The analysis of Delaware Station performance shows that there is some slight recirculation, but negligible in amount, as compared with the conditions at Richmond.

At the Chester generating station the intake water is drawn rom the upriver side, carried through and discharged on the downriver side of the station. Both intake and discharge channels act as slips for handling coal barges and are physically separated a distance of 400 ft. The water must travel in from the river about 300 ft to reach the intake, and on the discharge side it must go slightly more than 300 ft before it reaches the main river. The observations on this station show that there is no measurable recirculation.

Various theories were advanced with regard to the behavior of the water in the Delaware River. A study of the tide conditions and tidal currents[3] indicated that while the fresh-water discharge in the Delaware River averaged about 12,000 to 14,000 cfs, the maximum upriver flow, due to tide, reached about 150,000 cfs. The downriver flow, due to tide and fresh-water discharge, is about 130,000 cfs maximum, but is of a longer duration. A maximum channel velocity of about 2 fps upriver or downriver can be expected at times of mean tide.

The surveys made by the United States Engineer Office in Philadelphia over an extended time, at different periods of the year, under different weather, wind, and tide conditions, showed that these velocities were sufficient to cause a thorough mixing of the water in or near the channel. In the many thousand observations taken, the measured difference in temperature between the surface and the bottom of the channel rarely exceeded one degree F, and except for occasional isolated instances, never exceeded

[3] "Tidal Hydraulics," by Brig. Gen. George E. Pillsbury, U.S.A. (retired), published by Corps of Engineers, U. S. Army, 1940.

two degrees F. This showed clearly that there was no stratification of the water in the Delaware in the vicinity of Philadelphia and adjacent to the channel.

Field Temperature Measurements

Further investigation was needed to determine the behavior of warm water discharged from the condensers and to fix the distance required for this water to travel before it blended completely with the main flow of the river. The Chester Station offered the best opportunity to investigate this matter, since it simulates to some degree the proposed design of the discharge channels at Southwark.

It was decided to make temperature measurements in the discharge channel and the area in the river beyond the bulkhead line. Observations were made at intervals of about one hundred feet in this area on traverse lines, as shown in Figs. 5 and 6.

Special thermocouples were prepared to give temperature readings at different elevations, and check readings were made with a separate thermometer held one foot below the surface, against which the thermocouples could be given an approximate calibration at every station where measurements were made.

Fig. 5 shows the differences between mean river-water temperature and the temperature measured at various depths on an incoming tide. Fig. 6 shows another analysis of these same relations on an outgoing tide. The cross-section views demonstrate that the warm water has a very definite tendency to rise to the surface and spread out in a thin layer which gradually merges with the river flow.

These tests were run between July 28 and August 5, 1941, when the Delaware River temperatures were between 82 and 84 F. It will be noticed that the discharge-water temperature is approximately 8 to 10 degrees above the intake temperature. The air temperature on July 28 reached a maximum of 102.5 F and on July 29, a low of approximately 78 F. It is interesting to note that the river-water-temperature observations shown in Fig. 2 reach a maximum of 80 to 85 F during the latter part of July and the first part of August, and that they go as low as 35 F in December or January. The tests made at Chester were, therefore, comparable to the mean high-temperature conditions to be expected on the river.

The observations showed conclusively that the warm water

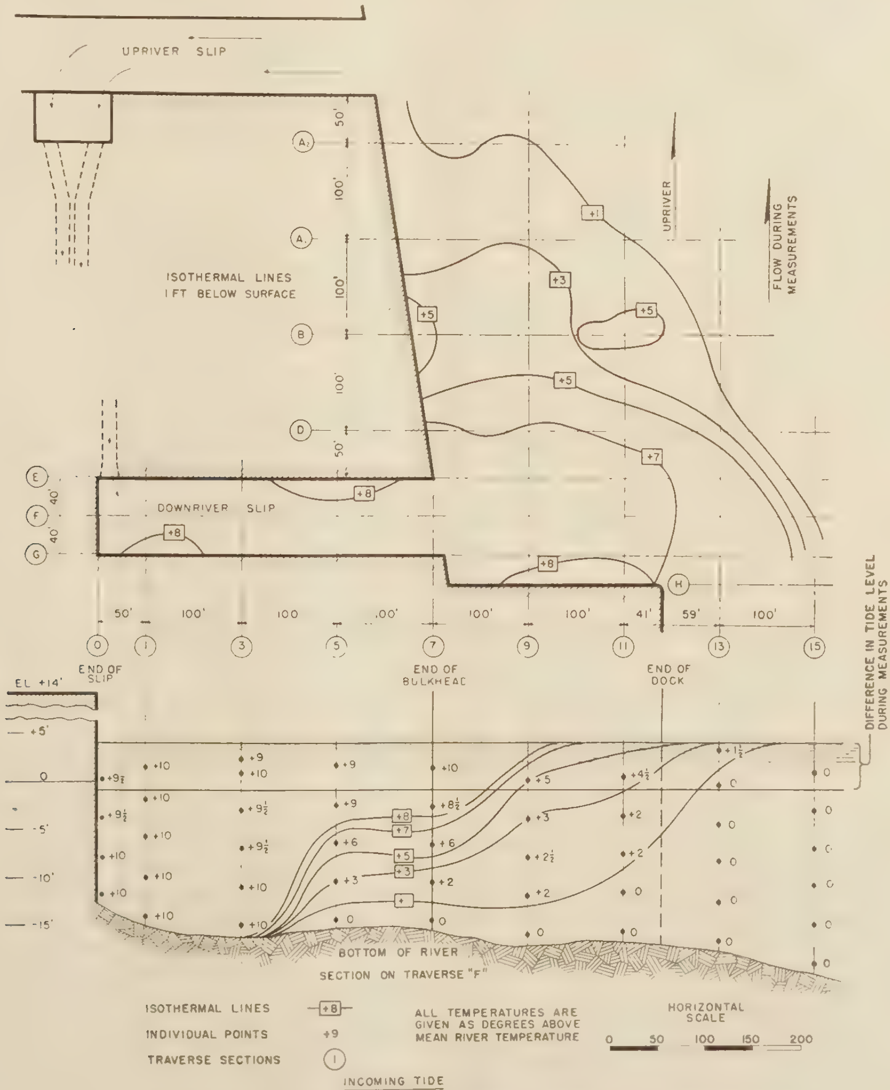

Fig. 5 Temperature Measurements at Chester Station on an Incoming Tide

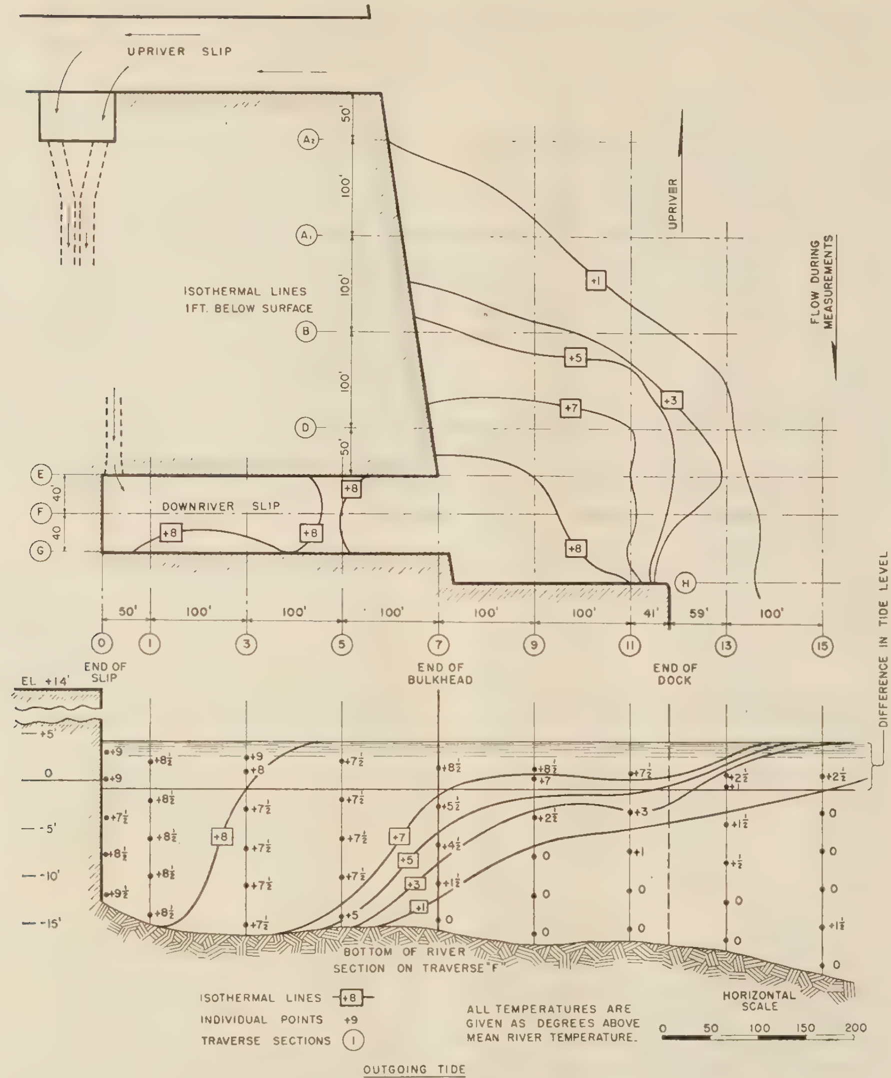

Fig. 6 Temperature Measurements at Chester Station on an Outgoing Tide

rises to the surface within 300 ft from the tunnel outlet, and by the time it was 400 ft beyond the bulkhead line, it approached the mean river-water temperature and only a thin surface layer remained.

Based on standard tables, the difference in density of the water in the temperature range observed at Chester is less than 0.1 lb per cu ft.

Relating these observations to the Southwark Station design, it is felt that the warm water will rise to the surface by the time it reaches the bulkhead line, some 450 ft from the tunnel outlet. The thin layer of warm water extending out in the river should pass through the open pile construction of the piers at low tide, or be deflected into the upriver or downriver flows well above the deep intake for the circulating pumps, located at the ends of the piers near the ship channel.

As a result of these investigations, the final arrangement was fixed as shown in Fig. 3, with the floor of the intake located approximately 22 ft below mean low water. From this point out, the river bottom takes a gradual slope to the 35-ft-channel depth. The discharge of the condenser-outlet water into the slip adjoining the Quartermaster pier could then be considered independently of the recirculating problem.

Pump Operating Conditions

Once the general design of the station was determined, the operating conditions for the circulating-water system could be investigated in detail. As previously outlined, the Delaware River in the vicinity of Philadelphia is really a tidal estuary. The fresh-water flow under normal conditions amounts to less than 10 per cent of the tidal flow, and hence, can be neglected in so far as the relative location of intake and discharge passages is concerned. The water at Philadelphia is free from sea-water contamination. Occasionally during the summer months and with extreme low fresh-water inflow, the water at Chester (approximately 15 miles below Philadelphia) shows a brackish tendency but can still be classed as fresh water. Materials suitable for fresh-water applications can therefore be used and the more expensive marine-type construction avoided.

The high and low fresh-water inflow does not cause more than one to two feet variation in the Delaware River levels at Phila-

delphia. The principal influences are due to tidal flow and to wind conditions in combination with the tide. A study of the river-level variation was made on the basis of information secured from the United States Engineer Office in Philadelphia, as well as from company records and referred to the United States Coast and Geodetic Survey Datum being used in the design and construction of the station.

The total variation between maximum and minimum water level is 15.35 ft. Normal variation is approximately 5.4 ft, corresponding to the difference between mean high tide and mean low tide. The extreme flood level recorded was elevation plus 9.0. The mean high tide is elevation plus 3.2. Extreme low tide is minus 6.35.

The center line of the pump-discharge conduits was set at elevation plus 5.5, placing the bottom of the conduit at about mean tide level. The surface of the pier is at elevation plus 10.5, but the walls, doors, and other entrances to the pumping station and to the station itself are held slightly higher.

An unusual factor, influencing the elevation of the floor levels in the station, was the location of the New York Shipbuilding Company directly across the river. A recording gage installed at the Southwark site was in operation during the launching of the U.S.S. *South Dakota*, June 7, 1941, and showed a reading of approximately two ft above high-tide level due to waves set up by this large battleship.

The intake and screen losses were established for various discharges, based upon manufacturers' guarantees and upon the operating experience of the Philadelphia Electric Company. The conduit between the pumping units and the condensers was analyzed for head loss. An estimate was prepared on the use of two conduits, each 78 in. ID, with a normal velocity of 5 fps.

The head loss through the condenser was taken from the manufacturers' guarantees and checked against experience with other types of condensers for large generating units. The outlet from the condensers was studied in relation to the arrangement of the equipment in the generating room, the floor levels, and also the foundation conditions under the generating station.

It was found desirable to raise the condenser sufficiently to maintain a single floor level at elevation plus 11.0 in the generating room. Due to the very large capacity of these units and the size of the condenser, the top of the condenser-outlet water box extended a considerable distance above extreme low water.

With outlet temperatures which could be expected during summer months, calculations showed that the free water surface should be not more than 27.5 ft below the top of the discharge water box of the condenser. This introduced a definite head loss at all times when the tide level was below the elevation corresponding to this free water surface. It was also necessary to provide some sort of a seal which would prevent breaking the water column in the downpipe of the condenser, and yet not impose an excessive head loss when the tide elevation approached the normal free water surface.

Head-Duration Curves

To arrive at an economic design, a study was made of the net effective head available on the pumps at all conditions of tide. Curves and data, Fig. 7, were secured from the United States Engineer Department on the variation of water level for mean, spring, and neap tides. The occurrence or frequency curves for the various tide ranges were also related to time. In this manner, a static-head-duration curve, Fig. 8, was derived which indicated that the condenser could be raised substantially without any excessive increase in pumping costs throughout the year.

With the friction-head values already determined for the intake, the conduit, the condenser, and the discharge passages, a series of head-discharge curves was prepared for the various general conditions, namely, maximum head, minimum head, normal annual average, and normal maximum head. These are shown in Fig. 9. The intersection of these curves with the desired value of 152,000 gpm determined the estimated range in head at rated discharge and gave a nominal rating for each pump of 76,000 gpm at 25 ft total head. Due to the tide variations and other conditions, the normal daily variation with two pumps in operation is expected to range from 21 ft up to 27 ft. Under extreme low-water conditions where the static-head loss at the outlet of the condenser will be a maximum, the pumps will have to operate under a head

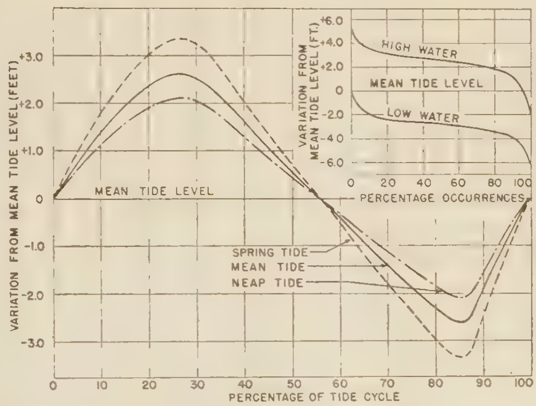

Fig. 7 Tide Variations and Occurrences at Philadelphia

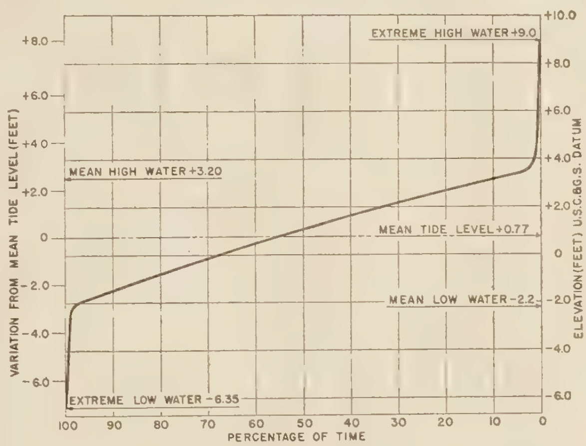

Fig. 8 Static-Head-Duration Curve

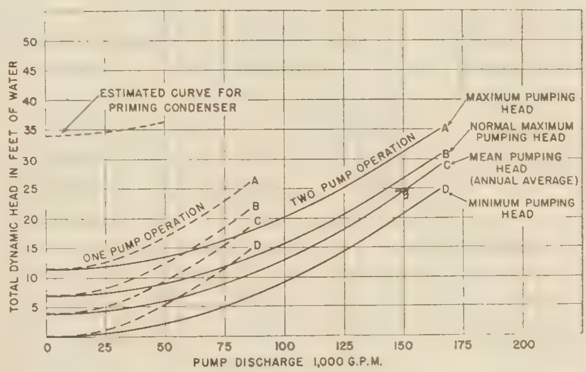

Fig. 9 Head-Discharge Curves for Circulating-Water System

of 31.5 ft. The records available in the City of Philadelphia and the United States Engineer Office showed that extreme low water could be expected to occur less than 0.5 per cent of the time, and the normal maximum head of 27 ft is not expected to be exceeded for more than 2.5 per cent of the time. The minimum head which occurs when the tide is sufficiently high to submerge the sealing weir will probably not occur more than 1 or 2 per cent of the time.

Pump Characteristics

Due to the location of the pumping units at the end of the coal piers and immediately adjacent to the deep-water channel, it was possible to arrange the structure to utilize the full value of submergence of the pump impellers and thus permit the use of high-speed pumps. The normal submergence obtainable at mean tide level is approximately 18 ft. Even at extreme low tide the submergence will be on the order of 11 to 12 ft. This gives an additional safety margin against the possibility of excessive accumulation of trash on the intake racks and screens, as a drawdown in the suction chamber of as much as 6 or 8 ft will still give a substantial seal over the suction of the pump.

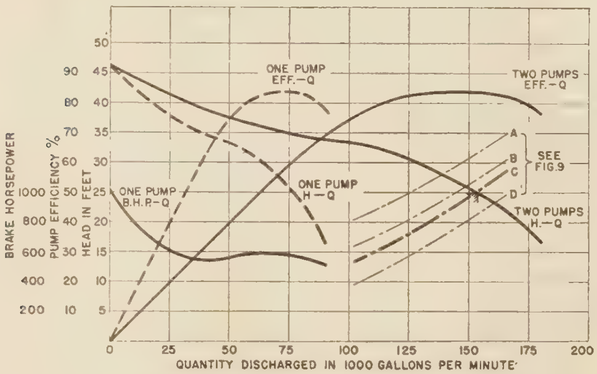

Fig. 10 Pump Characteristic Curves

Advantage has been taken of design improvements to insure against difficulties with the pumping units by providing for ample width of water passage and sufficient submergence to have the pumps operate well above the cavitation limit.

A preliminary investigation was made with the co-operation of the various pump manufacturers, the individual practice of each pump builder being studied prior to the issuance of the specifications. The maximum and minimum widths of water passages, the distance from the bottom of the suction bell to the bottom of the intake, the relation of the bell to the walls of the passage, and the degree of submergence desired were all studied.

It was finally decided to set up limits of width, depth, and submergence which would impose no penalty on any of the manufacturers. Almost without exception, it was possible to allow more liberal dimensions than they required, and, under all tide levels, a substantial margin of safety against cavitation was indicated.

Since intake conditions have a very marked effect upon the performance of propeller pumps, as well as axial-flow and centrifugal pumps, it was decided to require, as part of the pump contract, that the manufacturer conduct complete model tests, in his own experimental laboratory, on a unit similar to the full-scale unit and under all conditions of head, discharge, and inlet level.

It was further decided to insure that all features of the hydraulic design of the intake and of the pumping unit were suitable for Southwark conditions by requiring the completion of the model tests and their approval by the power company before the manufacturer can proceed with the fabrication of the main pumping units.

These pumps will be connected to long conduits, and water measurements can be made with a high degree of accuracy. The right was retained by the power company to make final acceptance tests in the field, even though the model tests should indicate that the performance of the unit would meet the contractual requirements.

To prime the condenser automatically without the necessity of using an ejector or other similar device, it was assumed that a discharge of about one third of the normal flow would sweep out the air in the discharge water box and establish the siphon effect. This was confirmed from the experience at the existing stations of the Philadelphia Electric Company system. An approximate water-requirement curve for priming was included in the pump specifications.

The pump characteristics proposed by the successful bidder are shown in Fig. 10.

Cavitation

Impeller submergence becomes increasingly important as the specific speed of the pump is increased, particularly where wide fluctuations in suction levels exist. The research work, carried out on pumps and turbines recently, has shown that the relation between the suction lift or positive suction head and the total effective head of the pump can be set up in the simple relation, known as "sigma," in

$$\sigma = \frac{(H_b - H_{vp}) - H_s}{H_0}$$

where

σ = cavitation factor
H_b = barometric head, in feet of water
H_s = static head, measured from center line of impeller to free-water surface or its equivalent
H_{vp} = vapor pressure of water at maximum temperature to be expected in intake
H_0 = normal effective head on pump

Cavitation tests on a model pump can be made through varying the suction and discharge pressures simultaneously by the same increment of head, thus giving the effect of raising or lowering the pump with respect to the suction level. So long as the pump impeller is submerged sufficiently to maintain the required absolute pressure on the under side of the blades, the water will remain against the blades and there will be little or no change in the pump performance. As the cavitation limit is approached, the water tends to depart from the blade, causing local areas to be alternately filled with water vapor or to collapse. The pump characteristics will then change and, as the condition is aggravated, will cause excessive loss of efficiency and discharge.

This critical "sigma" value, representing the point at which the water passing through the pump impeller departs radically from its normal flow pattern, is the value to be used in fixing the suction lift of the pump or in determining the required submergence of the impeller below suction level.

In selecting the pumps, it was found in many instances pumping units were specified for the maximum possible head conditions. With centrifugal pumps of low specific speed, a change in head would have only a small effect on the discharge. The efficiency curve is flat and the loss of efficiency, due to operation at substantially lower heads, does not impose an excessive penalty.

With high-speed pumps of the axial-flow or propeller type, the shape of the efficiency curve is much steeper than with centrifugal pumps, and the range of high efficiency is much narrower. The head curve tends to be flatter and, since the total head is low, a small change in head usually amounts to a substantial proportion of the total pumping head and causes impairment in

discharge. It may also cause the pump to operate at a point far beyond the maximum efficiency. The loss of efficiency alone is important but it is also most desirable to avoid running such pumps beyond their best efficiency, since the tendency toward local cavitation, vibration, and other difficulties becomes more pronounced.

By giving the manufacturer complete information on the expected operating requirements, the range in discharge and range in head for normal conditions, and by requiring sufficient experimental work to prove out the proposed designs, it is hoped to have as complete freedom from operating difficulties from this source as possible.

Check Valves

Between the pumping units and the conduit it is necessary to have some form of shutoff valve. After a study of the operating requirements, it was decided to install hydraulically operated butterfly or pivot valves, which could be opened or closed sufficiently fast to permit them to operate as check valves. This avoids the necessity of draining and refilling the discharge lines each time the power is cut off from the pumps or during emergencies. The butterfly valves will be arranged with a separate oil-pressure system and an accumulator tank which will have a sufficient supply of power fluid to close the valves upon a power failure, hold them closed, and reopen them upon the restarting of the pumps. Such controls are quite common in waterworks and hydroelectric practice and have been utilized in all parts of the country with very low maintenance requirements.

The practice of rating the circulating pumps as a function of the diameter of the discharge elbow tends to be misleading. With the pumps selected for this project, the outlet diameter was reduced to 54 in. and the butterfly valve connected directly to the pump discharge. Between the pump discharge and the 78-in. conduit an expanding tapered section is provided which has a total angle of flare not exceeding 10 deg to insure the recovery of approximately 80 per cent of the velocity at the throat of the valve.

The controls for these valves will be interconnected with the controls for the pumps. Induction-type motors are being used for driving the pumps and liberal torque allowances have been made for starting the unit. It is not expected that it will be necessary to open the check valve in advance of starting the pump.

On shutting down the pump, the check valve will be closed automatically, making the first part of its travel at a rapid rate and the last part at a much slower rate. This will provide against excessive backward flow through the pump and will retain most of the water in the conduit. The check valve itself will act to relieve any surge due to water hammer, and timing adjustments can be made to permit the valve to go through each part of the closing stroke at any desired rate.

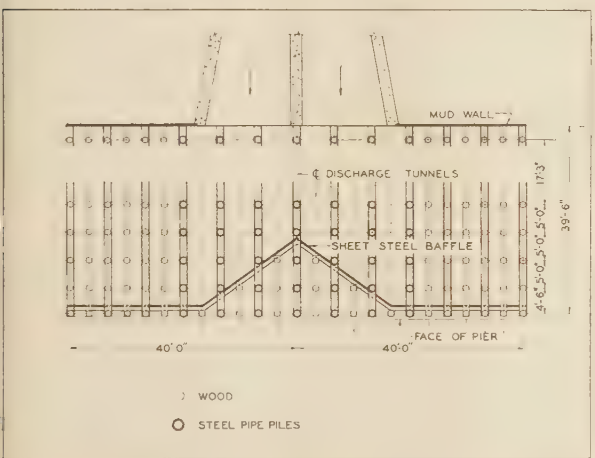

Fig. 11 Preliminary Design of Outlet Baffle

Pump-Discharge Conduits

In selecting the type of pipe for the conduit between the pumps and the condenser, consideration was given first of all to steel pipe which could be encased solidly in concrete. The superimposed load of the railroad tracks and other equipment would be carried by this reinforced concrete to the foundation piles.

Alternative plans were studied, using steel pipe with flexible couplings laid in a concrete trench and backfilled. Wrought-iron pipe and cast-iron pipe were also considered, as well as reinforced-concrete pressure pipe of the "lock-joint" type used for many years in water-supply practice.

The friction head losses for each type of conduit were carefully reviewed, and it was found that the differences were not in excess of 0.5 ft at maximum discharge. An analysis made of the installed cost showed for Southwark conditions that reinforced-concrete pressure pipe was the least expensive. Consideration

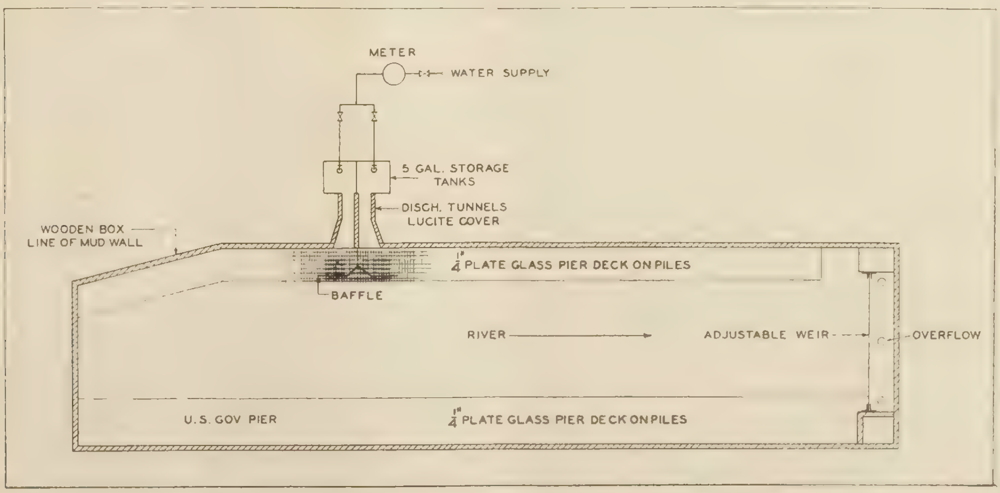

Fig. 12 Model of Outlet Works and Navigation Slip

was given as well to the relative difficulty of securing various types of material as a result of the defense program.

It was decided to use reinforced-concrete pressure pipe since it required a minimum of steel and prompt deliveries could be secured in the particular sizes needed. The fabrication of the pipe will be carried out on company property, a short distance away from the site. Each of the four individual conduits is 78 in. ID, arranged with access manholes at either end and with an air-release valve at the invert beyond the coal-handling tower. The pipe has a wall thickness of 7 in. throughout and has a nominal pressure rating of 50 ft. A steel reinforcing cage is cast in each section, as the continuous steel membrane used to seal high-pressure pipe was not considered necessary. Each line is approximately 650 ft in length and two such conduits are needed for each generating unit.

Outlet Model Test Program

The first part of the model-test program was devoted to the design of the outlet passage into the Quartermaster slip. The first model constructed for this study was to $^1/_{24}$ scale and consisted of an outlet tunnel, and the piling and deck immediately adjacent to it. It was found that the presence of the piles alone was not sufficient to break up high-velocity currents, but that a deflecting baffle, Fig. 11, would divide the flow and turn it through 90 deg in such a way that it was diffused through a longer length of piling, its velocity cut down to less than 1 fps, and the energy in the water at the tunnel outlet dissipated, so that no heavy currents were found beyond the face of the wharf. Following these tests, it was possible to secure the necessary government permission for rebuilding the bulkhead and marginal wharf.

A second model to $^1/_{100}$ scale, Fig. 12, was constructed to develop the final details of the design of this baffle and its relation to the silting problem in the adjoining slip, as well as to fix the limits beyond the tunnel outlet itself that must be paved or otherwise protected against wash from the discharge currents.

This second model-testing program has not yet been completed, but a description of the model itself may be of interest. The space between the two cutoff walls, adjoining the slip and the marginal wharves on both sides of the slip, is reproduced in detail. The piling has been included to scale for a distance equivalent to more than 100 ft on either side of the condenser outlet, and the outside line of fender piles on the full perimeter of the slip have been used to support the plate-glass cover corresponding to the pier deck.

The model is constructed of wood with the piles made of $^1/_8$-in-diam dowels. A weir has been located at a point beyond the bulkhead line and centered on the axis of the slip. The crest of the weir is adjustable to give the equivalent of either high-tide or low-tide conditions. The discharge tunnels have been reproduced to scale and are connected to separate sources of water supply, which can be regulated individually and give the equivalent of from one to four units in operation at any one time and with any combination of units in the respective channels. Since the design contemplates the connection of alternate units to the divided tunnel sections, the model can be operated at any condition which might be encountered in the ultimate development. Photographic recording of the test is planned, together with studies of the silting of the basin and the effect of the discharge upon the present filled section under the wharves.

Condenser Model

The design of the condenser water boxes is also the subject of an experimental investigation, particularly with respect to the outlet water box. In order to lead the discharge down to the sealing pool below the main floor at elevation plus 11.0, a design was proposed which would split the stream into two parts and carry them down to a common rectangular discharge opening at the bottom of the water box. The tube sheet is sealed by a U-shaped wall, and the discharge water flows over the top of the legs of the U.

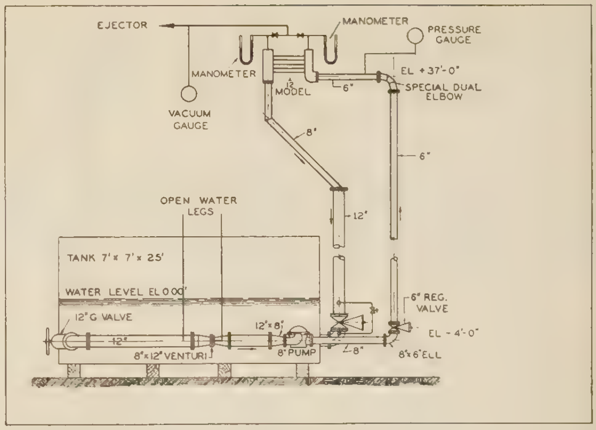

Fig. 13 Model of Condenser

A model of the condenser was constructed and set up for tests under conditions of temperature and vacuum corresponding to those encountered in actual service. Arrangements were made to determine the distribution of water flow in the various sections of the condenser by utilizing large-diameter tubes, each of which is equivalent to a number of smaller condenser tubes. An orifice piece is arranged in each tube to simulate the frictional resistance of the full-scale condenser tubes, and also to act as a measuring device to determine whether or not any wide variations in flow occur in the different portions of the condenser.

The model is constructed with transparent end covers and the flow can be observed through these windows. The complete series of tests had not yet been finished at the time that this paper was written, but the results will be made available at some later time.

The engineering design for the Southwark Station is being carried out by the Philadelphia Electric Company, with such assistance as they may desire from United Engineers & Constructors Inc., or other consultants on specific problems. The construction work is being done by United Engineers & Constructors Inc.

Appendix

Research Program

At the time the paper was written, portions of the research program had not been completed. It is now possible to release the results of these investigations.

Condenser Model

Tests made at the manufacturer's laboratory in co-operation with the Philadelphia Electric Company disclosed that the split-stream design for the outlet water box could not be used satisfactorily in this project. The width of passage needed to turn the water through 180 deg without inducing cavitation required more lateral space than was available in the plant. The larger mass of water contained in this water box, as compared with the more usual design, tended to introduce higher eccentric loadings on the turbogenerator than were considered desirable. The final arrangement for the outlet water box and also the down pipe, the barometric sealing weir, and the connection to the outlet tunnels is shown in Fig. 14. Some additional tests are scheduled to develop the final design of the connections to the inlet water box and to reduce the turbulence and air inclusion at this point to a minimum.

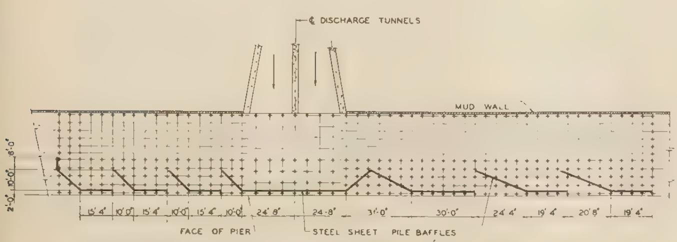

Fig. 18 Details of Final Baffle Arrangement for Diffusing Flow From Condenser-Tunnel Outlet

Intake and Pump Tests

The model tests in the pump manufacturer's laboratory have been completed in so far as the intake and physical setting of the pump are concerned. The original design with the bottom of the bell located 4 ft above the floor (approximately 0.65 times the bell diameter and about equal to the impeller diameter) proved superior to a greater distance (1 bell diameter) and gave a more stable performance curve, and from 1 to 2 per cent better efficiency in the operating range. The model tests also showed that the design based on a gradually accelerating velocity, with the water carefully guided into the pump suction, gave the best results. There was complete freedom from cavitation in the model throughout the required operating range. The final design closely approximates that shown in Fig. 3 of the paper.

Tunnel-Outlet Model

The tunnel-outlet model proved that practically all the original ideas concerning the behavior of the water in the Quartermaster slip were in error. Tests with the diffusing section alone and with dependence placed upon the piling to break up any heavy concentrations of flow showed that this scheme was most ineffective. Fig. 15 is a simplified diagram of the flow pattern with this first arrangement. Heavy currents swept across the slip and cut under the government pier.

The second series of tests was based upon the design shown in Fig. 11 of the paper. There was some reduction in the intensity of the flow concentrations, and the high-velocity currents under the government pier were not as pronounced. There was a very large primary and secondary eddy, as indicated in Fig. 16, which would have caused heavy depositions of silt in the navigable section of the slip.

The final design, adopted after more than 40 separate experiments, gave the flow pattern shown in Fig. 17. There were no heavy currents across the slip under simulated high- or low-tide conditions and the outflow water was distributed uniformly across the 270 ft of length needed for the baffle section. The design is indicated in greater detail in Fig. 18. The baffles are to be of interlocking steel sheet piling driven in the pattern shown. The section opposite the tunnel outlet is closed off completely and the water made to pass under the wharf platform. In this manner much of the energy of the water is dissipated, because of the turbulence caused by the wood piles and the inward projecting wings of the baffle.

Color moving pictures were taken of the three basic proposals at simulated high- and low-tide conditions with

exaggerated velocities and with the flow scaled down to maintain a constant Froude number. Dye was injected into the tunnel sections and the progressive development of the flow pattern could thus be recorded.

All tests of the final design showed a most satisfactory distribution of flow, as well as complete elimination of concentrated eddies and heavy currents. Formal approval was secured from the governmental agencies concerned and construction of these deflecting baffles is now under way.

Discussion

W. E. Caldwell.[4] The dual-pump arrangement described by the authors is very commendable in that it affords service reliability and high availability for the main unit, in addition to other advantages of an operating nature. In some plants with this arrangement and divided condenser water boxes, alternate halves of the condenser may be cleaned with the units in service. The high summer water temperature probably accounts for the large pump capacity installed, as this factor is an important influence in choosing the size of the condensing plant. However, for a number of months during the year, the circulating water is cold, and the flow may be materially reduced without appreciably impairing the vacuum in the condenser.

It is common practice in some installations to provide variable-speed (or two-speed) drives on the circulating pumps in order to save pumping power during the cold weather. No mention was made of variable-speed operation in this installation, and it may be possible that such provision has been made. The height of the condenser and water-box discharge, with respect to low water, handicaps low-speed considerations, since the occasional low tides, with incomplete siphon recovery, would necessitate undue operating vigilance by the pump attendants to avoid loss of circulating water. While it may be possible to operate one pump on the whole condenser with some saving in power, it is a less attractive method, since the change in head-volume relations results in operation at an unfavorable point on the efficiency curve. Furthermore, reliability is sacrificed, since the entire machine is dependent upon the single pumping unit.

Experience indicates that with the water-temperature conditions reported in the paper, there is economic justification for reduced-flow operation, at least 4000 hr per year.

With induction-motor drive, the choice of the low speed depends upon the winter water temperature and the number of poles required for high-speed operation. With water temperatures indicated in the paper and favorable hydraulic circuit, economic considerations would probably establish the low speed at about 60 per cent of summer speed. At 60 per cent speed, the head on the pump drops to 9 ft, assuming full siphon recovery, resulting in a saving in pumping power of about 700 hp per unit.

There would be a slight reduction in vacuum during part of this time which would be largely offset by increased condensate temperature for the entire period which, combined with the inability of the turbine to profitably utilize extremely high vacuum, practically amounts to a thermal standoff. Aside from the large power saving, resulting from reduced-speed operation during the cold-water season, lower maintenance on pump and condenser tubes follows the reduction in water velocity.

The large capital value of the power-saving possibilities with reduced-speed operation would seem sufficient to exceed the cost of correcting almost any foundation problem necessary to permit more complete siphon recovery.

Authors' Closure

In reply to Mr. Caldwell, the circulating pumps at Southwark Station will not be connected to variable-speed drives. Consideration was given in the design of the circulating-water system to the possible use of variable-speed drives, or adjustable-blade propeller-type pumps. Of the two methods for varying circulating-water discharge, the latter appeared to be the more advantageous. Both schemes, however, were discarded when investigation indicated that operating savings were insufficient to pay an adequate return on the added investment.

The low-pressure turbines at Southwark Station are of the double-flow type. The blading in the last stages has been carefully designed to eliminate crowding. These machines will, we believe, profitably utilize the extremely high vacuum, made possible by the use of large quantities of cold river water during the winter months. Rather than level off the vacuum at a point obtained by two-pump operation and summer water temperatures, the saving in the coal rate together with the elimination of a comparatively costly variable-speed drive and control will, viewing the situation broadly, more than compensate for the additional power used at the pumps. Increased condensate temperature is, of course, only obtained at the sacrifice of working the turbine against a higher back pressure with the resultant drop in over-all efficiency.

As has been indicated, it will be possible to carry a substantial load on the turbogenerator with one circulating pump. Under these conditions, it is true that the pump is working to the right of and below the best point on the efficiency curve. However, one-pump operation will be resorted to only in the event of pump failure, which with this type of equipment is a remote possibility.

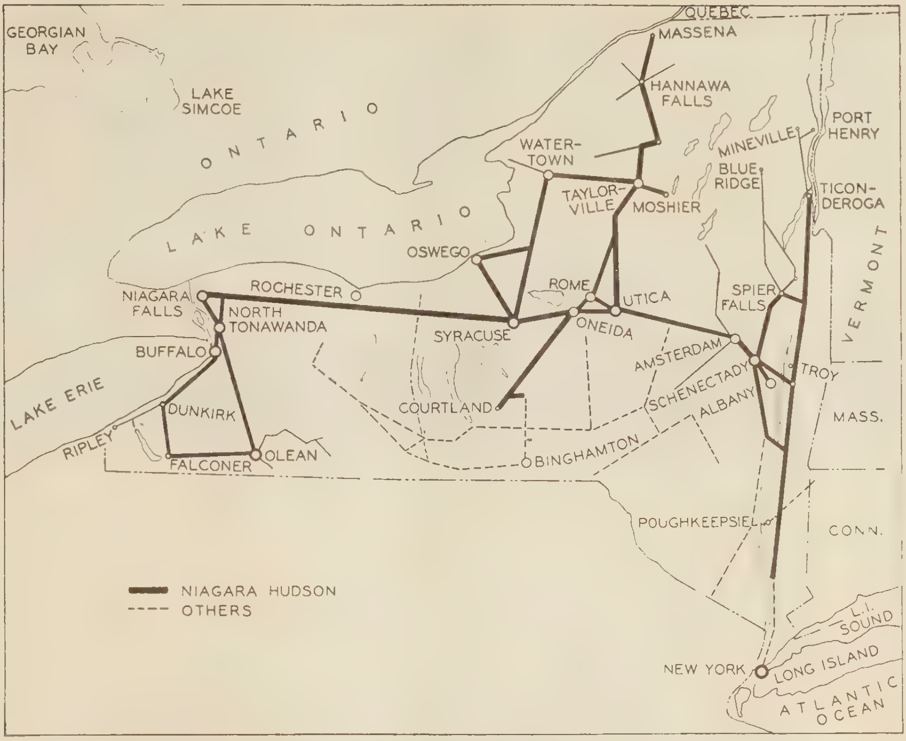

Fig. 1 Map Showing Central Location of Oswego Steam Station on Niagara Hudson Transmission System

Advanced Design—Original Features Embodied in New 160,000-Kw Oswego Steam Station

By N. R. Gibson[1] and H. M. Cushing,[2] Buffalo, N. Y.

Advanced design is the keynote of the new 160,000-kw Oswego Station of the Niagara Hudson Power System. In the present paper, the many outstanding and original features incorporated in this two-unit, one-boiler-per-turbine plant are described and illustrated. Among these are the 80,000-kw single-spindle condensing turbine for 1250-psi 900-F steam; soot blowers which use 250-lb compressed air for the blowing medium to save 1250-lb steam, and which operate automatically in succession on a preselected schedule; electric couplings of the eddy-current type for control of fan speeds; pilot operation of boiler safety valves for obtaining better protection and reduced maintenance; acceleration of the main generator for synchronous-condenser operation by motorizing its direct-connected exciter.

The normal growth of the Niagara Hudson System is in the order of 40,000 kw per year. Its annual peak is in excess of 1,500,000 kw. About two thirds of the energy used is generated by hydro and one third by steam. Its high-voltage transmission lines extend from Buffalo to New York City through the industrial sections of New York State, as shown in Fig. 1. The System is operated as three divisions, Eastern, Central, and Western. The yearly growth of the 60-cycle loads is about equal in the three divisions. To provide for growth and to maintain adequate reserves, it was decided to add 80,000-kw steam-generating units, one for operation in 1940, one in 1941, and a third unit in 1942.

Selecting a Site for the New Station

Load studies showed that the first two units should be installed

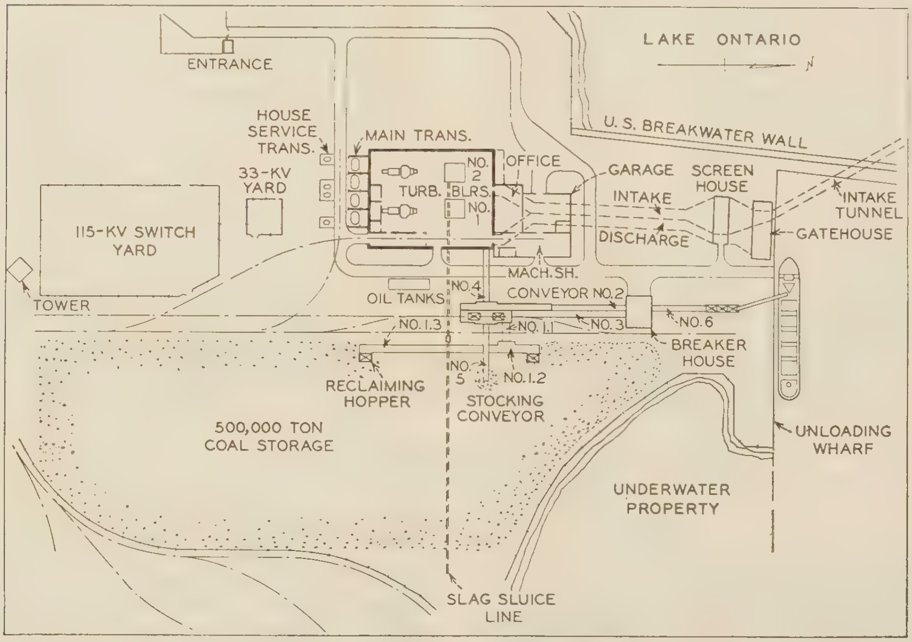

Fig. 3 Plot Plan of Oswego Steam Station

in the Central Division and the third unit in the Western Division. Sixteen possible powerhouse sites (twelve lake and four river locations) were studied before the present site at the west end of the Oswego harbor was selected for the location of the first two units. This new station is designed for an ultimate capacity of 400,000 kw. An unlimited supply of clean cool condensing water is available from Lake Ontario. Rail and water facilities already existed for bringing in the coal. This site has excellent foundation conditions, and it was possible to work in the open while constructing the foundations, intake and discharge canals, and the intake tunnel. Fig. 2 shows the steam plant as it is viewed from the harbor, and a plot plan, Fig. 3, shows its location on the property. Circulating water for condensing purposes is normally drawn from the lake through a 550-ft-long rock excavated tunnel under the west end of the breakwater wall and discharged into the harbor. The circulation can be reversed to meet storm and ice conditions, or it can take place wholly within the harbor, or be partially recirculated.

Service conditions required that the plant be built for maximum flexibility of operation, i.e., for maximum load during low flow at the hydroplants, minimum load of 4000 kw per turbine on stand-by, and rapidly varying load on frequency control. The generator may readily be disconnected from the turbine for operation as a synchronous condenser during maximum flow of the hydroplants. Each 80,000-kw turbogenerator is supplied by a single steam generator, having a capacity of 900,000 lb of steam per hour. This capacity of the unit is about five per cent of the system's peak load.

The reasons for selecting a one-boiler-per-turbine plant were recognition of the reliability of modern boilers, simplification in the station design, and lowest capital, maintenance, and operating costs.

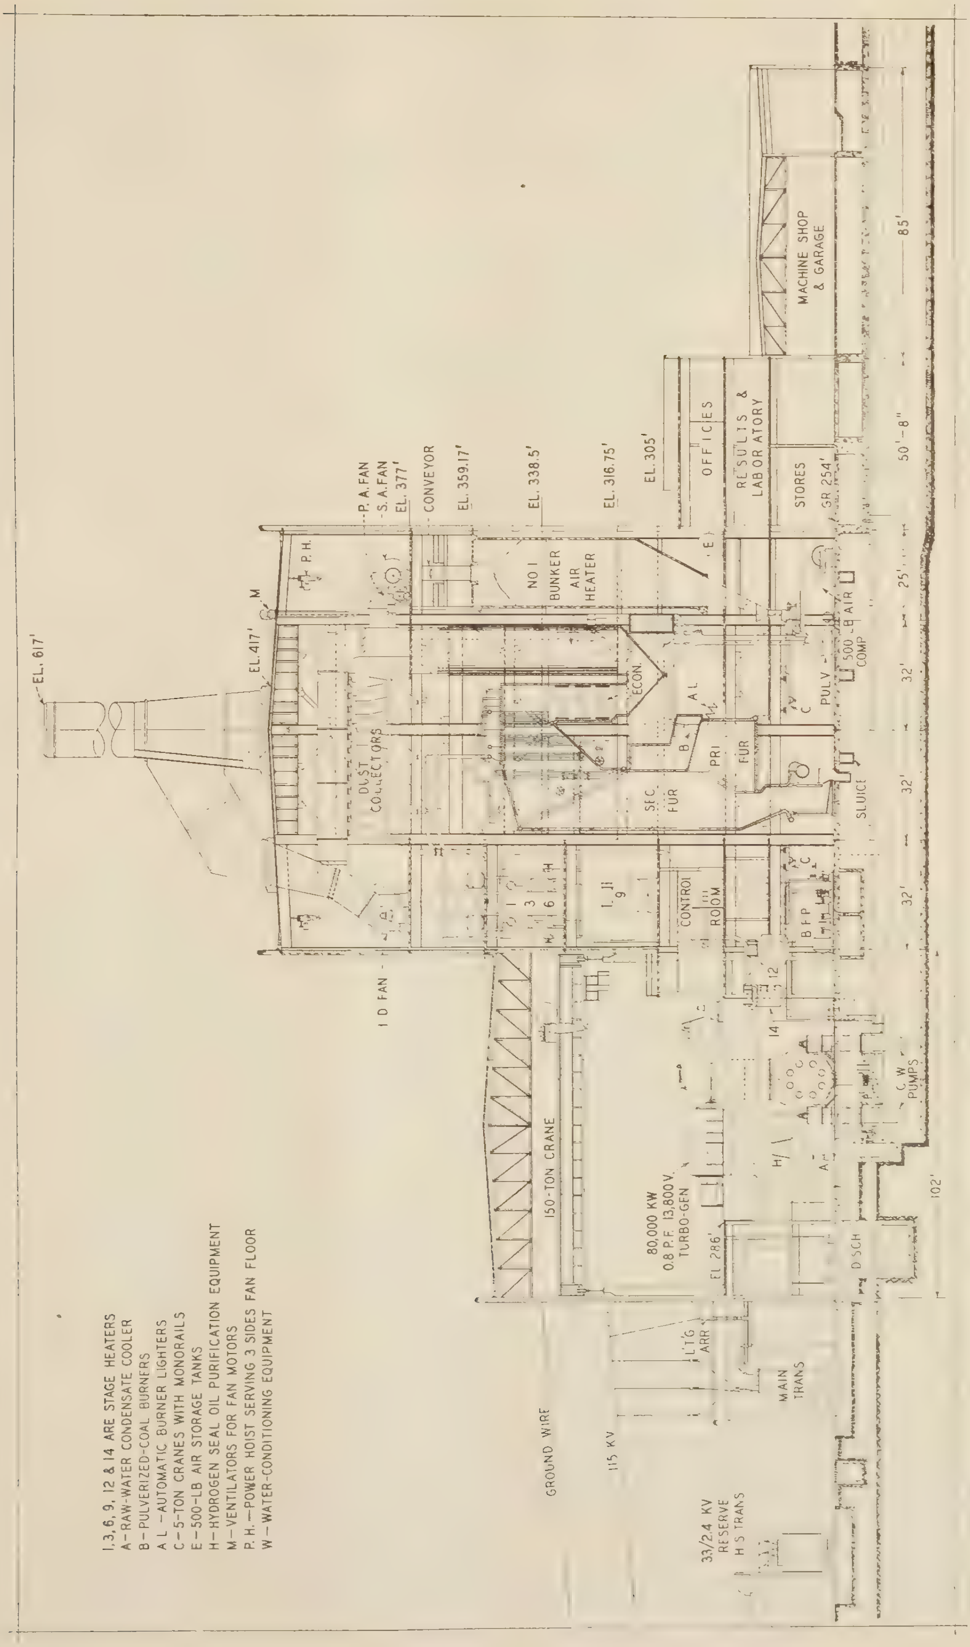

FIG. 4 CROSS SECTION OF OSWEGO STEAM STATION

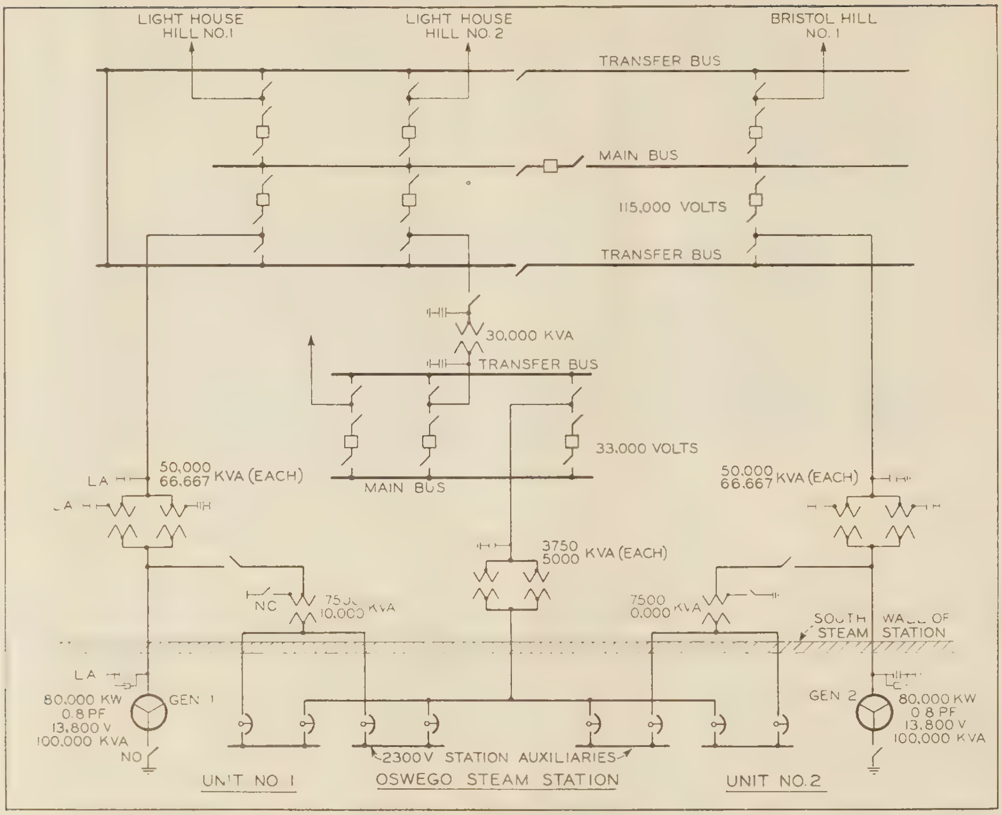

Fig. 5 Schematic Diagram of Main Electrical Connections

Coal Handling

Standard road-building equipment is used for storing, compacting, and reclaiming the coal. Diesel-powered tractors of 113 hp, having a bulldozer attachment, either push the coal to its position or pull a 23-cu-yd-capacity wagon which can be loaded or emptied when in motion by the tractor operator. The coal is stored in a layer and compacted, as the next layer is being deposited, to prevent spontaneous combustion. Thus there is no limit to the height to which the coal can be stored. Space was available for storing 500,000 tons of coal and additional space will be made available by filling the underwater section of the property with slag from the plant. Coal is delivered in 4000-ton-capacity self-unloading vessels which discharge at the rate of 800 tons per hr. Two hopper-bottom railroad cars can be unloaded simultaneously over track hoppers. Rubber-lined canvas belts 42 in. wide of 600 tons capacity per hour (400 fpm) transport the boat- and rail-delivered coal to the bunkers or to the initial pile for storage. The same belts carry the coal from the reclaiming hoppers in the storage yard to the bunkers. A Bradford breaker is in the circuit mainly for cleaning but will also be used for crushing lump coal. A test sample of coal for the laboratory is taken automatically from the stream of coal as it discharges from one of the belts. All coal is weighed on a weightometer as it passes over No. 3 belt en route to the bunkers or to the yard storage. This weightometer is equipped with a master register for all the coal passing over it and a subregister for each of three delivery points.

Building Equipment and Stacks

The mechanical equipment of the building consists of (1) two automatic push-button-operated elevators, one in the service building and one in the boilerhouse; (2) two 100-hp oil-fired heating boilers; (3) one 150-ton 100-ft-span turbine-room crane with a 15-ton auxiliary hoist; (4) three 15-ton cranes with power hoists, one for the machine shop, one for the gatehouse, one with a monorail attachment on the top floor of the boilerhouse; (5) two 5-ton hand-operated cranes with monorail attachments to move material from the track bay lengthwise of the plant to the pulverizers and boiler feed pumps, respectively, with a crosswise monorail at each of the equipment locations. All of these devices were used extensively during construction. There are two stacks each 16 ft in diam, fabricated of steel sheets butt-welded, lined with 2 in. of gunite, which extend 200 ft above the powerhouse roof.

Turbogenerators and Electrical Connections

The turbine generators are rated 80,000 kw, 0.8 pf, 13.8 kv, 3 phase, 60 cycle, 1800 rpm, 1250 lb, 900 F, 17 stage, single cylinder, and each is supplied by a 900,000-lb steam per hr radiant steam generator. The first unit was placed in regular service on December 1, 1940, and the second unit on August 1, 1941. These two generating units, their auxiliaries, and three 115-kv and one 33-kv transmission lines are controlled from one centrally located control room shown in Fig. 4. The station is connected to the main, east-west, 115-kv bulk-power system and also to the local 33-kv system. The 33-kv system is supplied normally by a number of near-by hydrostations and becomes, therefore, a reliable alternative source of power for starting up the steam-station auxiliaries. The connections of the station to the high-voltage transmission system are shown in Fig. 5. Two 3-phase, 50,000-kva (66,667-kva fan-cooled), delta-wye, 13.2/115-kv transformers are connected solidly to the leads of each generator without intervening switching. A main and a transfer 115-kv

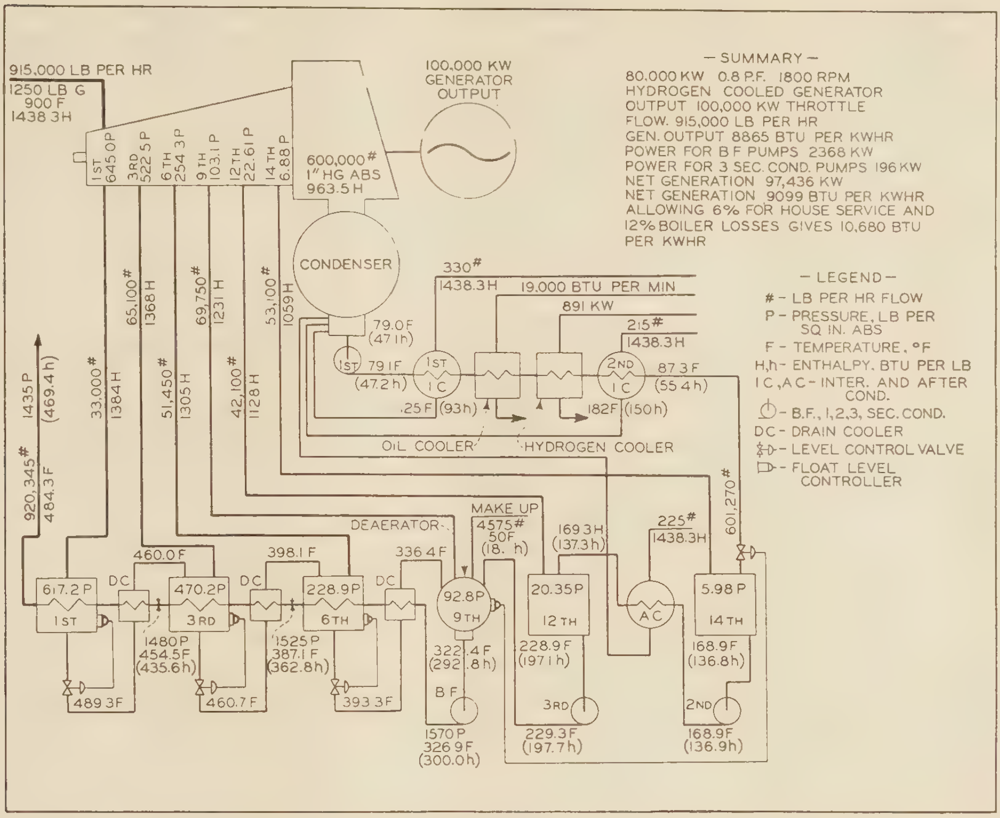

Fig. 6 Heat-Balance Diagram for 100,000-Kw Unity-Power-Factor Output From Oswego Turbogenerator

bus are provided. The 33-kv local system is connected to the 115-kv station bus through one 30,000-kva, 33/115-kv, wye-delta bank of three single-phase transformers which were rewound for this service. Phase-to-ground current of a generator fault is limited by the impedance of the 7500-kva station-service transformer which is connected solidly to the generator leads. The turbogenerator is hydrogen-cooled and has 250-v excitation from a 300-kw, direct-connected, shunt-wound exciter with a 4-kw, 250-v, direct-connected pilot exciter. The main exciter is used as a starting motor to accelerate the generator (when it is disconnected from the turbine) for synchronous-condenser operation. A 500-kw motor generator set supplies the accelerating power. Automatic frequency control has been provided to enable this station to assist in the regulation of system frequency when the units are not operating at their maximum or minimum capacity.

Lightning protection is provided for all of the transformers by arresters and gaps, and for the generators by arresters and capacitors. The outdoor switching stations are protected from direct strokes by the station stacks, supplemented by extensions to the outdoor steel structures to form lightning rods. An extensive grounding grid was installed underneath the entire powerhouse and outdoor stations.

Turbines

Each turbine is so designed that all the steam passes through the first-stage nozzles and the first-stage wheel. Ten normal operating valves, five in the upper valve chest and five in the lower, admit steam to different sections of the first-stage wheel, and four overload valves by-pass the second- and third-stage wheels. The turbine will pass 956,000 lb of steam per hr with 1250-lb 900-F steam and $2^1/_2$-in-abs Hg back pressure when operating with full extraction from its six bleed points. A motor-operated turning device is used to keep the turbine shaft straight during cooling.

The turbine-generator unit has been provided with a complete set of electronic-tube-operated supervisory instruments whose respective functions are:

1 The eccentricity recorder indicates and records in mils the eccentricity of the front end of the turbine shaft.

2 The vibration-amplitude recorder indicates and records in mils the transverse vibrations occurring at the four turbine-generator bearings.

3 The interference detector serves as an electric listening rod with a loud-speaker. It is of greatest service during starting and may be switched on or off at will.

4 The expansion recorder gives a continuous graphic record of the axial movement of the head end of the turbine, caused by the expansion of the shell.

5 The speed and camshaft-position recording equipment provides a continuous graphic record of the speed of the turbine during starting and shutting-down periods. When the turbogenerator is synchronized an auxiliary switch on the main circuit breaker cuts out the speed recorder and connects in the camshaft-position device which indicates the amount of valve opening, as a measure of the turbine loading.

The solid coupling between the turbine and generator has been designed so that it can be easily and quickly disconnected when the generator is to be used for synchronous-condenser operation. The turbine-exhaust shell and condenser casing are protected against excessive pressures by a vacuum relay, which will trip the turbine stop valve only on rising pressure, should the casing pressure rise above predetermined values. It is now set to op-

erate at 20-in- and 10-in-abs Hg. As a backup protection a copper diaphragm in the exhaust casing will rupture at 18 lb abs.

All oil pumps and the twin oil coolers are located in the main oil tank which is installed below the basement floor level. The main lubricating-oil pump of 430-gpm capacity is driven from the main turbine shaft through worm gears and extended shaft drive. Three motor-driven pumps are installed, one full-capacity a-c-driven, one half-capacity a-c-driven for synchronous-condenser operation, or when the unit is on the turning gear, and one half-capacity pump operated from the 250-v station battery for backup protection. All pressure oil lines are carried through the return lines in an all-welded construction. The main hydraulic-control mechanism is located in the turbine standard from which the oil drainage is conducted down the main-pump drive-shaft chute to the oil tank.

Heat Balance

The turbine is provided with six bleed points of which three supply direct-contact heaters and three supply surface heaters. Two independent constant-speed motor-driven condensate pumps are installed, each of which is built in three sections, incorporated in a common shell. One pump is normally in service, the other a stand-by. The flow of condensate through the three pump sections, the fourteenth-stage jet-type, the twelfth-stage tray-type contact heaters, and the ninth-stage deaerating tray-type storage heater (43,600 lb capacity) is shown on the heat-balance diagram, Fig. 6. The water level in this ninth-stage heater is automatically regulated by a three-element control which operates a diaphragm-type control valve located in the condensate line supplying the fourteenth-stage heater. As shown in the diagram, the condensate picks up heat from the inter- and aftercooled condensers of the air-removal equipment, from the lubricating-oil and hydrogen coolers, as well as from the heaters supplied from the six bleed points on the turbine. The throttle flow to the turbine for 100,000 kw gross generation is expected to be 915,000 lb of 1250-psi gage 900-F steam which makes the throttle heat rate 8865 Btu per kwhr of gross generation. The total house-service power for the station, including that used for lighting, miscellaneous power, and coal handling, has been running less than 6 per cent of the gross generation.

Auxiliary Power

The auxiliary power is supplied normally from two 3-phase, 7500-kva (10,000-kva fan-cooled), wye-delta, 13.2/2.4-kv outdoor transformers (one connected to each generator) and, for starting up and reserve, from two 3-phase, 3750-kva (5000-kva fan-cooled), wye-delta, 33/2.4-kv outdoor transformers, operated as a single bank. There are no steam-driven auxiliaries.

All motors of 150 hp and larger are supplied at 2.3 kv, those smaller at 575 v. Both the 2.3-kv and 575-v station-service supply is divided into two sections. All auxiliary service is supplied by at least two motor-driven devices, i.e., there are two boiler fans of each type, two condenser-circulating-water pumps, two hot-well pumps, etc., connected to opposite sections of their respective buses. As shown in the schematic diagram for the electrical auxiliaries, Fig. 7, each unit normally supplies its own auxiliaries with a backup from the 33-kv system. In case of a voltage failure to a 2.3-kv bus, it will be automatically transferred to the reserve supply. The numeral at the arrow, which indicates a feeder, designates the number of feeders of that type which are connected to that section of the bus. The house-service transformers, stepping down to 2.3 kv, are oil-filled, whereas, those

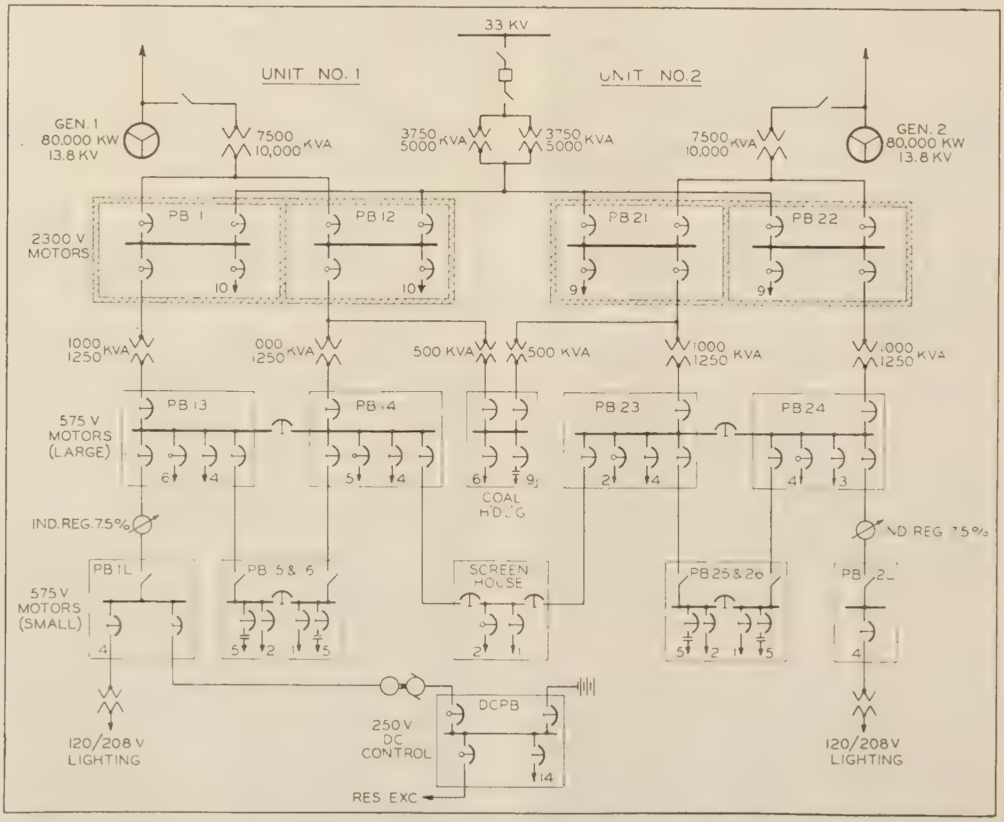

Fig. 7 Schematic Diagram of Electrical Connections for Auxiliary Power

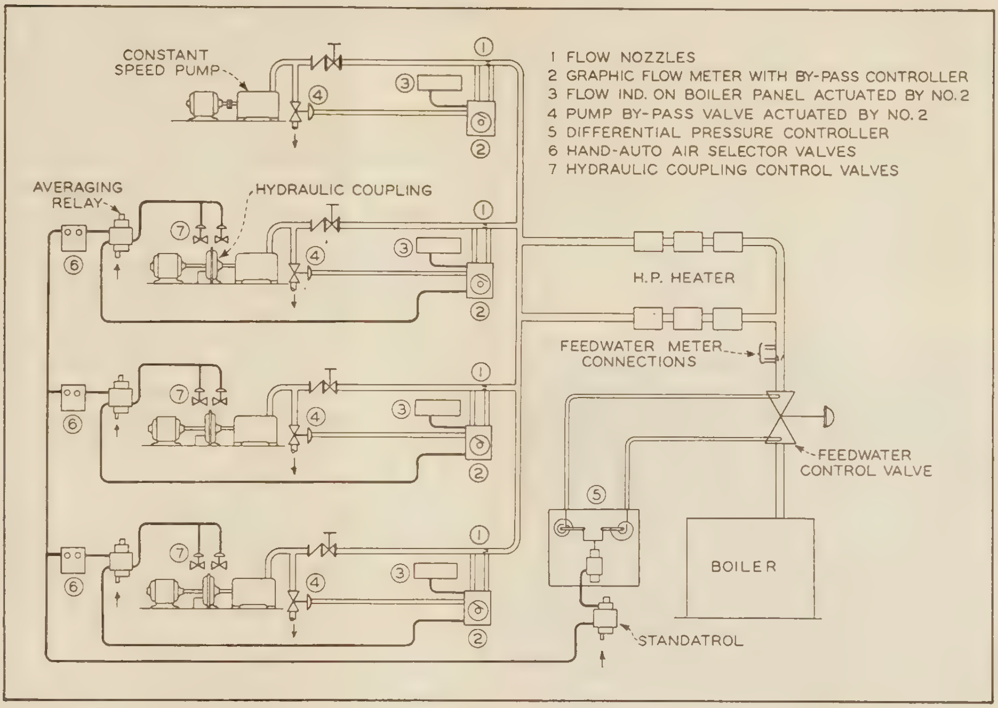

Fig. 8 Controls for Boiler Feed Pumps With Variable-Speed Drives for the Three Large Pumps

stepping down from 2.3 kv to 575 v are pyranol-filled and are located in the boilerhouse adjacent to the 575-v power boards.

Main Condensers

Each 58,600-sq-ft single-pass surface condenser will maintain 1.5 in. Hg abs pressure at the turbine exhaust when 588,000 lb per hr of 974.4-H heat-value steam is being condensed with 83,500 gpm of 70 F circulating water. It has $^7/_8$-in. diam admiralty-metal condenser tubes 29 ft, $8^1/_2$ in. long, and muntz-metal tube sheets and is bolted to the turbine-exhaust shell with part of the weight taken by spring supports. The condenser has a steel shell, which was shop-welded in four sections to facilitate transportation, and bolted together in the field. The cast-iron water boxes have vertical partitions to permit one side of the condenser to be cleaned with the turbine operating at reduced capacity. A sectionalizing gate valve in the inlet-water-box partition, together with a gate valve between each 59,000-gpm vertical-shaft circulating-water pump and the condenser, makes it possible for either pump to supply both sides of the condenser at times of light load. The air-removal apparatus consists of one set of 15-cfm and two sets of 25-cfm three-stage steam ejectors which are supplied with steam at 225 lb, obtained by throttling the 1250-lb 900-F steam by means of a "Flo-control" valve. The inter- and aftercoolers are cooled with condensate.

Boiler Feed Pumps and Their Controls

Three 550,000-lb per hr, 8-stage, 3600-rpm and one 220,000-lb per hr, nine-stage, 3600-rpm boiler feed pumps are installed for each boiler with no feedwater connections to the other unit. Each of the larger pumps is driven by a constant-speed, 1800-rpm, induction motor through a variable-speed, 1800-rpm, hydraulic coupling and a 1-to-2 step-up herringbone gear. The smaller pump is for use at light loads and is driven at a constant speed by a 3600-rpm motor.

The boiler feed piping is welded throughout from the flange at the outlet of the boiler feed pumps to and including the inlet to the economizer. The main carbon-moly steam pipe is also welded throughout, with only one flange in the line between the boiler and the turbine and that is located at the connection to the top turbine valve chest. This chest is integral with top half of turbine and must be raised for turbine inspection.

The pump control is illustrated diagrammatically in Fig. 8. This system is designed to save power by operating feed pumps at the minimum speed required to maintain the desired excess pressure across the three-element feedwater-control valve, and also to regulate automatically the speed of each individual pump so that it carries its share of feedwater. This share may be the same or different from that carried by the other pumps and it may be varied by the operators. Another function of this control is to protect the high-pressure pumps from overheating should feedwater requirements be reduced below the minimum allowable rate of flow. If such a condition occurs, a by-pass valve automatically opens so that the pump circulates at least the minimum allowable flow. The ratio of pressure at the inlet to that at the outlet of the feedwater-control valve is measured by two Bourdon tubes which operate a pilot valve through a ratio linkage. The air loading pressure established by this pilot represents the required feedwater-header pressure. As such, it is transmitted to each pump. Here by means of an averaging relay it is combined with the loading pressure established by a flow controller in the outlet line. In this manner a final control pressure embodying the feedwater-header-pressure requirement as well as the individual pump-speed requirement is established by the averaging relay. The final control pressure for each pump regulates the speed of that pump by means of a variable-speed hydraulic coupling. A constant-speed pump is also installed, and the feedwater flow is controlled only by the boiler feed valve. This pump is intended to operate by itself at times of light load.

Steam Generators

The steam generators are of the radiant type, rated to deliver 900,000 lb of 1320-lb 900-F steam with a furnace heat release of one billion Btu per hr. The boiler has a 66-in-ID top drum and a 30-in-ID bottom drum and is suspended from the building steel 111 ft above the basement floor. It expands downward $4^3/_8$ in. from cold to hot. It has a primary and secondary furnace, two nondraining superheaters having a total heating surface of 25,300 sq ft, one 26,900-sq-ft steaming economizer, and two tubular air heaters having a total heating surface of 147,500 sq ft. The primary furnace has a volume of 9900 cu ft and is lined with partially studded tubes, while the secondary furnace has a volume

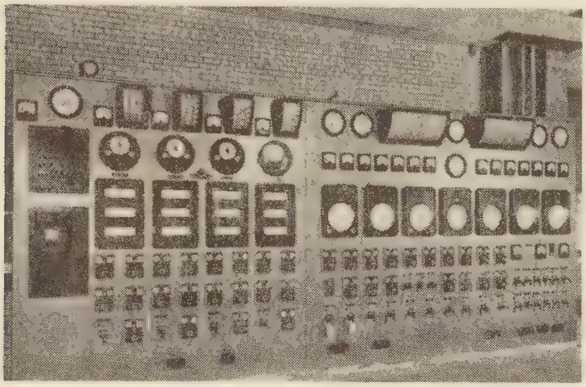

Fig. 9 View of Boiler- and Turbine-Control Board for Unit No. 1

(This room is air-conditioned and contains the control boards for both units including the main electrical control board.)

of 33,620 cu ft and is surrounded on three sides and the roof with closely spaced bare tubes. The energy of discharge of the water entering the drum is put to useful work by the cyclones in the drum to separate the water from the steam as the mixture of steam and water rush into the drum from the generating tubes. The water recirculated amounts to 15 times the output of steam from the boiler at its rated capacity, and a higher proportional value at lower loads. A damper in the center gas by-pass between the two superheaters provides a means of controlling the superheat temperature, and dampers in the exit-gas circuit from each superheater afford means for equalizing the temperatures at the outlet of each superheater. Their operation is effective in keeping the temperatures together under all operating conditions, including that of one pulverizer carrying two thirds of the rated boiler capacity. No metal covering is provided over the heat insulation of the boiler and furnace.

The furnace is of the continuous-tap design and the slag drains through two openings in the screen tubes between the primary and secondary furnaces into a water-filled compartment from which it is periodically sluiced to the yard. The boiler controls, located in the control room, occupy the left-hand two thirds of the control board shown in Fig. 9, the turbine controls occupying the remaining third. Four type E56 pulverizers, each with a pair of vertical intertube burners, have been provided. Three of these are guaranteed to operate the boiler at 900,000 lb of steam per hr when grinding 60-grindability, 8 per cent ash, 13,000-Btu coal to a fineness of 70 per cent through a 200-mesh sieve. A load of 600,000 lb of steam per hr has been carried for one hour by one pulverizer grinding 55,000 lb per hr of 90-grindability, 8 per cent ash coal with power input to the pulverizer motor of 72 kw.

The most highly prized accessories to the pulverized-coal-firing equipment are the fuel-oil lighters. The push of an electric button on the boiler panel starts the fuel-oil pump. The oil pressure injects the lighter into the furnace and an electric spark ignites the oil. Within seconds a fat oil flame is burning beneath each pulverized-fuel burner, resulting in positive ignition of pulverized coal as soon as it appears in the furnace. The lighters are used each time a new burner is brought into service whether or not there is coal flame in the furnace from other burners. There never has been even a minor puff in the furnace.

The following special metering equipment has been provided to indicate and record the condition of feedwater, boiler water, and flue gases: (1) Ohmmeters to give the conductivity of the condensate from the main and evaporator condensers; (2) steam-purity meters to give in microhms the purity of the steam entering and leaving the superheater; (3) a meter with degasifying equipment to show the hydrogen emitted with the steam; and (4) also an oxygen-analyzing equipment to record the percentage of oxygen in the flue gases.

Safety Valves

All drum and superheater safety valves are provided with actuating cylinders which enable the valves to be popped by air from a centrally located control station on the operating floor or by steam from pilot safety valves. These pilot-actuator safety valves are installed, one on the boiler drum and two on the steam lines at the turbine stop valve. These give added protection to the superheater and turbine because of the big drop in pressure in the superheater and steam mains, Fig. 10. Gate valves, installed under the pilot valves, permit them to be maintained without a boiler outage, because the main valves provide the boiler-code requirements. The advantages of the scheme are: (1) It reduces the wear on the main valves by forcing them to have a

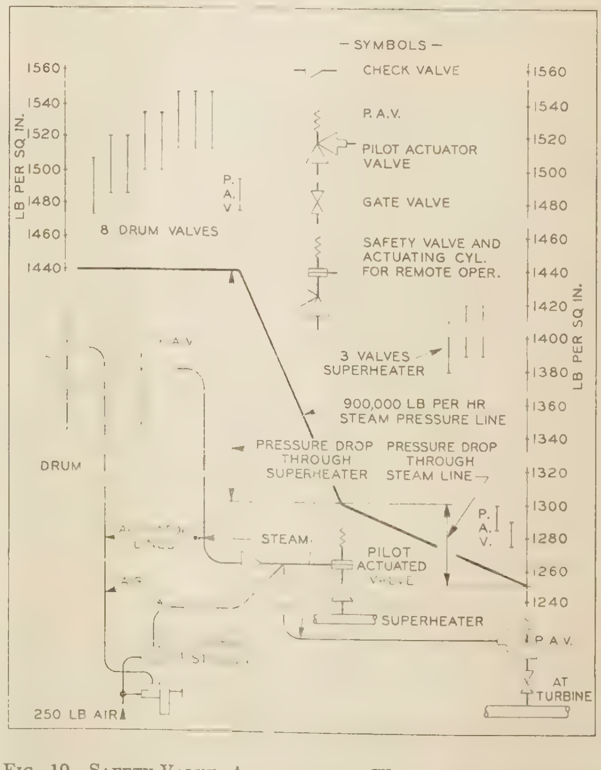

Fig. 10 Safety-Valve Arrangement Which Provides Added Protection to Turbine and Increased Operating Continuity of Boiler by the Use of Actuating Cylinders on Main Valves, Together With Pilot Safety Valves With Actuating Lines

sharp opening and closing; (2) most of the wear is taken on small valves which are easier and less expensive to repair; (3) it reduces the boiler outages required to repair safety valves; and (4) more effective protection is afforded the superheater and turbine.

Soot Blowing

The conventional method of cleaning boilers has been to use steam as the blowing medium but this becomes less desirable as higher steam pressures are used. The decision was made to use 250-lb air, after carefully considering four means of obtaining steam. The studies show that air-blowing takes no more energy from the coal pile, takes no water from the boiler, eliminates the expansion and warming-up problems of the steam-blower piping, lends itself admirably to automatic control, and is more suitable to combine with water than steam with water, should the blowing conditions call for water. Four 500-cfm 500-lb compressors, with storage tanks and pressure-reducing valves, supply a 250-lb tank from which the air for blowing is obtained. With the operating conditions obtaining to date, the blowers are actually taking about one half the air provided for blowing and are doing an excellent job. Poorer coals and worn tube surfaces will require more air. The automatic program board is at the extreme left of the boiler panel, shown in Fig. 9.

The advantages of this automatic soot-blowing system are as follows:

1 Preselected sequential automatic operation from a central point reduces labor and operating costs; assures a definite time duration for operation of each unit, each time it is blown, without the attention of the operator; gives direct control of boiler cleanliness independent of the human element; enables the operator to tell at a glance which group is then operating, and which groups have completed their operation.

2 The blower grouping sectionalizes the heating surface into zones so that normal heat absorption can be maintained in each zone by the frequency of group operation.

3 Puff operation on units provides automatic rotation of the soot blowers with a minimum amount of air.

4 The use of nozzles of the mass-blowing type provides greater bank penetration and does not require maintaining accurate alignment with the tube lanes.

5 Retracting units are used in all locations where equipment permanently installed in gas flow may not give satisfactory life.

6 Intermittent blowing is employed on the traveling-frame air-heater blowers to save air and to avoid impingement on the tube sheets.

7 The telescopic blowers are projected into the boiler at twice the retracting or normal cleaning speed to save 25 per cent of the air required for a complete cycle at normal speed.

8 No blower can start operation unless the air pressure is up to a predetermined value, thereby assuring effective cleaning.

Control features for protection of the automatic equipment are:

1 Alarm system both visible and audible indicates motor overload. It is arranged to show the same percentage of load regardless of different motor sizes.

2 The air-control valves to the telescopic blowers have electrically operated latches to prevent their closing should current fail. This assures cooling air for the blowers until the primary-air receivers are exhausted. When current is restored, the blowers automatically return to their retracted positions even though they had been moving forward when current failed.

Automatic Combustion Control

The combustion-control system is based on the correct proportioning of the coal and the air to each pulverizer and its burners. The premeasuring system, as originally developed by R. C. Roe, has been modified to increase the speed of response to provide for rapid changes in load. As previously stated, each turbine is supplied by one boiler having a complement of two primary-air fans, two forced-draft fans, two induced-draft fans, and four type

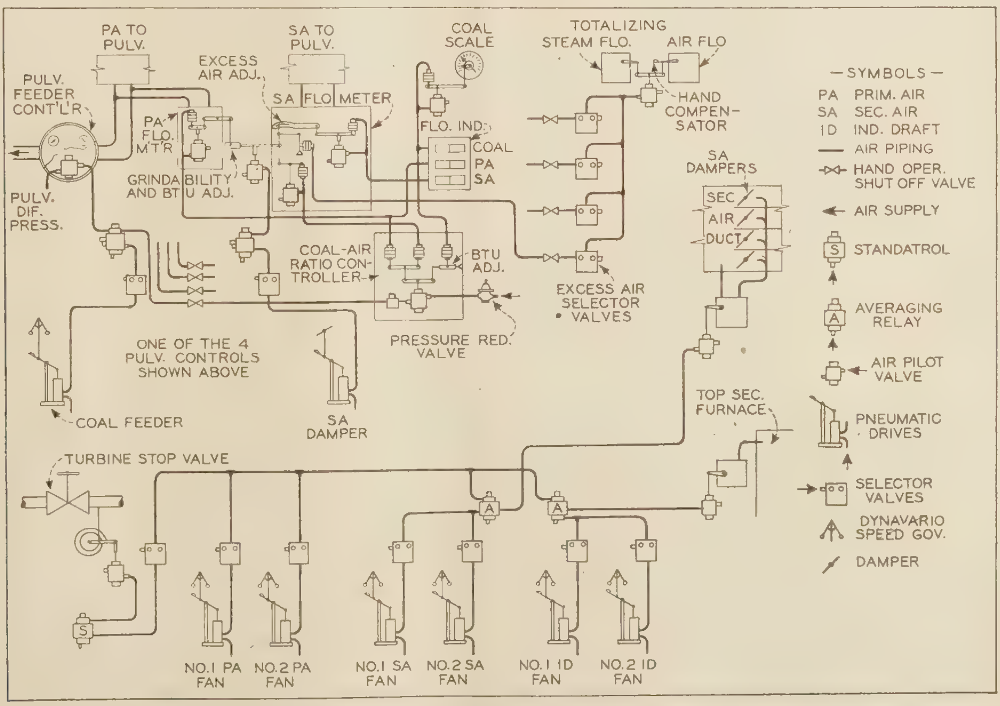

Fig. 11 Automatic-Combustion-Control System for 900,000-Lb per Hr Steam Generator, Using Compressed Air as Control Medium

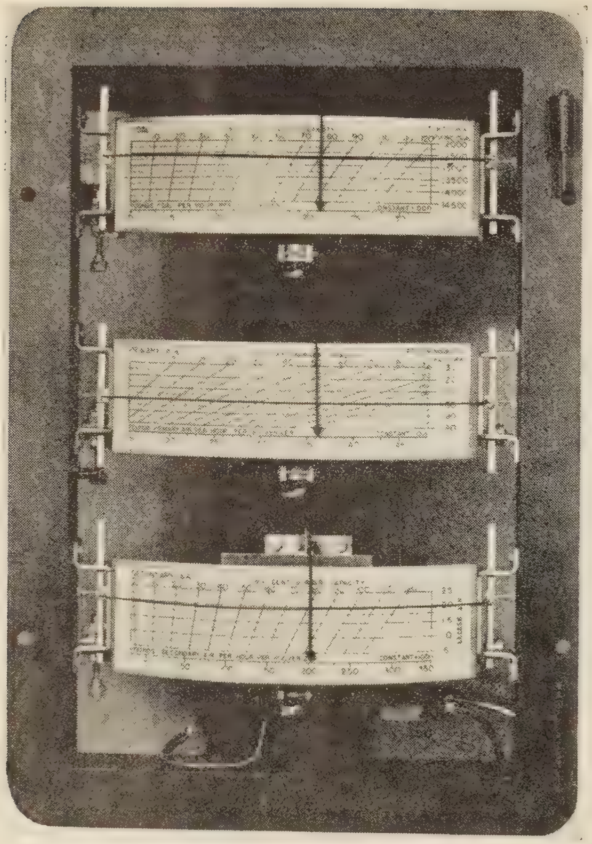

Fig. 12 Furnace-Flow Indicator, One for Each Pulverizer, Showing Pounds per Hour of Coal, Primary Air, and Secondary Air to Each Pair of Burners

E pulverizers, each with its coal scale and raw-coal feeder. Each pulverizer supplies two burners. The fans and raw-coal feeders are individually driven by constant-speed motors through variable-speed eddy-current couplings. The coupling speed in each case is controlled by a built-in Dynavario governor whose setting is positioned by a pneumatic-drive unit. The primary air and secondary air, and the coal for each pulverizer and its burners, are measured in the manner shown in Fig. 11. The air-measuring elements are equipped with automatic temperature compensators. These meters supply flow indicators, Fig. 12, which indicate the rate of flow in pounds per hour of the coal, of the primary air, and of the secondary air being delivered to each pulverizer and its pair of burners. These indicators are located on the control panels as shown in Fig. 9.

The control is actuated by a master steam-pressure controller connected to maintain constant pressure at the turbine stop valve. The control medium is compressed air supplied by compressors with carbon rings, aftercoolers, and filters which keep the air supply free from oil, water, and dirt. The steam-pressure controller sends air loading pressure simultaneously to the pneumatic drives which adjust the speed of the primary air, secondary air, and induced-draft fans. Changes in primary-air flow immediately affect the pressure drop across the pulverizer. This change in pressure drop calls for adjustments in the fuel feed through the action of the pulverizer-feeder controller, whose pilot valve sends a loading pressure to the coal-feeder pneumatic-control drive. Therefore, a loading pressure set up by the master pressure controller increases or decreases the speed of the primary, secondary, and induced-draft fans and also the speed of the raw-coal feeders, as required by variations in steam pressure. The induced-draft and the secondary pneumatic-control drives are further modified from other control points by means of averaging relays in the air circuits, i.e., the induced-draft-fan speeds are readjusted to maintain 0.3 in. water suction at the top of the secondary furnace, and the secondary-air-fan speeds are readjusted to maintain a predetermined minimum pressure drop across the control dampers in the secondary-air ducts. While these operations are taking place, the premeasuring control equipment is readjusting the fuel and air conditions to each individual pulverizer and its pair of burners, for the purpose of maintaining the proper relation between the primary air and the secondary air, and the proper relation between the coal feed and the sum of the primary and secondary air.

A common method of automatic combustion control is based on the assumption that the volumetric products of combustion as they leave the furnace or pass by the boiler heating surface are a true index of the amount of air required for combustion. This assumption is not correct, and at best the index is only an approximation. The volume of the gas, consisting of the products of combustion, in relation to its weight, varies with changes of both pressure and temperature and also varies to some degree due to different proportioning of the constituent elements of the products of combustion. The volumetric measurement referred to is generally taken across some portions of the heating surface of the boiler or its appurtenances. Inasmuch as draft loss (and hence the pressure of gas at the point where the measurement is taken) varies both with the rating of the boiler and with the cleanliness of the heating surfaces, and inasmuch as the temperature of the gas at the point where the measurement is taken also varies both with the rating of the boiler and the cleanliness of the heating surface preceding the point of measurement, it is readily seen that a volumetric measurement is not a true indication of the weight of the products of combustion. It has been claimed that these volumetric measurements repeat themselves for the same steam-flow conditions from the boiler. However, this too is not a fact because the cleanliness of the boiler affects both heat transfer and draft losses; and draft losses, of course, affect pressure. Therefore an adjustment of the meter to give air quantities based on volumetric measurement of flow of the products of combustion is in essence a reasonably accurate adjustment only for the conditions existing at the time the adjustment was made and may vary with other conditions of cleanliness, or with a change of fuel, or with other changes in basic conditions which were not present at the time the adjustments were made. Further, the assumption that a volumetric measurement of the products of combustion is equivalent to weight is based on complete combustion, which may or may not be the case.

It is further pointed out that, with installations using two or more pulverizers, the fuel and air ratio for each pulverizer with its burners may vary widely from the ideal ratio, although the total fuel bears a correct relation to the total air entering the furnace. In other words, the burners supplied by one pulverizer may be operating with too large an amount of air and those supplied by another pulverizer may have a deficiency of air resulting in unburned carbon. Therefore, while the totals are correct, the combustion in the furnace may be badly unbalanced. With the system installed at Oswego, the correct amount of fuel and air is supplied to each combination of pulverizer and burners. It is expected that this premeasuring scheme will result in a coal saving in the order of one half of one per cent.

In order that a comparison may be made between the two systems of control, i.e., the premeasuring unit system and the post-measuring total system, a steam flow-air flow controller was also provided so that the combustion-control system may be operated either on the premeasurement basis of coal and air to each pul-

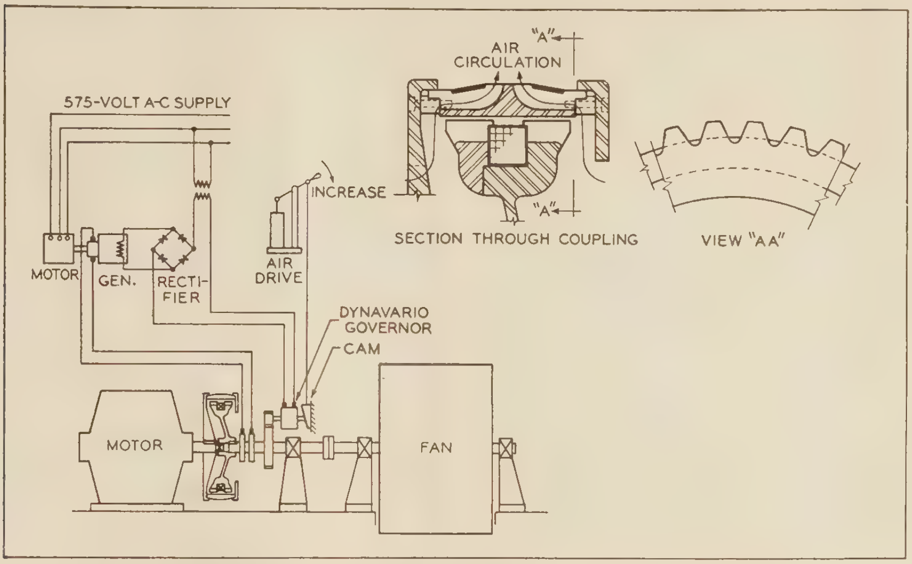

Fig. 13 Variable-Speed Eddy-Current Coupling for 1250-Hp Induced-Draft Fan

verizer or by proportioning the total products of combustion to the total fuel.

The rate of coal feed supplied to each pulverizer is measured by a coal-conveyer-and-scale assembly, which consists of a synchronous-motor-driven conveyer mounted on a Toledo scale so that the actual quantity of coal on the conveyer is measured by the scale at all times. The readings of the scale are pneumatically transmitted to the indicator located on the boiler panel. The coal feed is readjusted to give the correct coal-air ratio to each pulverizer by the individual coal-air-ratio controllers.

The secondary-air control dampers are used for proportioning secondary to primary air for each pulverizer unit. The secondary-air flow to the burners corresponding to each pulverizer is measured and maintained in a definite relation to the primary-air flow by means of primary-air-flow–secondary-air-flow ratio controllers.

Individual shutoff dampers with pneumatic-control drives, for the induced-draft, secondary- and primary-air fans, are provided and so connected as to be actuated by the differential pressure across the dampers, in order to insure maintaining the capacity of any fan of a pair when its mate fails. Pressure connections are made into the duct in such a manner as to obtain the benefit of the velocity effect when the dampers are in a wide-open position at which time the differential pressure across them would be exceptionally small. Thus, whenever a fan is started up, the differential pressure acts in such a way as to open up the corresponding dampers. In case this fan should fail during operation and the slightest amount of recirculation should occur, the dampers would automatically close. The primary ducts to the pulverizers, being supplied from a common plenum chamber, are provided with pneumatically operated shutoff dampers, which serve also as a means of dividing the load between the pulverizers and for cutting them in or out of service. The ten pneumatic damper controls mentioned herein are not shown in the diagram as they are not a part of the automatic combustion controls.

Variable Speed for Fans

Because of the loading conditions on the plant, it was very de-

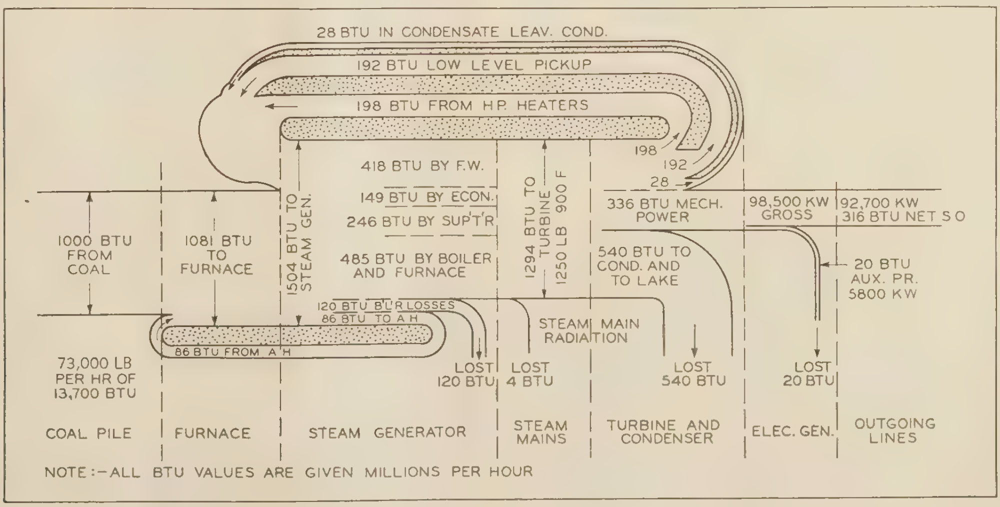

Fig. 14 Heat-Flow Diagram for 900,000-Lb per Hr Output From Oswego Steam Generator

sirable to select fan drives that would permit a wide range in speed adjustment. After careful consideration of the various types of drives and methods available, it was decided to install electric couplings of the eddy-current type for the induced-draft, secondary-air, and primary-air fans. Some of their outstanding advantages are: (1) No large quantities of oil are required; (2) speed reductions up to 90 per cent are obtainable by simple means; (3) an infinite number of speed points are available; (4) response is practically instantaneous; (5) the heat is generated in the constant-speed drum and dissipated by the fan action of the coupling itself; (6) permit the use of a single motor of the squirrel-cage type; and (7) the governor is designed for linear speed characteristic of the fan, i.e., fan speed directly proportional to control air pressure.

Reference to Fig. 13 will show the elements of a 1250-hp coupling on an induced-draft fan and the pneumatic drive for adjusting the position of the governor. The speed of the fan can be varied from maximum speed down to 10 per cent of maximum speed. At maximum speed, the slip of the coupling is 2.5 per cent of the motor speed and the excitation power is 2500 w. At Oswego, motor generator sets supply the excitation of all the large couplings, except those on the primary-air fans where copper-oxide rectifiers are used.

The variable-speed drives for the raw-coal feeders also contain eddy-current couplings. These drives are rated 2 hp and derive their excitation from selenium rectifiers.

The largest eddy-current coupling built at the time the order was placed for the first Oswego couplings was 150-hp capacity and on that account the first 1250-hp coupling was rushed to completion, installed with its regular motor and fan, and given extensive field tests before the work was released on the other five couplings. The same design of couplings was ordered for the second unit at Oswego and similar couplings for a new unit in the C. R. Huntley Station.

Automatic Controls

In addition to the automatic controls previously described, float-controlled air-actuated valves control the water levels in the high-pressure heaters, and in the hot wells of the main and evaporator condensers. For the main condenser, a second air-operated valve admits water from the open condensate storage tank in case of low water. The superheat temperature at the turbine throttle is controlled by a two-element type of air control, initially positioned by steam flow and readjusted by the steam temperature, which actuates a damper in the gas by-pass around the superheater. The hydrogen is normally cooled by heat exchangers mounted in the turbogenerator frame, but in case the cooling is insufficient because of hot condensate (or new condensate not available in the case of synchronous-condenser operation) the temperature control positions a butterfly valve in a raw-water supply to a special heat exchanger, which is always in the condensate circuit ahead of the hydrogen coolers.

Heat-Flow Diagram

The flow of Btu's through the station when the steam generator is delivering 900,000 lb of steam per hour requiring a heat release in the furnace of one billion heat units per hour is shown in Fig. 14. The heat above 32 F in the air to the forced-draft fans and primary blowers is omitted in order not to complicate the diagram further. The heat which circulates through the steam generator, when operating at its rated capacity, is 50 per cent greater than the heat in the fuel that is being fired. The heat flowing in any part of the circuit, expressed as a percentage of the heat in the fuel fired, is obtained by dropping one digit, for example, the condenser loss of 540 million Btu is 54 per cent of the energy in the fuel.

Fire Protection

Very complete protection against fire hazard is being installed. Fixed water-spray systems are provided for all of the oil-filled power transformers, the oil-filled hydraulic couplings in the boiler feed pumps, turbine-oil tanks and piping, turbine-oil storage room, turbine-oil treatment equipment, repair pit in the turbine room, and the coal-handling conveyer galleries. Some of these systems are automatic in operation and others manual. Fixed hose racks and hose lines with adjustable-spray nozzles are provided throughout the powerhouse in an arrangement whereby any fire can be fought simultaneously by two hose lines. Hose houses were built near the outdoor switching structures which contain hose lines with "poweron" nozzles, and CO_2 and carbon-tetrachloride portable equipment. Portable devices of various types and sizes, including large "foam generators," are strategically placed throughout the property.

Appendix

Equipment Data for Oswego Power Station

Plant Capacity:

Initial capacity....................................160,000 kw
Ultimate capacity..................................400,000 kw

Coal and Ash Handling:

Coal-storing capacity..............................500,000 tons
Coal is received in hopper-bottom railroad cars and in 4000-ton-capacity self-unloading freighters
Belt-conveying equipment for transporting coal to the bunkers or into or out of storage on 42-in. belts at the rate of 600 tons per hr, complete with lump breakers and pan conveyers under the reclaiming hoppers, automatic coal sampler with "Ridler" conveyer, also a Knittle crusher......Stephens-Adamson Manufacturing Co.
Herringbone-gear speed reducers for drives on coal-handling equipment................................Farrel-Birmingham Co.
Rubber-lined 6-ply 32-oz 42-in-width canvas belts..Hewitt Rubber Co.
Weightometer with master and three individual delivery-point registers......................Merrick Scale Manufacturing Co.
Bradford-Hammermill, 12 ft × 19 ft.....Pennsylvania Crusher Co.
3 Model D-8 113-hp Caterpillar Diesel tractors with Model CK-8 LeTourneau angle dozers and two Model W, 23-cu-yd Carryall scrapers.................................Syracuse Supply Co.

Boilers and Furnaces With Auxiliaries:

2 boilers, each rated 900,000 lb of steam per hr continuous at 1320 lb pressure 903 F total temperature, and each with 66-in-ID upper drum and 30-in-ID lower drum, containing 7307 sq ft boiler heating surface; 9779 sq ft of heating surface in primary and secondary furnace walls; 43,520 cu ft furnace volume; armored blocks for primary furnace floor and secondary furnace sidewall observation lanes..................................Babcock & Wilcox Co.
4 pendant-type (2 per boiler) 12,650 sq ft superheaters with a gas passage between.........................Babcock & Wilcox Co.
2 (1 per boiler) 26,900-sq-ft steaming economizers..Babcock & Wilcox Co.
4 (2 per boiler) 73,750-sq-ft-tubular air heaters for primary and secondary air to furnace with dampers to by-pass the second and third air passes to control minimum exit-gas temperatures...Babcock & Wilcox Co.
Superheater refractory side walls...............M. W. Detrick Co.
Boiler and furnace heat insulation.............Johns-Manville Co.
Smoke breechings and ducts............Connery Construction Co.
Steel stacks, 200 ft high, all-welded construction..Chicago Bridge & Iron Co
Stack linings...................................Cement Gun Co
Gage glasses (Bi-color)..............Diamond Power Specialty Co.
Three-element feedwater control of drum level...Bailey Meter Co.
Air soot blowers, preselected automatic blowing..Diamond Power Specialty Co.
8 pulverizers, 12.5 tons per hr capacity.......Babcock & Wilcox Co.

8 raw-coal feeders........................Babcock & Wilcox Co.
8 coal-feed drives (10-to-1 variable-speed a-c motors)..Louis Allis Co.
4 induced-draft, 4 secondary-air, and 4 primary-air fans..........Buffalo Forge Co.
12 variable-speed couplings for fan drives.......Dynamatic Corp.
Dust catchers (multicyclone type)..............Prat-Daniel Corp.
Hydrojet system of dust removal...........Allen-Sherman Hoff Co.
Slag hoppers and slag-handling equipment...Allen-Sherman Hoff Co.
Coal hoppers; extensions to concrete bunkers...Chicago Bridge Co.
Valves in raw-coal spouts...................Stock Engineering Co.
2 two-stage hot-process lime-soda water-conditioning system, with integral deaerating heaters arranged for phosphate feed into second stage; capacity 30,000 lb per hr................Cochrane Corp.
2 evaporators with evaporator condensers; capacity each, 30,000 lb per hr...............................Griscom-Russell Co.
Heat exchangers for evaporators..............Alberger Heater Co.

Turbines and Auxiliaries:

2 turbine generators 80,000 kw, 0.8 pf, single cylinder, 17 stage, 1250 lb, 900 F, 3 phase, 60 cycle, 13.8 kv with $1^1/_2$ rpm turning gear and hydrogen cooling for generator, 300-kw, 250-v, direct-driven exciter and 4-kw pilot exciter.....................General Electric Co.
2 single-pass steel-shell condensers mounted on springs and bolted solid to turbine exhaust; 58,600 sq ft of surface. Condensers have $^7/_8$-in-OD admiralty tubes, divided water boxes, reheating hot wells, and steam-jet air-removal equipment with inter-, after-, and tertiary condensate-cooled condensers..........Worthington Pump & Machinery Corp.
2 sets (1 per turbine) of direct-contact heaters, with vent condensers for fourteenth-, twelfth-, and ninth-stage bleed points of turbine.........Foster Wheeler Corp.
4 sets (2 per turbine) of high-pressure horizontal heaters, with hairpin tubes and subcoolers for sixth-, third-, and first-stage bleed points of turbine; capacity 457,000 lb per hr, each..Griscom-Russell Co.
2 raw-water coolers for condensate for synchronous-condenser operation......................................Ross-Heater Corp.

Pumps:

4 vertical-shaft (2 per unit), 59,000-gpm, 400-rpm, circulating-water pumps with rubber guide bearings..........Worthington Pump & Machinery Corp.
4 (2 per unit) three-section condensate pumps to deliver condensate to the direct-contact heaters..............Foster Wheeler Corp.
6 (3 per unit) 550,000-lb-per-hr (2000 lb at shutoff), 8-stage, 3600-rpm, horizontally split casing boiler feed pumps. Ingersoll-Rand Co.
6 herringbone 1750 hp, 1-to-2 step-up gears for boiler feed pumps.........DeLaval Steam Turbine Company
6 variable-speed hydraulic couplings, 1750 hp 1800 rpm to give 22 per cent speed reduction for boiler feed pumps.........American Blower Co.
2 nine-stage, 3600-rpm, constant-speed, boiler feed pumps; capacity 220,000 lb per hr, each.....................Ingersoll-Rand Co.
2 "Hydroseal," 1000-gpm, horizontal-shaft, slag-handling pumps with adjustable-speed V-belt drive...........Allen-Sherman Hoff Co.
2 horizontal-shaft slag-sluicing pumps; capacity each 750 gpm at 518 ft total head.........................Buffalo Pumps, Inc.
1 horizontal-shaft house-service pump; capacity 750 gpm at 200 ft total head...............................Morris Machine Co.
3 horizontal-shaft low-service pumps; capacity 1200 gpm at 115 ft total head...............................Morris Machine Co.
2 pumps of 1700 gpm capacity, 25 ft head, supplying raw water to auxiliary coolers..........................Morris Machine Co.
4 condensate-circulator pumps; capacity 700 gpm at 25 ft head.........Ingersoll-Rand Co.
3 screenhouse washing pumps; capacity 350 gpm at 200 ft head.........Worthington Pump & Machinery Corp.
2 vertical-shaft sump pumps for hot-well pit; capacity 300 gpm at 20 ft head.............................Buffalo Pumps, Inc.
2 evaporator-condenser distillate pumps; capacity 150 gpm at 143 ft head.................................Ingersoll-Rand Co.
2 No. $1^1/_2$ rotary Aroclor pumps.........Worthington Pump & Machinery Corp.
2 rotary fuel-oil pumps, 2-in. size, for burner lighters.........Worthington Pump & Machinery Corp.
7 vertical sump pumps, three 60 gpm 15 ft head, three 30 gpm 30 ft head, and one 30 gpm 15 ft head.............Taber Pump Co.
2 sewage sump pumps, $7^1/_2$ hp...............Yeoman Brothers Co.

Air Compressors:

4 cross-compound air compressors, 500 cfm 500 lb, direct-connected to 200-hp synchronous motors for soot blowing. Ingersoll-Rand Co.
3 carbon-ring air compressors, 125 cfm 100 lb, for meter service and automatic controls........Worthington Pump & Machinery Corp.

Pipe Fitting and Valves:

1 crane for gatehouse, 15 ton....Shepard-Niles Crane & Hoist Corp.
1 transfer crane and hoist for fan floor, 7½ ton.................. ....Shepard-Niles Crane & Hoist Corp.
2 transfer cranes and hoists, 5 ton..........Chisholm-Moore Corp.
All-welded rectangular condensate surge tank for 29.5 in. Hg vacuum ....Chicago Bridge Co.
Thearle portable dynamic-balancing equipment. General Electric Co.
2 mill seal D-4 blowers.........................Allen Billmyre Co.

Discussion

J. R. Baker.[3] It is obvious that the designers of a new station to serve a system which stretches the length and breadth of the State of New York could look to the ultimate in size of individual generating units. The choice of 100,000-kw electric units, however, does not reflect such an approach but rather the selection of the maximum capacity of the simplest type of turbogenerator to operate on the highest proved steam conditions, the steam to be obtained from the smallest number of the largest boilers that have indicated feasibility. A single-cylinder condensing turbine operating at 1800 rpm is probably the least complicated turbogenerator yet devised for operation with high-pressure and high-temperature steam; previous units of large capacity have generally utilized a tandem or cross-compound arrangement with double flow in the low-pressure section, and sometimes with reheating of the steam between sections of the turbine. It appears that the commercial maximum sizes in the selected types of electric and steam generating units also fit into the system requirements with respect to operating flexibility. Thus, the design seems to embody or to approach closely the present-day peak of thermal efficiency combined with the minimum of capital costs.

It is believed that the analysis which led to the adoption of an 1800-rpm single-spindle condensing turbine of 100,000-kw capacity to operate on steam of 1250 psi and 900 F, and to the discarding of possible alternatives in capacity, speed, and arrangement, portrays the basic advance in design represented by the station, and far overshadows the development of the comparatively minor items such as automatic soot blowers and pilot safety valves, useful as they may be. The authors have been too modest in setting forth their real achievement.

The thermal efficiencies, indicated in Figs. 6 and 14 of the paper, of 10,680 Btu per kwhr and 31.6 per cent, respectively, appear to correspond to full load on the turbine. Is it expected that the point of best loading will decrease the thermal rate? What is the expected thermal rate on a yearly basis, reflecting operation under stand-by conditions? The thermal rates mentioned in the paper are partly explained by the authors' statement: "The heat which circulates through the steam generator, when operating at its rated capacity, is 50 per cent greater than the heat in the fuel that is being fired." Perhaps the influence upon thermal efficiency of the six bleeder heaters and the oil and hydrogen coolers could be more directly stated by pointing out that, of the heat going to the turbine, 26 per cent is converted to power, 32 per cent is returned to the boilers, and 42 per cent only is lost to the circulating water. The heat contributed to the steam generator by the air heaters amounts only to between 8 and 9 per cent of the heat in the fuel fired, as contrasted to 42 per cent brought in by the feedwater.

Returning to the main emphasis in the paper, that of automatic control and supervision of equipment, no one can question the desirability of seeking the utmost in continuous reliability of essential equipment for the full operation of the station and of the large savings possible in capital cost by the elimination of duplicate equipment the only function of which is that of replacement for equipment in trouble. Automatic control can also contribute to fuel and labor savings by maintaining operation at a predetermined level of efficiency and by eliminating manual attendance for many repetitive procedures. In fact, the modern-steam-plant operator, in contrast to his progenitors, has in recent years become largely the handmaid of automatic-control equipment. Until the Oswego Station was designed, such jobs as soot-blowing had, however, been left to the personal attention of operators. The authors now find that this innovation will pay its way.

Apparently, coal and ash handling, perhaps the control of boiler-water conditions, and certain starting and stopping procedures comprise the only manual functions expected of operators, although in certain cases of starting and stopping, the equipment is so interlocked as to compel the proper routine. In connection with the starting of the boilers and turbines, a description of the steps required in bringing the equipment into operation from a cold condition, together with the time required, would be of interest. It has been reported that a half day or more has been required in other stations of similar characteristics. This period would seem critical and appears to present the only condition for which some automatic-control equipment has not been specifically mentioned in the paper. Instruments for noting the starting conditions of the turbines have of course been provided, and the juxtaposition of the boiler, turbine, and electrical control boards in a central location between the turbines and boilers should facilitate the starting procedures. The question might be asked if the controls of the condensate, boiler feedwater, and circulating-water pumps are also located in this control room. What is the organization of personnel in the control room; that is, does one operator manipulate all controls, or is there a segregation of duties according to the basic divisions of the station?

C. H. Delany[4] and V. F. Estcourt.[4] In this paper the authors give some interesting details covering the design of a modern steam plant intended for quick pickup operation in connection with a large hydroelectric system.

For the last ten years we have been operating a 1250-lb steam-turbine plant containing two 50,000 kw vertical compound units operating at 750-deg steam temperature with the steam reheated to the same temperature before entering the low-pressure turbine. This station is operated as a stand-by station. Some of the results of emergency load pickup at this station were described in a paper by V. F. Estcourt.[5] Operation of this plant has been entirely satisfactory and there have been no important troubles that can be ascribed to the high pressure.

One advantage of a high-pressure plant which is not usually recognized is the fact that steadier boiler operation is obtained due to the greater density of the steam at high pressure than at low pressure. This results in less fluctuation of water level in

[3] Assistant to president, Pennsylvania Water & Power Company, Baltimore, Md. Mem. A.S.M.E.

[5] "Design and Operating Problems with Gas- and Oil-Fired Boilers for Stand-By Steam-Electric Stations," by V. F. Estcourt, Trans. A.S.M.E., vol. 59, 1937, paper FSP-59-1, p. 7.

boilers, which is of special advantage where sudden load pickups occur.

Maintenance has not proved a serious matter in the high-pressure plants. The advent of high temperatures and pressures has forced a marked improvement in the design and construction of valves and flanges, as well as the development of more suitable alloys. Thus the frequency of maintenance work is no more than in a low-pressure plant. Some difficulty has occurred in valves in the feedwater line because of water getting under the threaded seats, but this has occurred as much on the 600-lb pressure line as on the 1400-lb line. On the newer jobs this trouble has been prevented by the use of welded seats on all valves.

It is stated in the authors' paper that the Oswego station contains two units with one boiler per turbine. It is not stated whether there is any interconnection between the boilers and turbines of the two units. We have found that for quick pickup there should be available about 40 per cent more boiler capacity than is required for operating at full load. This being the case, interconnection between boilers of the separate units is very desirable, as it makes possible an instantaneous pickup of full load on one turbine as long as both boilers are in operation.

It is also stated that one of the reasons for the selection of one boiler per turbine was the recognition of the reliability of modern boilers. However, the availability of boilers cannot be considered equal to that of turbines and therefore some turbine shutdowns must be charged against forced boiler outages in a one-boiler one-turbine installation. Whether or not this is an acceptable condition will depend upon whether system conditions as a whole justify carrying the additional reserve in turbines necessary in order to allow a certain number of turbine outages chargeable against boiler outages. This statement of course would not apply to the Oswego installation, if interconnection between the two boilers has been provided with sufficient reserve capacity in each boiler to carry some additional load on the second turbine.

The use of 250-lb air for soot blowing is noted. Since, with certain types of fuels, deposits on boiler heating surfaces is a serious problem which has not been entirely solved by means of steam soot blowers, more detailed information on the actual operating performance of this installation would be of interest, both from the standpoint of soot-blower and air-compressor operation and maintenance, and also the results obtained in deposit removal as compared with steam.

In some cases a plant of high efficiency may be justified even for stand-by operation, because of the fact that it may later be used as a base-load plant; and furthermore the more efficient the plant, the smaller the boiler capacity and the condenser capacity required. The condenser equipment is smaller not only because less steam is required at the throttle but also because of more extraction points, resulting in much less steam going to the condenser. This results in less cost of circulating water intake and discharge tunnels and tends to offset the extra cost of the high-temperature, high-pressure equipment. In this connection, it is noted that the Oswego turbines have six extraction points, which is more than would normally be used in a plant designed for lower pressure.

In deciding upon the operating pressure, the size of the unit will also be a factor. For example, in so far as the turbine is concerned, there is an optimum size for maximum turbine efficiency based on the two factors of size and steam pressure. If too high an operating pressure is selected for a small-sized unit, a sacrifice in efficiency must be made due partly to the small bucket sizes required in the first-stage wheel.

J. C. Hobbs.[6] It would appear that this station is the result of the combination of long years of actual experience, including the pioneering of "high pressures" in the C. R. Huntley plant, and the many subsequent power developments originating in the Buffalo General Electric plants. The best theory and practice made available by committees and individuals of the A.S.M.E. and by public-utility organizations were utilized in this development.

This paper indicates very clearly that a great deal of attention to details, and successful solutions to many problems, were required to obtain the proper functioning of the component parts of a power station of such large size. Not only does the equipment appear to be designed to function properly, but the instrumentation appears to be such that the operators, many of whom cannot be trained technical men, because of their scarcity, are furnished at all times with sufficient information so that they can obtain the desired economical result.

Years ago the central station which contained a condensate- or a coal-weighing system which could be used for making periodic tests was the envy of those built without such features, but today (and this station appears to represent the best) a station is on continuous test and the operator knows at all times whether the equipment is performing properly and, if not, what is necessary to make it function. Air was once considered a free component of combustion but this station includes air meters. The entire installation seems to be built to give the operating staff complete information so that they will have an opportunity to obtain creditable performance.

It is interesting to note that today's practice, as represented in this station, includes bank-balance methods of accounting for all items of value. At the same time, it is observed that modern banks now use electrical devices for accounting for the dollars and pennies which they handle. It was formerly customary for concerns, even public utilities, to place under bond the petty-cash clerk, who handled only a few dollars, in order to make certain that every penny was accounted for. These same companies employed firemen who might not even be able to speak the English language, whose job it was to handle thousands of dollars worth of fuel—many times recklessly. No provision was made for instrumentation to determine how much unburned fuel was being discharged through the stack or shipped out in the ash cars.

The adoption of 1250 lb pressure for a condensing plant is another step in the right direction. At first thought the 1250 lb now appears to be so relatively low that its significance is not realized. There are many reasons for the adoption of the 1250 lb which should not be forgotten just because the present-day practice has not reached this standard. Each improvement advancing the power art has been criticized. Pulverized-coal and water-cooled furnaces got their share.

High pressure, in spite of a considerable number of topping plants, operating at 1200 lb and above, is not appreciated in proportion to its merit. There seems to be an antipathy for high pressures by those who have not had actual operating experience. In one plant containing equipment operating at 700, 800, and 2200 lb, the operators much prefer the high-pressure apparatus even though, before it actually went into service, they were literally "scared stiff," as the expression goes.

A few fundamental reasons should not be overlooked:

1 That fewer pounds of steam are required to produce a kilowatthour with high pressure than with low pressure at the same temperature.

2 Considerably less heat or coal is required to make a pound of steam at high pressure than at low pressure.

3 Equipment such as piping, pumps, valves, and even turbine parts are much smaller when using high pressure than the relatively "low" pressure formerly considered standard. It is

[6] Vice-President, Diamond Alkali Company, Painesville, Ohio. Fellow A.S.M.E.

true that some of this equipment, such as valves, has not been commercially developed to take full advantage of increases in reliability and decreases in weight; but all in all, because of lower total steam consumption and the smaller piping, turbines, and condensers, the cost of a plant around 2000 to 2500 lb can actually be less than for the low-pressure plants of less than 1000 lb.

Another factor which should not be overlooked is that, because of the smaller piping and smaller valves, differential temperature stresses are less than they are in large equipment where greater temperature ranges may occur with correspondingly greater stresses and probability of expansion failures.

Commendation is due the designers for going to a 1250-lb straight-condensing plant. If any criticism were to be offered, it would be because they did not make full use of the opportunities offered at pressures of 2000 lb and above.

Sabin Crocker.[7] The A.S.M.E., and particularly its contingent of central-station engineers, is indebted to the authors for a thoroughgoing factual account of what equipment went into the Oswego Steam Station. Where pioneering work is being done, as in this case, it is a great help to others in keeping abreast of new developments to have those responsible take the time and make the effort to set forth the facts. Although steam conditions of 1250 psi g and 900 F have been used for some time in superposing new equipment on old plants, this is one of the few instances where these conditions have been used for a wholly new plant built for straight-through condensing operation.

It would be of interest to have the authors say something about the economic analysis which led them to adopt 1250 lb at 900 F for the straight regenerative cycle in preference to the 800 to 850 lb at 900 F which has been used in a number of other recent condensing installations. In the case of topping units, the reason for using as high a pressure as is commensurate with a 900 F throttle temperature is apparent, since greater installed capacity is made available thereby as well as improved heat rate. Under these circumstances the presumed higher first cost of 1250-lb equipment over 800- to 850-lb equipment will be defrayed on two counts, whereas, with new condensing plants, the higher pressure probably has to pay its way out of fuel saving alone.

The installation described by the authors will afford a valuable proving ground for demonstrating whether the actual performance results in such a plant are up to theoretical expectations for the cycle. It is interesting to note that six stages of feedwater heating are used at Oswego, and that the ejector condenser, oil cooler, and hydrogen cooler are used as heat traps besides. This results in an unusually high final feedwater temperature, which in turn dictates a small economizer and a correspondingly larger air heater. On first impressions, these refinements would seem to involve a considerable capital outlay of an optional nature which would need to be supported by the high plant factor associated with base-load operation. Yet, it would seem from the paper that Oswego is intended as steam stand-by for existing hydroplants.

Hence, the writer is puzzled why the pressure adopted for Oswego is 1250 lb, whereas, economic studies in his own company have led to the use of 815 lb at 900 F for new condensing equipment having a normal plant factor. These remarks are not offered in a critical vein, but are voiced in the hope that the authors will feel disposed to discuss why they chose 1250-lb steam pressure and used what might seem to be a multiplicity of extraction stages and heat traps. Perhaps, a brief exposition of some concepts held by the writer will help the authors in trying to clear up certain points for his benefit and that of others interested.

[7] Senior Engineer, Engineering Division, The Detroit Edison Company, Detroit, Mich. Mem. A.S.M.E.

Fig. 15 of this discussion serves to show the trend of net heat rates with increasing pressure, as taken from typical figures for existing plants. The lower curve represents the best performance to be expected of a plant under ideal conditions at something approaching full load on the turbines, or possibly under steady base-load conditions. The point for 1250 lb is the net plant heat rate for ideal conditions at Oswego, as computed from

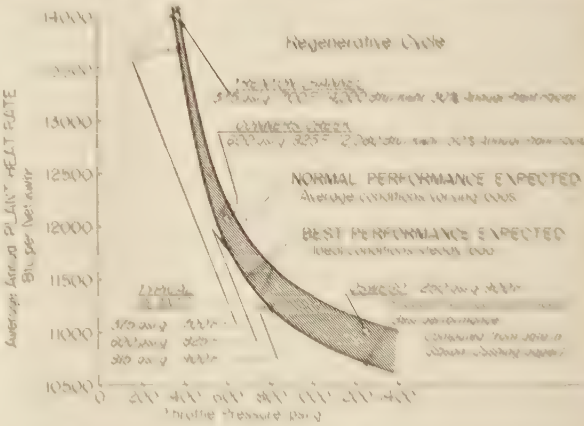

Fig. 15 Trend of Plant Heat Rates With Increasing Pressure

the throttle heat rate and auxiliary-power requirements given in the paper, and with an assumed boiler efficiency of 88 per cent. The upper curve, which simulates average annual plant performance, shows the effect of varying load, banking losses, condensing-water temperature variation giving back pressures higher than nominal, and similar factors of an adverse nature. Both curves serve to point to the possibility that the 1250-lb 900 F regenerating plant may be in the region of diminishing returns because the thermal gains due to increased pressure have tended to flatten out. That this might be true is indicated by the fact that the heat saving, shown for the 435-lb step from 815 to 1250 psi is less than for the 215-lb step from 600 to 815 psi.

The extent to which the adoption of optional refinements of the plant cycle is warranted hinges in a large measure upon whether the turbogenerators can be kept loaded to somewhere near capacity most of the time. In other words, if optional refinements are to pay for themselves out of fuel savings, the savings have to be realized on a large output of kwhr. The index commonly employed to express the use made of generating capacity throughout the year is termed "annual plant factor," which is the ratio of actual kwhr turned out by a unit or plant to the number of kwhr it could have turned out if it had been fully loaded to rated capacity throughout the whole year. With base-loaded units, the annual plant factor may be as high as 70 or 80 per cent, or perhaps 90 per cent in rare cases. Such favorable plant factors usually are short-lived, since, with the subsequent addition of still newer equipment, the once-favored units are apt to be relegated to system-average service. Many plants, particularly those connected with rapidly expanding systems, never get a chance at base-load service.

The graph of annual plant factors covering 16 years since starting such a plant is presented in Fig. 16 of this discussion, which was plotted from the records of the Trenton Channel Station of The Detroit Edison Company. During this period nearly 14 billion kwhr have been generated, which represent an average annual plant factor of 36 per cent. The straight dash line through the 36 per cent point placed above the [illegible] ordinate is merely the writer's personal guess as to a likely [illegible] in plant factor with time in this particular case.

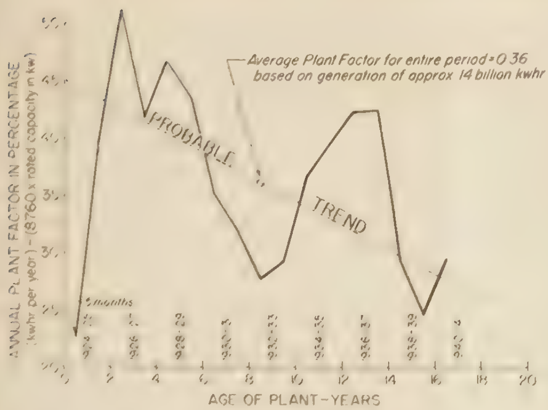

Fig. 16 Annual Plant Factor 1924–1940; Trenton Channel Power Plant

From reading this paper, the writer infers that Oswego is more in the nature of a stand-by than a base-load plant. If this is correct, the expected annual plant factors for Oswego hardly can be better than shown by the graph for Trenton Channel. It would be of interest for the authors to state what sort of annual plant factors over a period of years they would deem necessary to justify selecting 1250 lb steam pressure for a condensing plant over, say, 815 lb pressure, and what the investment differential would be.

F. P. Fairchild.[8] In many ways the new Oswego Station reflects recent progress in steam-station design, and the authors are to be congratulated for their vision and courage in adopting many new and heretofore untried features, including the following:

1 One boiler per turbine for units having a maximum output of 100,000 kw.

2 Single-shaft turbine for this size and 1250-psi 900 F operation.

3 Three-phase transformers for the main unit.

4 Omission of the usual unloading tower for water-borne coal, depending entirely upon self-unloading vessels.

5 Use of electric couplings for forced- and induced-draft-fan speed variation.

6 Automatic soot blowing, using air as the blowing medium.

Operating records of these new features will be watched with great interest by all those concerned with steam-station design.

The choice of 1250 psi is also interesting. During the period of 1935 to 1938, equipment for this pressure was developed to a high degree of perfection in connection with superposed plants, for which it is justified by additional capacity obtained, as well as by better efficiency. At the time the Oswego Station was designed, it is probable that, for a condensing plant, the theoretically most economical pressure was 800 to 900 psi by a small margin. The economical pressure does not, however, remain fixed, experience in the past indicating that it is continually changing toward higher pressures. In deciding on the steam conditions for a new station, such as Oswego, which probably will not be completed for many years, it is important to keep this factor in mind.

G. B. Warren.[9] This paper has been paralleled in recent months by several other papers in the technical press describing other new and outstanding power-station designs. In some cases, these design papers have been followed or supplemented by detailed reports of the operating results. A more common agreement as to what represents the best practice in all of the various phases of power-plant design should come from such an interchange of information by outstanding engineers as to their various design ideas, and by a frank discussion later of the results obtained. As a result, we should get power plants of even greater simplicity lower initial cost, higher efficiency, and greater reliability.

Although the steam conditions of 1250 psi pressure and 900 F temperature represent advanced and modern steam conditions, they are not so high as to present, at this time, a hazard to good operation. Boilers and turbines have now been operating commercially at 1000 to 1200 psi pressure in this country for somewhat over 15 years. According to the 1939 turbine-operating records in the latest Edison Electric Institute publications, the original turbines, and it is assumed the original boilers, for these conditions are still operating at load factors which closely approach those for modern machines. Since that time several million kilowatts of plant capacity have been installed to operate at this pressure or above.

The first station to operate commercially in this country at 900 F went into operation about 5 years ago and has been followed since that time by just under 3,000,000 kw, now installed and operating at this or higher temperatures, and by more than 3,000,000 kw now on order. So far as the writer can ascertain, no failure in service has occurred as a result of these high temperatures, which testifies to the thoroughness with which the metallurgists, the steel manufacturers, the equipment builders, as well as the power-plant designers have studied the problems of the effect of higher temperature on their materials and their machines and so have anticipated the difficulties which might arise and have guarded against them.

We who have been closely associated with turbine design over the last 20 years or so feel that, fortified with the additional knowledge we now have as to the performance of metals at high temperatures, we can design for these conditions more conservatively than we designed 15 or 20 years ago for the lower temperatures then in use. This was because of our deficiency in knowledge at that time as to the behavior of the materials which we were then using at those lower temperatures. Probably, the same is true of the design of all of the other parts of the equipment in the power plant which operate at relatively high temperatures.

The sincere efforts which have been expended to make this station outstandingly economical from the fuel-consumption standpoint no doubt have been inspired by what the writer believes may be the correct long-range viewpoint, namely: (1) Fuel prices in the future are apt to increase relatively to other prices; and (2) a station which is designed and built now for high economy may not have its load factor depreciated as rapidly in the years to come as one which does not have such a good fuel economy, or as has the average plant with which we have had experience over the last few years.

The salient features of the turbines have been described in this paper, and the detailed internal construction was further described in a paper[10] presented by the writer.

The turbines, Fig. 17 of this discussion, are of the popular and rugged single-cylinder, single-flow condensing type, with numerous special features which have been incorporated in order to

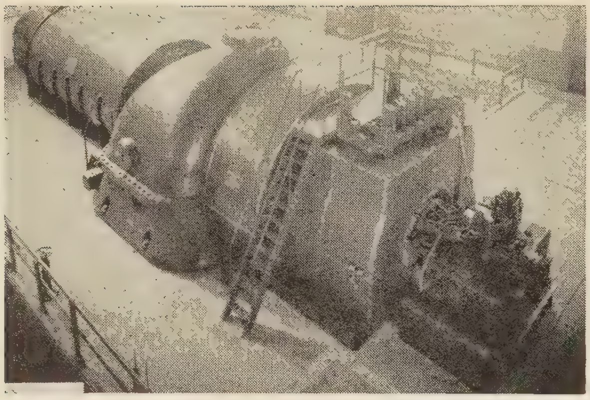

Fig. 17 Single-Cylinder, Single-Flow, Condensing-Type Turbine at Oswego Steam Station

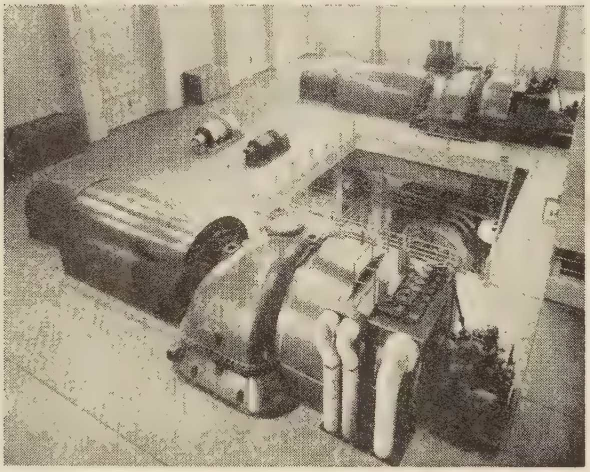

Fig. 18 Single-Cylinder Turbine Preferred Because Greater Capacity Than Tandem-Compound-Type Turbines

adapt this type of turbine to the high-pressure and temperature conditions at which they operate.

There seems to be an almost universal preference for such single-cylinder machines on the part of turbine-operating men.

On the other hand, because of the inherent limitations as to the number of wheels which can be put between two bearings, and because of the necessarily large shaft which such turbines require, it is sometimes impractical to make the economy of such a machine under normal load quite as good as it may be possible to obtain in a tandem-compound or a cross-compound turbine of similar excellence of design. This was discussed in the paper[10] by the writer previously referred to and in a companion paper presented in collaboration with P. H. Knowlton.[11] This difference, however, in a machine of this capacity and for these conditions is not great, and, where prospective turbine purchasers have been offered the alternatives of such compound turbines and single-cylinder turbines with the necessary differences in price and economy, by far the larger number have chosen the single-cylinder turbines where conditions of capacity, steam conditions, and speed permit such a design.

The single-cylinder turbine, Fig. 18 of this discussion, has been preferred by many over the tandem-compound type of turbine because of its generally shorter length with resultant lower station costs, or because installations of greater capacity have been permitted within the limitations of existing stations. It has also been preferred by many over the cross-compound type of turbine because of the simpler foundation structures, the simpler switch gear, and the simpler operation resulting.

In this matter as in many others with respect to power plants the opinions of competent engineers differ, and for this reason turbines of different designs continue to be built. Out of such experience the final best design will emerge.

E. Klafstad.[12] Since details of the safety-valve arrangement used by the authors may be of some general interest, the main points of valve arrangement and construction will be presented. The arrangement is a new idea designed to improve upon the established uses of spring-loaded safety valves without sacrificing safe practices, also to add to the flexibility, foolproofness, and general all-around adaptability.

The subject installation makes use of the required spring-loaded code valves (of which eight are located on the drum and three at the superheater outlet) to a decided advantage.

In addition to the eleven code valves (all 3-in. size) there are three pilot valves (also spring-loaded safety valves) of purposely low-capacity ratings, one of which is located on the drum and two on the steam line at the turbine stop valve. The pilot valve on the drum actuates two of the valves at the superheater outlet, one on either side of the divided superheater. These same two superheater valves are also actuated by the highest-set pilot valve at the turbine throttle. The lowest-set pilot valve at the turbine throttle actuates the third valve at the superheater outlet. The pilot valve on the drum, being set at a pressure lower than the drum valves, gives positive assurance that a demand for steam through the superheater will be created before any drum valve opens. The pilot valves at the turbine stop valve prevent the pressure at the turbine, under normal operating conditions, from rising above a safe maximum. Thus it is seen that protection is afforded to both the superheater and the turbine.

The advantages of this arrangement have been covered by the authors.

The pilot valves, also referred to as "actuator" valves, are, as stated, spring-loaded safety valves of small size and low capacity. They are not included in the required safety-valve setup in relation to aggregate capacity requirement but are in addition to the code valves and can therefore be placed on gate valves for maintenance removal without boiler outage. The pilot (actuator) valve is so designed that, when it pops, the body pressure created by the discharging steam is transmitted, through a separate vent at the side of the body, to a line which in turn is connected to a pressure chamber in the superheater (actuated) valve. The pressure acts on the underside of a piston fastened to the spindle of the superheater valve, thereby overcoming the spring load which holds this valve closed. The valve remains open until the pilot valve closes, then reseats immediately. The time lag on opening and closing between the two valves is less than 3 sec when the pilot valve is 150 ft away, as in the case of the turbine pilots, and less than 1 sec when the distance is 50 ft or less, as in the case of the drum pilot in the subject installation.

As the superheater (actuated) valves are in themselves recognized spring-loaded code safety valves, they can be adjusted to any desired self-actuating set pressure up to within a reasonable range below the lowest-set drum valve and, thereby, allow the pressure at the superheater header to be raised during opera-

[11] "Relative 'Engine Efficiencies' Realizable From Large Modern Steam-Turbine Generator Units," by G. B. Warren and P. H. Knowlton, Trans. A.S.M.E., vol. 63, 1941, pp. 125–135.

[12] Chief Engineer, Crosby Steam Gage & Valve Company, Boston, Mass. Mem. A.S.M.E.

tion without inadvertent popping of the superheater valves. There is added assurance, during "overfiring" conditions, when the pressure rises nearly an equal amount over the system without change in the rate of flow, that a positive demand will be created at the superheater outlet, because pilot valves are located at both ends of the system and will therefore respond before the drum valves under all operating conditions.

If and when "overload" conditions occur, with higher than normal pressure drops, again protection is provided from inadvertent popping of the actuated superheater-outlet valves, because of the higher than normal set pressure of these valves.

M. D. Engle.[13] The designers of the Oswego Station are to be congratulated upon the courageous manner in which they have proceeded with the design of this new generating station. They have apparently endeavored to utilize the results of their own experience in their other stations, where economical to do so, but have not hesitated to depart from their past practice, where experience elsewhere has indicated the wisdom of such a change, or where their own experience and the experience of others has not produced a satisfactory answer.

To mention only a few items: They have continued with the use of the slag-tap furnace which was largely developed in their own plants and which has proved satisfactory for the fuels which they customarily burn.

They have adopted the higher steam pressures and temperatures which have been proved reliable and economical in many other stations. As a result of this foresight, it is probable that this station will have a longer useful life than if more moderate pressures and temperatures had been used. Because of present world conditions resulting in greater than normal demands on all modern power-generating facilities, it is probable that the adoption of the higher pressure and temperature will show up more advantageously than expected.

They have pioneered with equipment of new design for the operation of boiler feed pumps, induced-draft fans, and soot blowers, because neither they nor anyone else has found an economical and thoroughly satisfactory solution.

The adoption of the unit construction of one boiler for each turbine should result in lower cost of construction and operation and has sufficient operating background to be justified for their system even though it required a boiler of abnormally large size.

The heat-balance arrangement adopted appears to many of us to be more complicated and expensive than is warranted. However, heat-balance arrangements have been for years almost as personal as one's religion, and certainly we should not criticize too severely when few of us ever put in two units with the same arrangement.

It would appear, however, that if high thermal efficiency was desired, as indicated by the heat-balance arrangement, a regenerative reheat cycle with a simpler heat-balance arrangement would have given better station economy and would not have been any more complicated.

The use of high-pressure air for soot blowing is indeed a novel experiment which will be watched with interest. To some of us, it would appear to be unduly expensive; it would add to the usefulness of the paper if the authors could explain how they were able to reach the conclusion that it was cheaper than steam soot blowers. Also how they will be able to take care of the deslagging blowers which may require higher pressures than provided for with the air compressors mentioned in the paper.

Some will also question the need for the greater complication in the combustion-control system, which endeavors to proportion accurately the air to coal from each pulverizer. It will be interesting to learn after several years of operation whether or not the additional first cost and maintenance costs have been justified. If it proves economical, the industry will again be indebted to this company for having pioneered for our benefit.

The use of road-building equipment for stocking and reclaiming coal in large quantities appears logical and economical. Such equipment is built for more rugged service than will be required for coal handling and should have a long life. Its low comparative cost and its flexibility should prove very attractive. Many of us will no doubt follow their lead in this innovation.

[13] Assistant Superintendent of Engineering, Boston Edison Company, Boston, Mass. Mem. A.S.M.E.

E. H. Krieg.[14] Good judgment has been shown by the selection of 900,000-lb per hr boilers and 80,000-kw turbine generators which are really good for 100,000 kw. Units of this size appear to be approximately correct for a 1,500,000-kw-peak system. The selection of a 1250-lb 900 F cycle, unusual for the anticipated wide load range of 4000 to 100,000 kw, is doubtless justified and gives an economical cycle which may permit base-loading in the future, since load conditions are bound to differ somewhat from the original estimates. No doubt the war has already changed the original expectations.

Some amplification of the following points would be appreciated:

1 Is it economical to install two 100-hp oil-fired heating boilers in contrast to the usual practice of using bleed steam for heating? It has not proved difficult to avoid contamination of condensate.

2 Cannot the variable-speed boiler feed pumps go down to 220,000 lb per hr? Or is efficiency at that point so poor that the 220,000-lb per hr boiler feed pumps are financially justified?

3 What is the function of the raw-water condensate cooler, labeled *A*, in Fig. 4? Were any objections found to the usual practice of recirculating condensate?

4 Would it not be somewhat better to place the deaerator, part 9 in Fig. 4, on elevation 377 floor rather than the 305 floor, particularly since it is built for 90 psi abs? We rather like to have as much static head on the feed-pump suction as possible to minimize difficulties resulting from changes in bleed pressure. What is the oxygen guarantee of these deaerators?

5 Why use direct-contact heaters on the two lowest-stage heaters? The accumulator effect of such heaters requires extra-safe nonreturn valves, with an appreciable pressure drop. Would not closed-type heaters give just as close, if not a closer, terminal difference if no nonreturn valves were installed? We have pointed out on several occasions that nonreturn (or check) valves are usually not required on the lowest-pressure closed-bleed heaters, since the available energy in the low-pressure steam is seldom great enough to overspeed the turbine. The steam also passes through relatively few turbine stages. Such valves were omitted at the Windsor, Atlantic City, Philo, and Cabin Creek plants.

6 Is automatic water-level control for the ninth or deaerating heater advisable? In the event of sudden load loss, the ninth-stage bleed steam pressure would probably have a much faster rate of change than the condensate flow into the heater. In such a case, does not the heater pressure drop too rapidly, making it possible to lose the necessary positive feed-pump suction pressure? The same effect might result from a broken boiler tube, causing a proportionately greater feedwater flow than usual for a given load or bleed pressure. What would be the objection to an uncontrolled level? On several deaerators, having 1,000,000-lb per hr flows, we have experienced no difficulty under any operating condition.

[14] Engineering Department, American Gas and Electric Service Corporation, New York, N. Y. Mem. A.S.M.E.

We agree that with an adequate outside power source, there is no need for turbine-driven auxiliaries. The latter practice was formerly required, but many engineers have found that steam-driven auxiliaries are not needed for plants which need not be self-starting. However, turbine drives are still very attractive for most superposed or topping stations.

W. P. Thomas.[15] The automatic sequentially operated compressed-air soot-blower system, outlined in the paper, has created so much interest that it is believed an elaboration of this subject will be of interest.

One of the most important problems encountered in the design of this plant was that of feedwater. The following sources of steam for soot blowing were investigated:

1 Directly from the boiler drum or superheater header, using soot blowers designed for full boiler pressure.

2 From the boiler drum or superheater header reduced to 600 psi through a reducing valve.

3 Bleeding from an intermediate stage of the turbine.

4 From the evaporators.

5 From a separately fired boiler.

All of these sources had definite drawbacks. The simplest method was installing a reducing valve on a saturated drum outlet. The reduction in pressure from 1250 to 200 psi required on the soot-blower nozzles would result in wet steam. In order to eliminate the possibility of trouble caused by wet steam, it was decided to study the use of compressed air blowing on the air heater and the economizer. The economy of air over steam indicated by this study warranted expanding the study to cover the entire boiler, including the furnace walls.

Experience with soot blowers on a boiler of similar construction indicated that an air pressure of 200 psi on the nozzles would be required for removing the soot and fine ash from the superheater, economizer, and the tubular air heater with tubes 50 ft long. Since this boiler would be fired with a larger variety of coals than on other boilers of this same construction with which we were familiar, it was impossible to predict whether or not this pressure would suffice for slag removal from the waterwalls. In order to provide a margin of safety, it was decided to make provision for mixing water with the air and also to have a source of higher air pressure available. Comparisons of 350 psi and 500 psi costs were made. All things considered, the higher pressure appeared more favorable.

With the air demand and pressure determined, a study of the duty cycle showed that two 500-cfm compressors feeding four 500-psi receivers of 500 cu ft capacity each would provide an excess air capacity of 20 per cent. Allowance of 50 psi drop through the pipe, valves, and soot-blower heads, plus the change in receiver pressure during blowing, determined the reducing valve required for dropping the pressure in the main receivers to that in the 100-cu ft ballast or low-pressure receiver.

The study of relative costs of steam versus air blowing showed that the increased initial cost for the air equipment would be offset in the first year of operation without taking into consideration the intangible value of the make-up water.

The use of compressed air as a soot-blowing medium was not new. It had been recognized as offering certain advantages over steam for nearly 20 years. In the early days, air-operated blowers proved uneconomical because of uncertain cleaning results (low air pressure was used), and because of the high capital investment required for large compressors and receivers. Both of these deficiencies arose from the lack of automatic controls. We had been working on this control problem for several years in our research department and had developed a comparatively simple control system. In the case of Oswego, however, automatic control fitted ideally into the picture because the entire station would be monitored from a central control room.

All the soot-blower units and air-control valves are actuated either by air pistons or electric motors. Air operation is used on the conventional rotating units installed within the boiler settings because it provides automatic operation at minimum cost.

The piping is of welded-header construction. Connection to the furnace-wall units is designed for 500 psi pressure, and all other connections are suitable for 250 psi pressure. All automatic valves are of the "Thrustor" flanged type. They were chosen for this particular service because of their quick opening and closing characteristics. These valves are all backed by hand-operated emergency valves to facilitate regrinding.

The electrical control was assembled from standard equipment, grouped to meet our specific requirements. The Oswego installation was made unusually complicated to provide for emergencies which never arose. Subsequent experience in the plant indicates that future installations can be simplified without sacrificing foolproof operation of every unit.

Very little trouble developed in over a year of operation. Long strap-type standing bearings bolted to lugs welded to the top of the economizer tubes in the by-pass section broke loose from the lugs and permitted the element to warp and sag. Changes had to be made in the Thrustor valves to make them satisfactory for this particular service. Both of these troubles have been eliminated. Contact trouble due to high resistance developed in the electrical control; it is believed this trouble can be eliminated by substituting different contact material. The method of making contact will be changed in future installations.

The use of air as a cleaning medium in soot blowers has been demonstrated to be economically sound in nearly 100 installations on low-pressure boilers, where the soot-blower equipment was entirely automatic. This Oswego installation is the first utility project where air has been used as a cleaning medium in soot-blowing equipment which is entirely automatic. After more than a year of operation, it appears that the economies figured by the engineers, in labor saving and maintenance of piping and equipment, as well as operation, have been fully justified.

R. C. Roe.[16] The writer's organization has enjoyed working with the authors and their associates as consultants during the design of this station.

There are several features of the station which perhaps deserve more comment than appears in the paper. One of these is the boilers. Inasmuch as the turbines were each to be served by a single boiler, and inasmuch as the capacity of the turbines was large and, hence, the effect of the loss of a unit on the system was great, the boiler designs were scrutinized with exceptional care by all those concerned, to the end that the maximum reliability and availability would be provided.

The hydraulic circuits are particularly noteworthy and are believed to have furnished an example which has been incorporated in designs following later. The arrangement of furnace surface and screen tubes to cool the gas before entering the tube banks has been very successful in operation, with the result that the tube banks are free from slag accumulations and are easy to keep clean under continuous service at high ratings. The operating record of the boilers has fully come up to expectation, both as to reliability and availability.

The use of high-pressure air for blowing soot automatically with a predetermined sequence is a step in advance for large

[15] President, Diamond Power Specialty Corporation, Detroit, Mich. Mem. A.S.M.E.

[16] Burns & Roe, Inc., New York, N. Y. Mem. A.S.M.E.

stationary high-pressure boilers. This method not only saves some fuel on a Btu basis, but also has a tendency to maintain a much cleaner boiler, to contribute less to corrosion in the air heater, to clean surfaces subject to slag accumulations more effectively, and to improve the reliability and availability of the boiler.

The use of an automatic premeasuring combustion-control system is a fundamental step in the right direction.

The use of electric couplings of the eddy-current type for the control of fan speed is believed to be the first use of such coupling for such service, at least on central-station steam boilers. When it is realized that these couplings, at the time they were built, were several times as large as any similar couplings then in existence, it is readily seen that the engineers had faith in the fundamental soundness of the design or they would not have used such a device in a place where the entire station depended upon its successful operation.

The use of a six-point regenerative cycle with three points using closed heaters having integral drip coolers and three points with direct-contact heaters is not only a fine design thermodynamically, but also sound from an operating viewpoint.

The direct-contact-heater system, with its multisection heater pumps, the last two sections of which pump a mixture of steam and water in the form of a fluid of lower density than would be the case if the fluid were solid water, was the largest direct-contact-heater system yet built. It has been very successful in operation and free from any serious difficulties.

Taken as a whole the Oswego Steam Station is one of the most progressive yet safe and conservative designs that has come to our attention.

A. T. HUTCHINS.[17] This paper is replete with descriptions of interesting design features which include one of the most complete systems of automatic control that has come to our notice. A brief analysis of the turbine performance indicates that, in addition to the gain by carrying the feed-heating cycle to six stages and a final feedwater temperature of 485 F, there is a gain in turbine efficiency due to the increase in flow to the throttle while, at the same time, the exhaust losses are kept reasonably low, because of the reduced quantity of steam flowing to the condenser.

Possibly, one of the boldest features of this design is the requirement that a generating unit swing from full load to 4000-kw load almost instantaneously. In order that this might be possible on a single-cylinder unit of this size with steam conditions of 1250 psi and 900 F, the manufacturer has designed and built these units so that all the steam at any load passes through the first-stage nozzles and first-stage wheel. This results in limiting the high temperature to the steam chest and the first-stage nozzles and first-stage blades.

The arrangement of pilot pop valves to secure a predetermined pattern of steam release and so protect the turbine steam chest from excessive pressures is well worked out and should give excellent results. One of the important results from this arrangement is the positive protection of the superheater.

A unit arrangement of boiler and turbine invites close control of every feature of operation, and the accessories, provided in this design for giving the operator an indication of the performance of every piece of equipment in respect to any feature of operation, deserve special attention. The devices chosen for such indications and records should give the required information as to the performance of all the important equipment.

In regard to combustion control, the size of the steam-generating unit warrants as complete control as may be desired, provided only that the operation of such control secures the result intended, that the control equipment does not become too complicated for quick and accurate manipulation, and that the maintenance does not require more attention than it saves in operation.

The writer is of the opinion that the maintenance of the proper steam-flow – gas-flow ratio, with the fuel supply to the burners closely following the heat demand, is more easily secured and gives better results than any other method of control in use. This statement is made because of the fact that a change in the heat content of the coal going to the mills will cause a much greater error in the ratios required for good combustion, when an attempt is made to maintain a fuel-air ratio than will normally occur due to sudden changes in the physical elements used in securing the steam-flow – gas-flow ratio.

As an example, a change of moisture in the coal, as weighed, from 3 to 10 per cent will disturb the fuel-air ratio approximately 7 per cent, while it will affect the steam flow – gas flow ratio by only a fraction of this amount, or approximately 0.9 per cent. We are pleased to note that the combustion control at Oswego is set up so that, under actual operating conditions, the relative value of these two methods of control can be determined for the range of fuel fired.

F. A. ALLNER.[18] In an earlier publication,[19] one of the authors had reported on design and economic features of Huntley Station No. 2. The data on capital investment of that station established a most enviable record for the author as a designer of low-cost steam plants. Similar cost data on this recent Oswego project, if and when such information is available, would be received with great interest by many engineers and would be a timely and pertinent supplement to this excellent paper.

S. M. ARNOW.[20] This paper describes a plant where few possibilities for heat recovery were overlooked. Six stages of bleeding, three direct-contact heaters, variable-speed drives for boiler feed pumps, subcooling of drains, and recovery of bearing and generator losses leave little chance for any noticeable heat-unit losses.

No doubt the individual economies of the various pieces of apparatus have been carefully considered and proved for this plant; however, some of the heat-recovery schemes rather complicate the piping and are expensive when compared with the benefits obtained, hence they may not be applicable in all cases. As an example, the rise in feedwater temperature between the condenser and the 14-stage heater is 8.2 F. This represents approximately 5,000,000 Btu of which 700,000 are recovered by the air-ejector condensers, which are essential for the proper operation of the ejectors. The remaining heat recovery equipment results in a reduction of about 10 Btu per kwhr and at best would be justifiable only in a plant having a very high load factor.

While the authors do not include the expected duration curve for this plant, they mention a minimum load of 4000 kw during the period of high hydrocapacity, full load during droughts, also rapidly changing load conditions, so that this plant will have periods of very light as well as very heavy loads.

Using condensate for hydrogen and oil-cooling presents the possibility of losing hydrogen during light-load and low-vacuum operation and low oil temperature during high-vacuum high-load periods. Because of the location of the oil coolers and the

[17] Commonwealth & Southern Corporation, Birmingham, Ala.

[18] President, Safe Harbor Water Power Corporation, Baltimore, Md. Mem. A.S.M.E.

[19] "Design and Operation of Huntley Station No. 2," by H. M. Cushing, Trans. A.I.E.E., vol. 54, 1935, pp. 632–645.

[20] Division of Mechanical Engineering, Philadelphia Electric Company, Philadelphia, Pa. Mem. A.S.M.E.

air ejectors in the basement, and the hydrogen coolers on the operating floor, a somewhat complicated piping system must result. There is also present the possibility of condensate contamination by oil. For these reasons, the value of this part of the heat-recovery scheme is somewhat open to question.

Inasmuch as a 6-stage bleeding machine is somewhat uncommon, an evaluation of the economies of the first-stage heater is interesting. At the load, shown in Fig. 6 of the paper, the installation of the top heater results in a saving of about 5,000,000 Btu per hr, which represents a reduction of about 60 Btu in the heat rate. If this heater were left off and a 5-stage bleeding machine giving the same final feedwater temperature were used, the increase in the heat rate would only be approximately 40 Btu per kwhr. Assuming coal at $5 per ton, 60 Btu on the heat rate represents a saving of about 90 cents per hr. Assuming further that the average saving would be 50 cents per hr for 7000 hr of operation, the total saving would be $3500 a year. A 40-Btu saving in heat would reduce this figure to approximately $2500 a year. It is questionable whether such savings will be attractive when balanced against the cost of the two high-pressure heaters, drain controllers, piping, and valves.

Fig. 4 seems to be inconsistent, as it shows the drain coolers after the drain-control valves, while in the list of equipment integral subcoolers are indicated.

While in general the desirability of variable-speed drives for boiler feed pumps depends upon the loading conditions, for the Oswego plant, where the pumps take their suction from a direct-contact heater, reduction in load results in reduced suction pressure, which would appear to reduce somewhat the gain attributable to the variable-speed operation.

Authors' Closure

It is true, as Mr. Baker says, that the very simplest design of turbogenerator was selected for Oswego, i.e., a single-shell turbine where all of the steam passes through the first-stage nozzles and the first-stage wheel. In this design, rapid changes in the turbine loading will produce the minimum of temperature and pressure stresses in the turbine rotor and its casing because of a large reduction in the temperature and the pressure of the steam as it passes through the first-stage nozzles. In fact, the stresses are lower than exist under similar load changes in the 250-psi, 750 F, 75,000-kw Huntley turbines of the conventional design installed in 1928 and 1930.

The station heat rates, given in Figs. 6 and 14 of the paper, apply to loads of 100,000 kw. A loading of 70,000 kw on a boiler-turbine unit will produce about 2 per cent lower values. It would be very difficult to predict the yearly thermal rate for a steam unit operating on the Niagara-Hudson system, because the monthly as well as the yearly loading for the unit depends upon an unpredictable value, i.e., the rainfall on the watersheds of the hydroplants.

An unusual feature, which has been introduced in the starting up and shutting down of the steam generators, is the practice of having the boiler drum full of water to minimize the difference in temperature of the various parts of the drum during the heating-up and cooling-down periods. The following starting procedure is based on keeping the rate of change of drum-metal temperature to within 100 F per hr.

Normally the drum is filled with 80 F condensate up to the drum vents. The superheater may have been left partially filled with condensate from the last cooling-down period or be entirely full from a hydrostatic test. While starting the steam generator, the turbine is being turned slowly by means of a turning gear. With boiler and turbine steam-line stop valves open and all of the drum, steam-line, and superheater drains and free-blows open, the automatic lighters are started and pulverized coal is introduced into the furnace from one pulverizer through one burner at the minimum rate of coal feed (approximately 5000 lb per hr). This firing is continued on a 10-minute-on and 10-minute-off schedule until the drum pressure reaches 35 psi gage. The water in the drum is dropped to normal operating level; the drum and main steam-line vents closed; continuous firing of pulverized coal is then established and the rate of rise of the drum pressure is controlled by the amount of steam drawn from the superheater-outlet drains. At 300 psi, the rate of coal feed is increased to about 10,000 lb per hr, and the hogging steam jet opened to bring up vacuum on the turbine. At 500 psi and 15 in. Hg vacuum, the turbine is started with steam and brought up to 300 rpm. The rate of rise of the steam temperature is controlled by adjusting the superheater by-pass dampers which had been closed up to this time.

Fig. 19 of this closure shows the time required for starting the

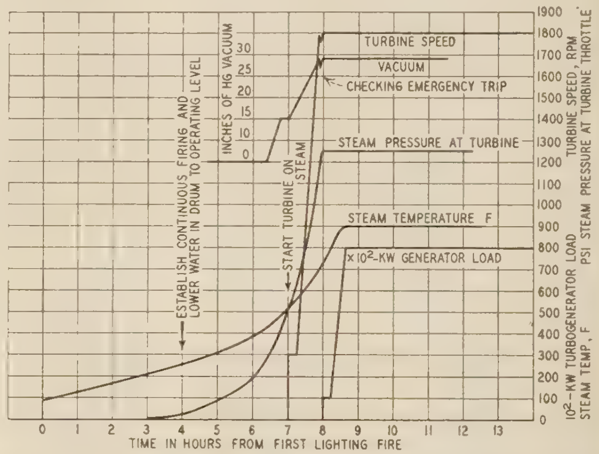

Fig. 19 Depicting Rate of Change of Boiler Temperature, Steam Pressure, Vacuum, Turbine Speed, and Loading for a Cold Start of Boiler-Turbine Unit

(Rate-of-speed change and loading of turbine-generator is censored by indications of supervising instruments.)

boiler and turbine and the rate at which steam pressure, steam temperature, vacuum, and turbine speeds are changed during this period. To aid in starting up and cooling down, rate-of-change templates have been carefully prepared for use in tracing the rate-of-change values onto the boiler and turbine control-meter charts. The fuel-firing controls, gas dampers, and superheater-outlet-drain valves are then so operated that the control-meter pens will retrace these template markings. The total elapsed time from the first lighting of the fire to the synchronizing of the generator is normally $8^1/_2$ hours.

The automatic level controls of condensate in the hot well, the deaerating heater, and the subcooling sections of the high-pressure heaters are in service during the starting period; but the automatic combustion controls are not put in service until the turbine is carrying load. Condensate and circulating-water pumps, pulverizers, and boiler fans are operated from the central control room. Boiler feed, house-service, slag, and sluice pumps and air compressors are operated from positions adjacent to the equipment.

Based on some 10 years of operating experience with 1250-psi condensing turbine generators, Messrs. DeLany and Estcourt bring out in the discussion and in the paper[5] to which they refer the many advantages to be gained by the use of 1250 psi steam pressure for a peak-load stand-by station, i.e., greater heat-storage capacity in the boiler and steadier boiler operation for sudden load pickups. Also, that maintenance has not proved a

Fig. 20 Output Chart, No. 1 Boiler Unit, for 900,000-Lb Per Hr Steam Generator
(Net output, 56,402,000 kwhr.)

serious matter nor required more frequent attention than in low-pressure stations. The advantages of 1250 psi steam pressure for base-load stations are unquestionable.

There are no steam or feedwater interconnections between the two one-turbine one-boiler units. The extra-large capacity of the pulverizers has enabled the firing rate to be increased at the rate of 10,000 kw per min, thus making another source of steam unnecessary for quick turbine pickups.

Considerable time and effort have been fruitfully expended by the engineers of our company, the consultant, and the boiler manufacturer, in studying and modifying those features of the equipment where a change would add to the reliability and the availability of the steam generators and their auxiliaries.

The excellent condition of the waterwalls and gas passages of No. 1 steam generator, which was recently out for annual overhauling, convinces the designers of the soundness of the decision to use 250-lb air for soot blowing. Up to the present, this equipment has required very little maintenance. The operating department estimates that the maintenance cost of the air soot-blowing equipment, including the air compressors, will be less than on steam-blowing equipment.

As Mr. DeLany points out, there is an optimum size of turbine for maximum turbine efficiency which should be considered in the choice of steam pressure; e.g., a 10,000-kw condensing unit would be too small to use 1250 psi efficiently because of the resistance loss in its small steam passages.

Mr. Hobbs, from the wealth of his operating experience, outlines some of the fundamental advantages of high steam pressures and suggests reasons why these high pressures have been avoided by some engineers. It is interesting to note his prediction that we need not necessarily expect 2000-psi steam stations to be more expensive than those built for 1200-psi conditions.

The authors are sorry they led Mr. Crocker to believe that Oswego is more of a stand-by than a base-load plant. The station is designed for both purposes, to operate as "spinning reserve," stand-by service during seasons of high flow at the water power plants, and also to operate as base-load during seasons of low flow. This dual-service feature characterizes the steam station which operates on a generating system supplied largely by water power, in distinction to the steam station which is just another unit on a system supplied mainly by steam.

Instead of Oswego being one of the few stations built for 1200 psi steam pressure and straight-through-condensing operation, it represents only two of forty-three such units which are operating or are now being built for 1200 lb or higher steam pressure.

Fig. 20 of this closure, which shows the load carried by No. 1 boiler in September 1941, is an example of the base-loading for which this station is designed. During the first 6 months of operation, after No. 2 unit was started, the station generated 624,477,000 kwhr, equal to a capacity factor of 89 per cent. The amount of energy used by the auxiliaries, coal handling, miscellaneous power, and station lighting amounts to 6 per cent of that generated. It is expected that as the operating personnel become more experienced and greater attention is paid to the small savings here and there, this percentage will be reduced. There are no steam-driven auxiliaries.

Fig. 16 of Mr. Crocker's discussion was given to illustrate how the plant factor varies with the age of a steam station which is a generating unit on a system supplied mainly by steam. This curve has been reproduced in Fig. 21 of this closure and shows, in addition, how the plant factor of the two-unit 160,000-kw Huntley Station No. 2, a steam-generating unit of a system supplied mainly by water-power generation, has varied since it was first put in service in October, 1930. Note that, whereas the trend of plant factor for the 16-year old Trenton Channel Station has been downward from its high of 51 per cent plant factor in its third year of service, the trend of the plant factor of the 425-psi 750 F Huntley Station has been upward, reaching 74 per cent in 1941, its eleventh full year of service. These facts are offered to explain why it was necessary to design Oswego for both stand-by and peak-load operation.

Mr. Crocker asks what led to the adoption of 1250-psi 900 F

steam for the straight regenerative cycle at Oswego in preference to 850 psi 900 F which a number of recent installations have used.

Many of the advantages of 1250 psi steam, as compared to the lower pressures, have been brought out in other discussions.

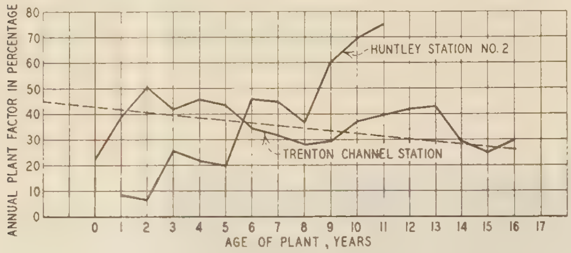

Fig. 21 Comparisons of Annual Plant Factors

It does not appear that those items most affected by pressure are relatively large in the following table showing how the Oswego costs were divided:

	Per cent
Land	1.0
Wharf, yard, and channel improvements	2.6
Rock tunnel, intake and discharge flumes with enclosing buildings for gates and screens	4.7
Main powerhouse buildings and foundations	13.2
Coal galleries and coal-handling equipment	5.5
33- and 115-kv switchyard and transformers	5.4
Turbogenerators and condensers	21.1
Boilerhouse equipment	22.5
Piping for high-pressure steam, bleed lines, boiler feed, condensate, house service, and instruments	5.6
Accessory electrical equipment	5.0
Miscellaneous powerhouse equipment	1.3
Construction expense and overheads	12.1
	100.0

From an economic viewpoint, construction costs come into the picture. Construction costs are only slightly affected by pressure but are greatly affected by design in its relation to pressure. To illustrate, in the Oswego Station the differential construction cost was minimized because the quantity and number of valves, fittings, and the length of the pipe in the high-pressure installation were reduced by the use of one boiler per turbine and no interconnections between units. If interconnections were provided or if any piping arrangement except one of Spartan simplicity were used, then the differential in cost would increase because piping is one of the big items affecting differentials in cost.

As was brought out in the reply to another discussion, condensate was used in the ejector condensers, oil coolers, and hydrogen coolers to keep the heat-transfer rates as nearly as possible to their design values and to save cleaning expense of the coolers, as well as to recover some Btu's. An appreciable amount of the pumping power and piping costs would have been required even though raw water had been used for this cooling service.

In regard to Mr. Fairchild's comments that it is a bit unusual to adopt 1250-psi steam conditions for condensing turbines, it is interesting to note that there are now in service or on order some 43 condensing turbine-generators in sizes from 20,000-kw to 150,000-kw, designed for 1200-psi or higher steam pressures.

As Mr. Fairchild points out, the theoretically most economic steam pressure does not remain fixed and is continually changing to higher pressures. Since 1780, when steam pressure of 15 psi was first used for steam engines, the discussion has been raging as to the comparative merits of higher steam pressures. Our engineers received more criticism for adopting 250-psi 700 F steam conditions in 1916 for the Huntley Station than appears at this time when 1250-psi 900 F steam conditions were adopted for the Oswego Station.

Mr. Warren's comments should allay the fears of the engineer who thinks of the 1250-psi steam conditions as entering far into the field of the unknown, when he points out that the metallurgical knowledge and the operating experience now available enable the engineer to design more conservatively for 1250-psi steam conditions than was possible for the low-pressure turbines some 15 or 20 years ago and that boilers and turbines have been operating at pressures of 1000 psi to 1250 psi for more than 15 years.

Mr. Klafstad explains the details of safety-valve construction, which makes possible this new safety-valve arrangement, designed to reduce boiler outages and give greater protection to the turbine.

As Mr. Engle mentions, the slag-tap furnace was developed by Niagara-Hudson engineers—this was in 1925. With the addition of the Oswego Station, the steaming capacity of the slag-tap furnaces on the system exceeds 7,000,000 lb per hr.

It is gratifying to hear one so intimately associated with the first 1200-psi steam-turbine installation mention the proved reliability of high steam pressure and predict that the adoption of these higher steam conditions for Oswego will probably give the station a longer useful life.

Although Mr. Engle speaks of these boilers, generating 900,000 lb of steam per hour, as being abnormally large, one boiler represents only about 5 per cent of the generating capacity in operation on the system. There are now 17 steam generators in this high-capacity class in operation and on order in this country.

The straight regenerative steam cycle was used in preference to the regenerative reheat cycle because of the simplicity of turbine design.

The authors did not intend to convey the impression that air soot blowing was cheaper in first cost than steam soot blowing with steam direct from the boiler; however, they believe that it does require fewer Btu from the coal pile. Steam soot blowing requires considerable quantities of steam to warm the lines before each blow. Experience with 250-psi compressed air for boiler cleaning indicates that higher pressures will not be required. The present system does a splendid job of cleaning the furnace walls and boiler passages.

The adaptation of road-building equipment to coal handling was first tried at the Huntley Station in 1931 when additional coal-storing equipment was required upon short notice in the middle of the coal-storing season.

Replying to Mr. Krieg's questions by number:

1 In regard to the installation of heating boilers, they paid for themselves during the first season by facilitating the erection of machinery during the winter months. The winters are long and cold. The heating boilers are of the fire-tube type. They were installed on permanent foundations in a wood enclosure before the service section of the station was built around them.

2 The small constant-speed boiler feed pump was provided because a wider range of speed was not then available in the 1800-rpm coupling to enable the large pumps to handle the small loads efficiently during the long hours that the station would be operating as a spinning reserve. These couplings were the first 1800-rpm units of a new high-speed line of hydraulic couplings. A greater speed range is being provided and the small pump omitted for the boiler feed pumps on a similar generating unit now being installed at Huntley Station.

3 The raw-water condensate cooler A in Fig. 4 of the original paper is required for cooling the hydrogen when the generator is operating as a synchronous condenser disconnected from the turbine. Extra cooling may also be required in the summer time because of high circulating-water temperatures occasioned by a

protracted period of wind blowing from the lake, piling up warm water along the shore.

4 There is no objection to placing the deaerating heater at a higher level. At its present level, it furnishes the suction head specified by the boiler-feed-pump manufacturer and provides the best arrangement of the equipment.

5 In regard to the use of the direct-contact instead of closed-type heaters in the two lower stages, our engineers believe that a direct-contact heater is a more rugged device, therefore needs no provision for by-passing, and provides some additional deaerating of the feedwater. The use of closed heaters would not eliminate the need for nonreturn valves as they would then be required to protect the turbine against a ruptured heater tube.

6 In the event of a sudden loss in load, the drop in pressure in the 9th-stage heater would be accompanied by a corresponding drop in temperature. The authors do not agree with the principle of using an uncontrolled water level above the pump suction.

Mr. Thomas gives some of the additional reasons leading up to the adoption of compressed air for soot blowing. The evaporators, which were mentioned in his item 4, as a means of obtaining steam for soot blowing, were separate and distinct units from those supplying the boiler make-up water. Pressure switches prevent the starting of the blowing units until full air pressure is available.

Mr. DeLany said that the availability of boilers was not equal to that of turbines. Mr. Roe's comments explain what was done in connection with the Oswego Station to improve this situation by using exceptional care in scrutinizing boiler designs. The wholehearted co-operation given by the manufacturers in discussing design details has accomplished much to improve the availability factor of the Oswego steam generators and their appurtenances.

The continuous and simultaneous premeasuring of coal and air to each pulverizer and its pair of burners should do much to lessen the likelihood of operating with a reducing atmosphere in contact with the furnace walls. Reducing atmospheres in contact with 900 F metal of the wall-tube surface, together with the presence of sodium sulphide (which can exist only in a reducing atmosphere) are now thought to be responsible for the wasting away of the tube metal.

Engineers from other operating companies who have inspected No. 1 steam generator after $1^1/_2$ years of service expressed surprise at the thoroughness with which air blowing has done its work. No hand-lancing has been used or has been required at any time. The 250-psi air does the job very satisfactorily.

While, as Mr. Hutchins points out, the carrying of 4000-kw load on 80,000-kw turbine-generators is an unusual feature, this practice has been followed at the Huntley steam stations for years. This low-load operation really became attractive with the advent of the multiple-admission type of steam turbine which gives a relatively flat efficiency curve through a wider range of loading than was practical with the earlier design of turbine, the "best-point machine."

As Mr. Hutchins states, the automatic combustion controls have been set up so that the relative merits of the steam-flow–air-flow postmeasuring total system of controls can be compared in actual service with the premeasuring unit system. One advantage of the one-boiler-per-turbine arrangement that is often overlooked is that the heating and cooling strains in the boiler and turbine are more easily controlled when the two are operating as a unit without interconnections to other units.

Mr. Allner asks about the relative cost of this station compared with Huntley No. 2, both built to house two 80,000-kw steam-generating units. With rock only a few feet below basement-floor grade, the Oswego steam station cost 35.8 cents per cu ft of volume for the powerhouse and service buildings with their foundations, whereas, Huntley No. 2 Station, built on steel caissons with rock about 40 ft lower, cost $36^1/_2$ cents per cu ft. The spacing of the equipment at Oswego was made liberal in order not to put space limitations on the future units. The station contains 12 per cent more volume than Huntley although it has no electrical bay, the 33- and 115-kv structures being located outdoors. Of the Oswego volume, 2,000,000 cu ft, or 34.7 per cent of the total, is in the service building and track bay which will serve the ultimate development of five units.

Volumetric comparisons in thousands of cu ft are given in the following table:

	Huntley No. 2, M cu ft	Oswego, M cu ft
Turbine bay	1500	1790
Boiler bay	3005	3460
Service building and machine shop	...	600
Electric bay and control room	708	...
Total—main powerhouse buildings	5213	5850

Mr. Arnow and others have commented on the use of six-stage bleeding and the use of condensate for cooling the hydrogen, the lubricating oil, and condensing the steam from the air-removal equipment, implying that the only advantage of so doing was to increase the cycle efficiency. There are other advantages, for example: A liberal bleeding of the turbine in the low-pressure stages assists in removing water from the turbine with the resultant effect of increased life of the turbine blades; the first-stage, the highest-temperature-bleed point, tends to reduce the temperature fluctuations of the feedwater due to load changes, thus reducing thermal strains on the equipment; the use of condensate instead of raw water for cooling reduces the cleaning problem to nil, lessens maintenance, and keeps the heat-transfer rate to a maximum in the hydrogen- and air-removal steam condenser and does not materially add to the piping cost. We have experienced no tendency toward the increased loss of hydrogen during light-load operation. Mr. Arnow is correct in assuming that the drain coolers of the three high-pressure heaters are an integral part of these heaters, and the level-control valves should have been shown after the drain-cooler sections, instead of as indicated in Fig. 6 of the paper.

Energy Transfer Between a Fluid and a Rotor for Pump and Turbine Machinery

By SANFORD A. MOSS,[1] CHESTER W. SMITH,[2] and WILLIAM R. FOOTE[3]

The paper presents an analytical treatment of the energy transfer between a working fluid and a rotor for pump and turbine machinery, which affords means for selection of the particular sort of vane angles and general arrangements best for a machine for a particular service, and for determination of the detailed dimensions of a machine for particular pressure conditions. A single general formula is given which applies to every sort of machine and which is reduced to a particular form for every particular machine.

In the analytical study a kinematic treatment of rotor energy is first given, which is followed by a hydraulic and thermodynamic treatment of fluid energy. The relations set forth are then applied to pumps and turbines of the axial-flow and of the radial inward- and outward-flow types.

Some of the matter here set forth has been given before, in discussion of particular machines; some of this old matter is here presented in a new way. However, it is doubtful if there has hitherto been presented a general expression for energy transfer correlated with its various applications and physical interpretations. It is the primary purpose of this paper to give such a presentation from many years of practical experience of the authors. In order to give an orderly presentation, the new and old matter are so intermingled to form a complete whole that it is difficult to make distinction and to give reference for the old matter.

The transfer of energy between a working fluid and a rotor is fundamental in the study of a wide variety of machines. Such machines are steam and water turbines, centrifugal pumps, fan blowers, and centrifugal compressors; and the fluids involved may be water, steam, air, or others. An analytical treatment of this energy transfer is here made. This gives means for selection of the particular sort of vane angles and general arrangements best for a machine for a particular service, and for determination of the detailed dimensions of a machine for particular pressure conditions. There is given a single general formula which applies to every sort of machine and which is reduced to a particular form for every particular machine. This gives a perspective and elegance not existing when the particular formula is independently deduced for every particular machine. The general and particular formulas are analyzed so as to display the physical actions which occur, so as to show what really makes each sort of machine operate.

In the analytical study, first, there is given a kinematic treatment of rotor energy. Expressions are derived for the energy transfer between rotor and fluid in terms of the fluid velocities and directions at the entrance and exit of the rotor, together with the rotor velocities at these places. Such expressions for the energy transfer are true regardless of losses that may occur while the fluid is passing through the rotor, the pressure differences that may exist across the rotor, or the path of the fluid through the rotor. They do not include the rotation loss due to the fluid friction on the sides of the rotor. It is not usually realized that these expressions in terms of the velocities are exact. This energy transfer between the fluid and the rotor, in foot-pounds per pound of fluid flowing, derived kinematically in terms of the fluid and rotor velocities, is here called the rotor energy, E.

Second, there is given a hydraulic and thermodynamic treatment of fluid energy. Expressions are collected for the energy transfer between rotor and fluid in terms of the changes of the fluid temperature and pressure through the machine. By taking the case of an incompressible fluid, or different compressible fluid processes, isothermal, adiabatic, or hyperadiabatic, a wide variety of such energy expressions is possible. The energy obtained in this way, in foot-pounds per pound of fluid flowing, is here called the fluid energy, w.

In pump machinery, because of losses, the fluid energy is less than the rotor energy. Thus a practical coefficient, called the hydraulic efficiency, is defined by $\eta = w/E$. On the other hand in turbine machinery the fluid energy is greater than the rotor energy so that the hydraulic efficiency is then defined as $\eta = E/w$.

Historical Résumé

The history of theoretical work on energy transfer between a fluid and a rotor properly begins in 1750 when Segner (1)[4] of Göttingen invented a hydraulic turbine which operated on the reaction principle. Various types of lift pumps and water wheels had been made from earliest times, but this was the first to attract the attention of the scientific world. Segner attempted to explain the operation of his turbine, but it was the mathematician Euler (2) who set down the laws of flow. However, this work was neglected for many years until it was resurrected by Combes (3), who in 1843 presented a two-dimensional theory of flow. The attempt was made to apply this two-dimensional theory to cases of three-dimensional flow with the result that the theory contributed little to the design of hydraulic machinery. Instead, machines were built according to the ideas of the engineers who invented them, with the help of experience only. The clear presentation of the theory of turbines and centrifugal pumps was not made until 1899 when Zeuner (4) published his work, "Theorie der Turbinen," which included not only hydraulic apparatus but steam turbines as well. The basic theory laid down by Zeuner is the filament or streamline theory of uniform flow that is largely used today and is here presented and enlarged upon. There have been some more recent developments in considering the pressure and velocity distributions around rotor blades by means of the hydro- and aerodynamic quantity circulation. Such items contribute refinements to the basic theory but are outside the scope of this paper.

Some of the matter here set forth has been given before in

discussion of particular machines; some of this old matter is here presented in a new way. However, it is doubtful if there has hitherto been presented a general expression for energy transfer correlated with its various applications and physical interpretations. It is the primary purpose of this paper to give such a presentation from many years of practical experience of the authors. In order to give an orderly presentation, the new and old matter are so intermingled to form a complete whole, that it is difficult to make distinction and to give reference for the old matter. Diagrams are given to illustrate the equations, accompanied in most cases by illustrations of typical machines culled from past publications, to assist in visualization.

Assumptions Regarding Rotor Energy

The theory to be presented makes various assumptions, given in what follows, most of which were originally mentioned by Zeuner. While it is realized that no actual machine operates exactly under the conditions imposed by these assumptions, it is necessary to make some such assumptions in order to construct a basic theory. In practice there may be deviations from these assumptions to a greater or lesser degree, as may be found by comparing the performance and characteristics of actual machines with those predicted from the theory herein.

The following assumptions are made in order to compute the rotor energy. The assumptions necessary for the various thermodynamical expressions will be indicated later when these expressions are introduced.

First, only steady-state operation is treated. There are transient phenomena occurring whenever a machine is started up or undergoes a change of load, but these are generally of short duration and do not greatly affect the general characteristics. With steady-state operation it follows that the flow of fluid, the speed and torque of the rotor, and the energy transfer between the fluid and the rotor are all constant with time.

Secondly, it is assumed that the flow of the fluid through the rotor is perfectly uniform. By uniform it is meant that every filament of fluid has a similar entrance to and a similar exit from the rotor. Thus the fluid in two different filaments will have the same velocity at entrance to the rotor and the same direction with respect to the radius vector. Similar conditions hold at exit. Of course there are actual departures from this ideal flow, which must be taken account of by practical coefficients.

This assumption of uniformity is most easily explained further by a discussion of blading, which is the chief cause of nonuniformity. In the region between blades the fluid velocity may be greater and in a different direction from that just along the edge of a blade. Furthermore, all blades tend to act as airfoils and set up pressure and velocity distributions around them. These distributions affect the uniformity of flow and also cause the fluid to leave the blade with a relative velocity in a direction different from that of the blade exit angle. This phenomenon is known as slip, and this is greater the fewer blades there are on the rotor. However, in the theory to be presented it is assumed that the flow is uniform and that there is no slip. As sometimes stated, this assumes a rotor having an infinite number of blades, each with an infinitesimal thickness. This assumption of uniformity applies only to fluid at entrance and exit. Conditions of flow along the rotor between these two points are matters of indifference.

Since flow is assumed to be uniform there can generally be found some average circumference along which it may be considered to take place. Thus in an axial-flow turbine the entire flow may be considered to take place at a pitch diameter. Herein, this pitch diameter is taken as the root mean square of the inner and outer diameters, so that there are equal flow areas on either side.

The assumption of uniform flow obviates a difficulty that occurs if nonuniform flow is dealt with. This is, that with nonuniform flow the mean velocity upon which the flow depends cannot be used to determine the kinetic energy of the fluid, since this depends on the square of the velocity.

In many rotors there is continuous uniform flow. This means that the flow at inlet or exit extends continuously throughout some area. In this case there is a continuous enveloping surface at inlet or exit which includes the rotor blade tips. Flow takes place with the same velocity through all parts of this surface, and the individual filaments of fluid are similar. In this case the volume rate of flow, Q, is given by

$$Q = AV \qquad [1]$$

Here A is the area of the enveloping surface which includes the rotor blade tips, and V is the component of the fluid velocity normal to this surface. A steam turbine with full arc admission is a machine in which this type of flow is approximated.

If reasonably close approximations to the fluid inlet and exit velocities can be found, so that uniform flow may be assumed, then noncontinuous flow is covered by the theory herein presented. Two such sorts of noncontinuous uniform flow may be mentioned. The first type occurs when the flow does not completely fill the passageways provided for it. An example of this is the exit of a centrifugal-compressor impeller. Here the fluid crowds against the forward side of the blades and separates from the back side. Hence the exit flow is in a series of jets even though the area provided for the flow is practically continuous. In this case the equation $Q = AV$ cannot be used since the area through which flow actually takes place is not known. However, this crowding effect usually is not very great and continuous uniform flow may be assumed and the effect of any departure thrown into the hydraulic efficiency.

The second type of noncontinuous uniform flow is that in which there are gaps in the surface through which flow may take place. Examples of this are the Pelton water wheel, Barker's mill, and a certain type of centrifugal-compressor impeller in which the discharge is through a series of nozzle-like openings. In the two latter machines the flow practically fills the nozzles, and the equation $Q = AV$ still holds provided A in this case is the area of the nozzles or openings.

It should be emphasized that existence of continuous flow merely determines whether the fluid velocity can be found from the volume rate of flow. The equations to be discussed later merely assume that the flow is uniform, regardless of whether it is continuous or not.

Finally, all losses that take place outside of the rotor are neglected. These losses are the loss due to by-passed fluid and the rotation loss. In any machine there is generally some fluid that by-passes, short-circuits, or leaks past the rotor, and hence contributes nothing to the energy transfer. This is neglected by considering only the fluid that actually passes through the rotor. The rotation loss arises from the friction of the fluid on the sides of the rotor, since the rotor is generally enclosed in an atmosphere of the working fluid. However, this loss is not here included, and the only energy considered is that transferred between the rotor and the fluid as it passes through. Thus in the case of a compressor the rotor energy is the shaft work minus the rotation loss, and in the case of a turbine the rotor energy is the sum of the shaft work and rotation loss.

Kinematic Treatment of Rotor Energy

The basic equation for the energy transfer between a fluid and a rotor will now be discussed. In Fig. 1 is shown a rotor revolving at constant angular velocity about an axis XX, with uniform flow through the rotor. The torque about the axis of the shaft

is constant. A fluid, compressible or incompressible, passes over or through the rotor, and the generality of its path should be emphasized. The fluid may enter the rotor at the center, at the rim, or at any intermediate point, and it may likewise leave at any radius. It enters at any velocity in any direction, passes through or around the rotor by any path whatever, and may leave on the same side or the opposite side from which it entered. The velocity of the fluid may stay constant during its passage through the rotor, or it may change because of change in flow area, or because of expansion or compression in the rotor passages. The rotor may be in a casing as is a steam-turbine rotor, or the casing may be unnecessary, as for a Pelton water wheel.

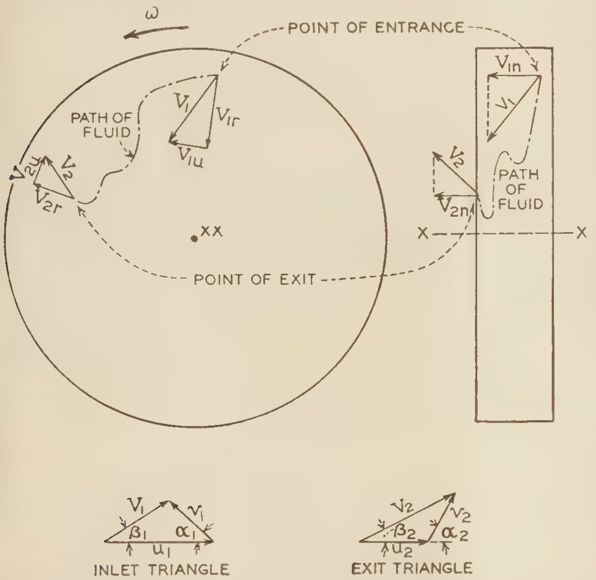

Fig. 1 General Diagram Showing How Fluid Enters Wheel With Absolute Velocity V_1, Passes Through by Any Path Whatever, and Leaves With Absolute Velocity V_2. Subscripts $_r$, $_u$, and $_n$ Designate Radial, Tangential, and Axial Directions Respectively

The notation which is to be used is defined at the end of this paper, but it is helpful to repeat some of it here and to explain the system that is used in defining the velocities. The absolute velocity of the fluid is denoted by V, the relative velocity with respect to the rotor by v, and the tangential velocity of the rotor at any radius by u. In addition, various subscripts are used. Subscript $_1$ refers to entrance to the rotor, and subscript $_2$ refers to exit. While the rotor velocity is always in the tangential direction, the fluid velocity may be in any direction, the only restriction being that the flow is uniform. Hence the fluid velocity has three components, a tangential component denoted by subscript $_u$, a radial component denoted by subscript $_r$, and an axial component denoted by subscript $_n$. The subscripts denoting the components are added to those denoting entrance or exit. Thus V_{1_u} is the tangential component of the inlet absolute velocity of the fluid, and v_2 is the total relative velocity of the fluid at exit. The components of the absolute fluid velocity are shown in Fig. 1.

By the application of Newton's laws of motion to the fluid, it is shown in Appendix 1 that for any rotor whatever, under all of the varying circumstances discussed, as shown diagrammatically in Fig. 1, the rotor energy is the very simple expression

$$E = \frac{1}{g}\,(u_2V_{2_u} - u_1V_{1_u}) \ldots\ldots\ldots\ldots\ldots [2]$$

In this equation E is the rotor energy in foot-pounds per pound of fluid passing through the rotor; E (as well as the fluid energy w) is positive if the energy transfer is from the rotor to the fluid as in a compressor, and negative if the transfer is from the fluid to the rotor as in a turbine. This equation is one of several alternate forms of the basic equation for the rotor energy that will follow. There are some features which may be pointed out.

First, the only fluid characteristics that are involved are the tangential components of the fluid velocities at inlet and exit. The equation is derived on the basis of the fluid entering and leaving with velocities in any direction, but it is only the tangential component of velocity that affects the energy transfer. The change in the axial component produces thrust on the rotor, and the change in the radial component produces stresses in the rotor, but neither change directly affects the energy transfer.

Since the equation involves no fluid properties except the fluid velocities, it follows that it is true regardless of the compressibility of the fluid or the pressure changes across the rotor. Of course both of these items, compressibility and pressure change, may affect the value of the exit velocity, but if the fluid velocities are known, then the equation gives the energy transfer regardless of compressibility and pressure change.

The equation as derived involves only the fluid conditions at entrance and exit. Hence it is independent of losses that may occur while the fluid is passing through the rotor. In particular it is independent of shock losses, losses due to friction against the rotor blades, or losses due to heat transfer between the fluid and the rotor. These losses affect the value of the exit velocity of the fluid and in this way are implicitly involved in the equation, but no term explicitly represents them.

Finally, it may be noted that the equation does not involve the blading except as the blading may affect the exit velocity. This is important from two standpoints. First, the change of tangential velocity of the fluid is a measure of the amount of turning or bending that the fluid undergoes while passing through the rotor. On this basis the equation shows that it is only the net amount of bending that influences the energy transfer. Machines have been invented in which the fluid entering the rotor is bent once, and then without leaving the rotor is bent again in the reverse direction in an attempt to get an increase in the energy transfer. Such a procedure is useless, since the rotor energy is independent of the path of the fluid through the rotor. Secondly, there is the matter of using airfoil sections as blades. With a rotor made up of airfoil sections attached to a drum, there are various velocity and pressure distributions which take place while the fluid is passing through the rotor, giving a change of pressure and hence a lift on each blade. However, regardless of this, the rotor energy is given by the tangential velocities at inlet and exit, always supposed uniform. The airfoil sections or any special blade may give a smooth passage for the fluid through the rotor and in this way affect the losses and the exit velocity, but there is no added effect due to the use of airfoil sections or any other special blade form beyond the effect on the losses and the exit velocity.

It is shown in Appendix 1 that Equation [2] may be put in a slightly different form

$$E = \frac{\omega}{g}\,(r_2V_{2u} - r_1V_{1u}) \ldots\ldots\ldots\ldots\ldots [3]$$

by the introduction of the rotor angular velocity and the radii at inlet and exit. In this form the energy transfer is seen to depend on the quantities r_2V_{2u} and r_1V_{1u}. This quantity, rV_u, is known as the "whirl" of the fluid, so that the rotor energy is directly proportional to the change in whirl. Whirl, an important concept in hydro- and aerodynamics, is related to the concept of circulation, but is outside the scope of this paper.

Finally, it is found to be convenient to express the rotor energy as

$$E = \frac{Ku^2}{g} \qquad [4]$$

In such a form K is a function of the ratios and angles of the velocity diagrams. The value u is the rotor velocity at inlet or at exit, depending on which is greater. K is a characteristic of conditions and is a convenient quantity by which various rotors may be compared. Expressions for K for various particular rotors are given later. Machines which differ in scale but have the same arrangement and angles, and similar velocity diagrams, are said to be similar machines operating under similar conditions, or to have similarity. Machines thus having similarity have the same K.

Hydraulic and Thermodynamic Treatment of Fluid Energy

Before proceeding further with the kinematic treatment of rotor energy, it seems best to consider the changes that occur in the fluid as it passes through the machine. In the case of a pump or compressor the fluid absorbs energy, whereas in turbine apparatus the fluid gives up energy. In any case the energy that the fluid gains or loses is evidenced by change of pressure and temperature. Usually there are also changes in kinetic energy and elevation. Generally, it is only the pressure that is of interest, since this is the useful portion of the energy. Then the fluid energy will be defined as the energy required for the pressure change of the fluid, with conventions on signs as given for Equation [2]. In general this is not the total energy the fluid receives from or gives to the shaft because of the losses represented by η and the rotation losses. Instead of the rotor entrance and exit, the machine entrance and exit will be used, since it is the pressure and fluid energy at these points that are of chief interest. These points will be denoted by subscripts $_0$ and $_3$ respectively. As will be shown, this bunches inlet- and exit-passage losses with fluid losses on the rotor to give the total fluid losses in the machine. In these passages, except for losses, there is conversion of static pressure and velocity head, with no change of total pressure or energy. All of the energy change occurs on the rotor.

For a liquid or incompressible fluid, the fluid energy is

$$w = (Z_3 - Z_0) + \frac{p_3 - p_0}{\rho} + \frac{1}{2g}(V_3^2 - V_0^2) \qquad [5]$$

This is merely Bernoulli's expression for the ideal energy change. In this expression the pressures are static pressures. The equation may be rearranged as

$$w = (Z_3 - Z_0) + \left(\frac{p_3}{\rho} + \frac{V_3^2}{2g}\right) - \left(\frac{p_0}{\rho} + \frac{V_0^2}{2g}\right) \qquad [6]$$

Here it can be seen that the fluid energy is defined as the change in vertical height $(Z_3 - Z_0)$ plus the change in dynamic or total head as given by the readings of impact tubes. We have already defined the hydraulic efficiency η. For a pump $w = \eta E$ and for a turbine $E = \eta w$.

In the case of a gas the matter is somewhat complicated by the fact that the pressures are dependent upon the temperatures, which may be given by various idealized processes such as isothermal, adiabatic, or hyperadiabatic. These matters have been treated in another paper (5), but may be briefly reviewed here. In case of a compressor there is compression of a given volume of fluid, and this volume depends on the heat lost or gained with respect to the surroundings and the friction losses within the compressor. Both of these items are reflected as change of temperature. An increased temperature increases the volume of the gas, which in turn makes it harder to compress. Thus, thermodynamically the gas undergoes an irreversible process with heat transfer. The fluid may be assumed to follow a law $pv^n = c$ as it is compressed. As a fair standard of comparison there may be used the theoretical work of compressing a gas with the existing pressures and temperatures given by an actual n. This is called the "hyperadiabatic energy" and is

$$w_n = \int v\,dp = \frac{nRT_0}{n-1}\left[\left(\frac{p_{3t}}{p_{0t}}\right)^{(n-1)/n} - 1\right] \qquad [7]$$

In this equation p_{0t} and p_{3t} are the total pressures at the entrance and the exit of the machine. The value of n is found from the relation

$$\frac{T_3}{T_0} = \left(\frac{p_{3t}}{p_{0t}}\right)^{\frac{n-1}{n}} \qquad [8]$$

The value of Equation [7] is called the work of hyperadiabatic compression and takes account of the heat transfer. As stated, it is a theoretical value and represents the mechanical energy needed for compression with temperatures as they actually exist. For an ideal compressor with no losses or heat transfer this reduces to the isentropic work. Complete details are given in reference (5).

The energy given by Equation [7] may be compared with the rotor energy. In Equation [4] this was expressed as $\frac{Ku_2^2}{g}$. As before, a practical coefficient η, called the hydraulic efficiency, may be defined by the equation

$$w_n = \eta\left(\frac{Ku_2^2}{g}\right) \qquad [9]$$

Such a hydraulic efficiency may be found from experimental work and then this value may be used in further design work.

The hyperadiabatic energy of Equation [7] is sometimes inconvenient to work with because of the variations of the value of n in machines of different types. For machines of a single type, the isentropic work is often used instead. Thus

$$w_k = \frac{kRT_0}{k-1}\left[\left(\frac{p_{3t}}{p_{0t}}\right)^{\frac{k-1}{k}} - 1\right] \qquad [10]$$

This is treated in full in the reference (6). By the introduction of the factor X, defined as

$$X = \left(\frac{p_{3t}}{p_{0t}}\right)^{\frac{k-1}{k}} - 1 \qquad [11]$$

the previous equation may be reduced to

$$w_k = \frac{kRXT_0}{k-1} \qquad [12]$$

As before, this value of the isentropic fluid energy may be compared with the rotor energy, and we may define

$$\text{Pressure coefficient} = \frac{w_k}{Ku_2^2/g} \qquad [13]$$

This pressure coefficient is used in work on that type of supercharger which is a high-speed centrifugal compressor. For these, the pressure coefficient varies from 65 per cent to 75 per cent with a value of about 70 per cent being quite common.

Finally, in the case of steam or other vapor for turbines and the like, the fluid energy is the isentropic change in enthalpy

or total heat from the initial temperature and pressure to the final pressure. Thus

$$w = J(h_3 - h_0) \ldots\ldots\ldots\ldots\ldots\ldots [14]$$

Multistage Compressors and Turbines

The preceding relations, as well as most of the matters treated in this paper, apply primarily to a single stage. In many cases, such as with reheaters between turbine stages or intercoolers between compressor stages, a multistage machine must be treated as successive individual stages. However, in the absence of heaters or coolers between stages, a multistage machine or a group of stages having similiarity may be treated as a whole. For every stage there must be geometrical similiarity, similar velocity diagrams, and consequently the same K. In the case of a multistage turbine, some of the losses of one stage are available in the following stages because of reheat. For an entire turbine or group of stages this reheated energy would be used as the fluid energy Σw_r. In the case of a multistage compressor, the hyperadiabatic energy Σw_n is the proper value for a group of similar stages. In the case of hydraulic pumps and turbines with groups of stages having similiarity, there are no thermodynamic complications, and Σw_n and Σw_r become simply the total energy for a group. For groups of similar stages for pumps or turbines, respectively, Equation [4] gives the following expressions which show equivalence of various combinations of stage diameters and peripheral speeds

$$\Sigma w_n = \frac{\eta K}{g} \Sigma u^2$$

$$\frac{K}{g} \Sigma u^2 = \eta \Sigma w_r$$

In the latter case, for steam turbines, a special form of Σu^2 is in use

$$\lambda = \sum \left(\frac{Dn}{1000}\right)^2 = 0.05253 \Sigma u^2$$

Here D is the diameter in inches and n is the speed in rpm.

Alternate Form for the Rotor Energy

With this brief treatment of the fluid energy, the rotor energy may be discussed further. It is shown in Appendix 1 that Equations [2] and [3] may be put in the form

$$E = \frac{1}{2g} [(V_2^2 - V_1^2) + (u_2^2 - u_1^2) + (v_1^2 - v_2^2)] \ldots [15]$$

In this form the equation shows the nature of the energy changes that take place as the fluid passes through the rotor. This equation is as general as are the other expressions for the rotor energy. The rotor velocity is necessarily tangential, but the fluid velocities may be in any direction provided only that the flow at entrance and at exit is uniform. This equation has a physical meaning, probably never before given, which it is quite desirable to understand. In this discussion the passage of an incompressible fluid through a centrifugal pump is treated for simplicity. A similar physical interpretation can be given to the passage of any fluid through any rotor. To simplify the treatment it is assumed that all parts of the pump have the same efficiency η.

The first item in the equation, $\frac{1}{2g}(V_2^2 - V_1^2)$, is obviously the change in the kinetic energy of the fluid as it passes through the rotor. If the fluid enters at an absolute velocity V_1, and leaves with a different absolute velocity V_2, it has experienced a change in kinetic energy, and this energy comes from the rotor.

The term $\frac{1}{2g}(V_2^2 - V_1^2)$, the change in the kinetic energy of the fluid that takes place as the fluid flows through the rotor, is converted into the pressure change that takes place in the machine other than across the rotor. Thus, if there is no friction in the inlet passage to the pump

$$\frac{p_{0t}}{\rho} = \frac{p_1}{\rho} + \frac{V_1^2}{2g} \ldots\ldots\ldots\ldots\ldots\ldots [16]$$

In other words the velocity energy $V_1^2/2g$ was obtained by conversion of pressure energy, and the inlet conditions to the rotor may be taken as those at the inlet to the machine since the total pressures are the same. In case there is not perfect conversion of the pressure energy into velocity energy, the efficiency, supposed constant throughout, may be introduced. Thus, if V_1 is the theoretical velocity

$$\eta \frac{V_1^2}{2g} = \frac{p_{0t} - p_1}{\rho} \ldots\ldots\ldots\ldots\ldots\ldots [17]$$

Such an expression may be written for the entrance passage to the rotor of any pumping machine using any fluid. It is here done for an incompressible fluid for the sake of simplicity, but similar relations hold for a vapor or a perfect gas.

Similar to this is the diffuser and discharge passage from a centrifugal pump. In this case the fluid leaves the rotor with a high velocity which is largely converted into pressure at the exit of the machine. However, this conversion is not perfect, so that the efficiency is introduced. Thus

$$\frac{\eta V_2^2}{2g} = \frac{p_{3t} - p_2}{\rho} \ldots\ldots\ldots\ldots\ldots\ldots [18]$$

Hence the velocity term $V_2^2/2g$ represents pressure change in the discharge passage leading from the rotor to the exit of the machine. If Equations [17] and [18] are combined, then

$$\eta \left(\frac{V_2^2}{2g} - \frac{V_1^2}{2g}\right) = \frac{p_{3t} - p_2}{\rho} + \frac{p_1 - p_{0t}}{\rho} \ldots\ldots [19]$$

Thus these velocity terms represent the change in pressure that occurs other than in the rotor, by conversion of the kinetic energy. If inlet or discharge take place in a large region, with negligible velocity, p_{0t} and p_{3t} are static pressures. In any case they are total pressures.

The kinetic-energy terms of Equation [15] have been discussed. The other terms

$$\frac{1}{2g} [(u_2^2 - u_1^2) + (v_1^2 - v_2^2)]$$

remain. Together these will be shown to represent the static pressure change that takes place across the rotor. The term $(u_2^2 - u_1^2)/2g$ is a centrifugal effect. The values u_2 and u_1 are the rotor speeds at inlet and exit, respectively, and if they are different, the fluid flows radially and experiences a change of centrifugal force. This in turn gives rise to pressure differences. To clarify this, consider a body of fluid in a hollow cylinder, rotating at the speed of the cylinder. In order to force the fluid at any radius to rotate in a circular path a centripetal force is necessary, and this force can only be furnished by an increased pressure of all fluid at greater radii. Conversely, the fluid at any radius may be considered to exert a centrifugal force on all the fluid at greater radii, resulting in an increase of static pressure from the center of the cylinder to the circumference. If a pound of fluid is taken from a radius where the velocity is u_1 to a greater radius where the velocity is u_2, then

work of amount $(u_2^2 - u_1^2)/2g$ must be done on this pound of fluid. The situation in a radial-flow machine is complicated by the flow. However, the derivation of Equation [15] shows that this centrifugal effect exists with the other effects of flow superposed upon it, and the energy involved in this effect is additive to the energy involved in the effects of flow. This centrifugal effect is, of course, absent in axial-flow machines.

The final term in Equation [15] is $(v_1^2 - v_2^2)/2g$. This term is due to the change in the relative velocity of the fluid as it passes through the rotor. If there were no centrifugal effect this term would give the change in static pressure across the rotor. Thus in a pump there is generally a decrease of relative velocity of the fluid, and this corresponds to an increase of pressure. This is the same action that takes place in a stationary diffuser, and for this reason this action is known as the diffuser or velocity-conversion effect. In a reaction turbine there is an increase in the relative velocity accompanied by a drop in pressure across the rotor. This increase in relative velocity gives the kickback or reaction that helps drive the turbine.

It has been said that the centrifugal and the diffuser or reaction effects combined give the pressure change across the rotor. Thus

$$\frac{\eta}{2g}\left[(u_2^2 - u_1^2) + (v_1^2 - v_2^2)\right] = \frac{p_2 - p_1}{\rho} \qquad [20]$$

where η is introduced since the change is not ideal but involves losses, such as friction losses, shock losses, eddy losses, or others. If Equation [20] is compared with Equation [19] it will be seen that the terms of Equation [20] involve the pressure and energy changes across the rotor while the terms of Equation [19] involve the pressure and energy changes that take place elsewhere. If these equations are added, then

$$\frac{\eta}{2g}\left[(V_2^2 - V_1^2) + (u_2^2 - u_1^2) + (v_1^2 - v_2^2)\right] = \frac{p_{2t} - p_{0t}}{\rho} \qquad [21]$$

In other words the rotor energy for pumps, multiplied by an efficiency factor, results in the fluid energy as found by total pressures at entrance and exit of the machine.

In this section an incompressible fluid has been used throughout. This has been done only for simplicity. Similar treatments may be given vapors and compressible gases. Furthermore, the efficiency η has been taken as a constant for each part of the machine. Actually this efficiency varies widely, and in Equation [21] each term should be multiplied by its own efficiency factor and the sum taken to give the change in pressure across the machine. This was not done in this section in order to simplify the presentation. The only result here desired is the physical interpretation of Equation [15].

In this section only compressor or pump apparatus was treated, for which $\eta E = w$. A similar treatment can be given to turbine apparatus for which $E = \eta w$. The physical interpretation of Equation [15] would be the same, except that in this case it is the pressure terms rather than the velocity terms that are to be multiplied by an efficiency.

TABLE 1 CLASSIFICATION OF TYPES OF APPARATUS

		Radial flow — Inward	Radial flow — Outward	Axial flow
Pumps		.....	Centrifugal fan, pump, or compressor, Figs. 2 and 3	Axial-flow fan, blower, or compressor, Fig. 6
Turbines	Hydraulic	Francis turbine, Fig. 7	Fourneyron turbine, Fig. 8; Barker's mill, Fig. 14	Pelton water wheel, Fig. 13
	Gas or steam	.....	Ljungström turbine	Impulse turbine, Fig. 9; Reaction turbine, Fig. 11

Types of Apparatus

Now that the general expressions for the rotor energy and the fluid energy have been presented, it remains to apply these to various types of apparatus. The apparatus to be treated is classified in Table 1.

As may be seen, the apparatus is divided first into pump apparatus or turbine apparatus, depending on whether the energy transfer is from the rotor to the fluid (pump) or from

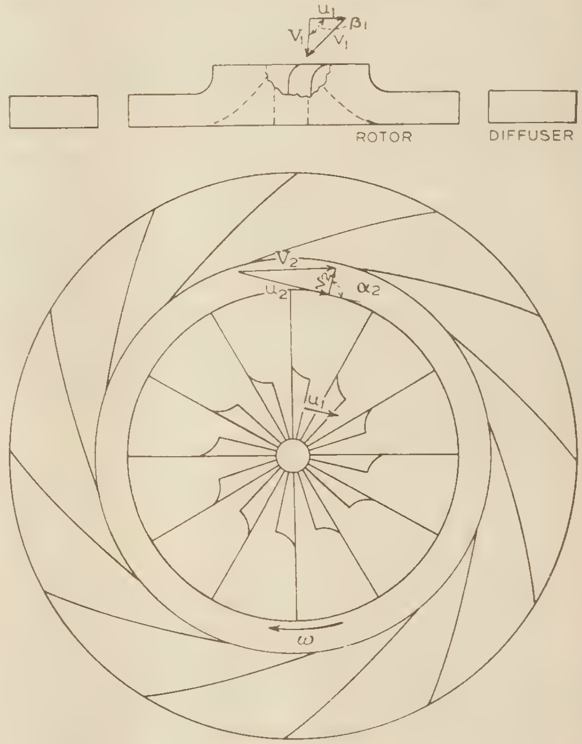

Fig. 2 Centrifugal Pump or Compressor, Axial Inlet

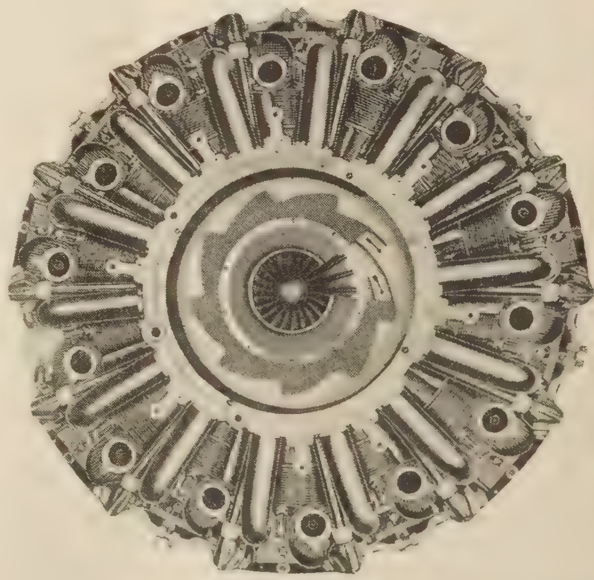

Fig. 2a Diagram of Centrifugal Compressor Used as Supercharger of an Airplane Engine

the fluid to the rotor (turbine). The apparatus is further divided into radial flow and axial flow. In the treatment to follow the pump apparatus is considered first and the turbine apparatus later. In the treatment of the turbine apparatus the foregoing order is not followed, but the Pelton water wheel and Barker's mill, being somewhat different from the other apparatus, are treated last.

Centrifugal Fans, Compressors, and Pumps

Centrifugal fans, compressors, and pumps are shown in Figs. 2, 2a, 3, and 3a. The fluid enters the rotor, which is generally known as an impeller, in an axial or radial direction. The entrance may take place through a set of stationary guide vanes, or these may be unnecessary. During passage through the rotor, the flow may be changed from the axial direction to the radial direction. At exit the fluid passes from the impeller to

Fig. 3 Centrifugal Pump or Compressor, Radial Inlet

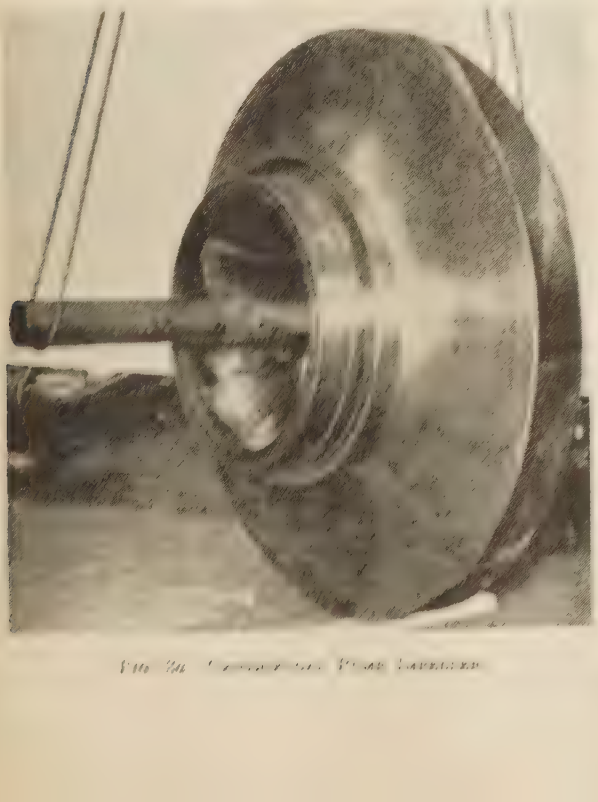

Fig. 2a Centrifugal Pump Impeller

a diffuser, which converts velocity energy into pressure energy. The diffuser may have guide vanes on it, or these may be lacking. Fig. 2a is a diagram of the sort of centrifugal compressor used as a supercharger for an airplane engine.

Recalling the previous discussion on the energy transfer between rotor and fluid, there appear several theoretical reasons for designing such a rotor with outward flow. First and foremost, outward flow takes advantage of the centrifugal effect due to the discharge of the fluid at the greater radius, and the pressure rise caused by it. Secondly, there is the effect of outward flow on the absolute velocity and hence on the change in kinetic energy of the fluid. At entrance to a centrifugal compressor or pump rotor there is no very good method of obtaining an appreciable fluid velocity, and hence it is desirable that the rotor velocity at entrance be small. However, at exit a larger absolute velocity of the fluid is possible and can be utilized, so that a comparable rotor velocity is desirable. Hence with outward flow there is an increase in absolute velocity of the fluid as it passes through the rotor, and this contributes to the energy transfer. Finally, outward flow, with increasing area for flow at larger radii, permits a decrease in the relative velocity of the fluid as it passes through the rotor, and this introduces a desirable velocity-conversion effect.

Centrifugal Pump or Compressor With Normal Absolute Inlet and Radial Relative Impeller Discharge

Perhaps the simplest construction for a centrifugal compressor or centrifugal pump is that in which there are no inlet guide vanes. It is an experimental fact, probably for a theoretical reason, that the absolute velocity at a rotor inlet is normal to an enveloping surface which includes the rotor blade inlet tips. This enveloping surface is a radial plane for an axial flow inlet such as Fig. 2, and the surface of a short cylinder for a radial inlet such as Fig. 3. Sometimes the inlet tips are inclined and the enveloping surface is conical. If the inlet is axial, as in Fig. 2, the inlet velocity is purely axial at the inlet tips of the vanes, and has no other components. In particular, there are no tangential components, so that $V_1 = V_{1a}$ and $V_{1u} = 0$. If the inlet is radial, as in Fig. 3, the inlet velocity is purely radial at the rotor blade inlet tips, and again there are no tangential components, so that $V_1 = V_{1r}$ and again $V_{1u} = 0$. Similarly, there is no tangential component with a conical inlet. Thus it follows from Equation [2] that the rotor energy is

$$E = \frac{u_2 V_{2u}}{g} \qquad [22]$$

In this case the rotor energy depends neither on the inlet velocities nor on the inlet diameter. If in addition to normal inlet the fluid leaves the rotor with a relative velocity in the radial direction, then $u_2 = V_{2u}$, and the value of the rotor energy is

$$E = \frac{u_2^2}{g} \ldots\ldots\ldots\ldots [23]$$

In the general relation of Equation [4], $E = Ku_2^2/g$, K is 1.00 for this case of normal inlet and relative radial discharge. The condition under which this equation holds in practice is that the exit blades of the rotor are radial and there are a sufficient number of them so that there is no slip of the fluid at exit.

The rotor energy has been found to be independent of the inlet conditions if the inlet is normal. It is of interest to note how the centrifugal and velocity-conversion effects change as the inlet diameter of the rotor is varied. Take the case that V_1 is constant and v_2 is kept constant or is negligible. This

implies constant inlet area as dimensions change. Then from the inlet velocity diagram, Fig. 3

$$v_1^2 = V_1^2 + u_1^2. \qquad [24]$$

This may be changed algebraically to

$$V_1^2 + u_2^2 - v_2^2 = (v_1^2 - v_2^2) + (u_2^2 - u_1^2) \qquad [25]$$

For a constant rotational speed, the left-hand side of this equation is constant. It follows that the sum of the centrifugal and velocity-conversion effects is a constant. Hence, as the inlet diameter is increased the centrifugal effect is reduced and the velocity-conversion effect is increased. This can also be seen from the inlet-velocity diagram, Fig. 3. As u_1 increases while V_1 remains constant, v_1 must also increase, indicating an increase in the velocity-conversion effect. In the Sirocco blower this interchange is carried to a great degree by a very large inlet diameter.

By means of Equation [23] where $K = 1.00$, a simple analysis can be made of the proportion in which the various items of energy are added which make up the total rotor energy. To do this it is assumed that the relative velocity of the fluid at exit, v_2, is negligible, which is a common situation. Then $u_2 = V_2$ and the kinetic energy of the fluid at exit is $u_2^2/2g$, which is just half of the total rotor energy. Thus half of the pressure rise that theoretically occurs, that due to the centrifugal effect and velocity-conversion effect, takes place in the rotor, and the other half of the pressure rise, which is that due to the conversion of this velocity head $u_2^2/2g$, into pressure, takes place in a diffuser. This consideration of energy division is important. A hasty analysis might possibly lead to the conclusion that the kinetic energy is the only energy input to the fluid (7), whereas the analysis here shows that the kinetic energy is approximately half of the total input.

A diffuser is needed to convert the velocity head of the fluid from the rotor into pressure. Several types of diffusers are used. One of these is the scroll diffuser, which collects the fluid from the rotor at velocity V_2 and at the same time expands this area to reduce fluid velocity. A second type is the Venturi-meter diffuser, which is merely an expanding pipe section. If this is used, a collecting ring is necessary to collect the fluid from the rotor at the rotor exit absolute velocity. A third arrangement is a combination of the scroll and Venturi where the scroll collects the fluid and diffuses it partially and the Venturi completes the process. A somewhat different type is the vaneless diffuser with parallel walls. These parallel walls are radial planes between which the fluid diffuses in a free vortex. Such a diffuser has a large exit diameter. A variation of this is the Moss-Robinson short-path diffuser (8) in which the distance between the walls changes with radius. The first change is a reduction that takes place as the fluid leaves the impeller, for the purpose of giving the fluid velocity a larger radial component. The second change in the distance between the walls is an increase near the outer diameter of the diffuser for the purpose of reducing the radial component of the fluid velocity, thus making it easy to collect the fluid in a collecting ring. This diffuser also has a large outer diameter. A final type is the vaned diffuser. This is similar to the two preceding ones except that vanes are introduced to effect the diffusion in a smaller space than would otherwise be required. Any combination of these types is possible.

Inlet Guide Vanes and Rotor Exit Angles

The directions of the fluid at entrance and at exit have an important effect on the amount of energy transferred to the fluid. Referring to Fig. 1, the important angles involved in this respect are the absolute angle of stationary inlet guide vanes, β_1, and the blade angle at exit from the rotor, α_2. The blade angle at entrance to the rotor is based upon the velocity diagram. To investigate the effect of these angles, Equation [15] may be put in the form

$$E = \frac{1}{g}(u_2^2 + u_2 v_2 \cos \alpha_2 - V_1 u_1 \cos \beta_1) \qquad [26]$$

as shown in Appendix 1. In this equation the angles β_1 and α_2 are acute if the inlet guide vanes and the rotor exit vanes direct the fluid forward in the direction of rotation.

If β_1 is less than 90 deg, that is, forward inlet guides, the greater the value of V_1 the less the rotor energy. The inevitable increase of friction with increased V_1 and inlet guides would further reduce the rotor energy. Since this is undesirable, inlet guide vanes turned forward are rarely, if ever, used.

If, however, the inlet guide vanes are turned backward so that β_1 is greater than 90 deg, cos β_1 is negative, and the term involving it becomes positive. Then the greater V_1 is, the greater the energy addition becomes. This statement would seem to contradict a conclusion from Equation [15] from which it would appear that a decrease of V_1 would be beneficial. However, from the velocity diagram, Fig. 3, it may be seen that an increase of V_1 effects an increase in v_1 also. Hence, by turning the inlet guide vanes backward the velocity conversion effect is increased, while the kinetic energy effect is decreased, but the

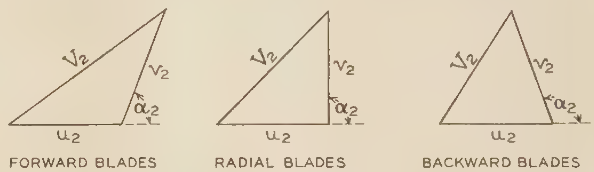

Fig. 4 Velocity Diagrams for Various Exit Angles

quantity $(v_1^2 - V_1^2)$ increases, thus giving a net increase in the rotor energy. However, this increase in energy input is usually not great if the rotor inlet diameter is small, and the little increase that is possible is accomplished by increases of V_1 and v_1, which in turn increase the friction and the shock losses at rotor entrance. There is also the complexity of the guides to be considered. For these reasons inlet guides are not often used.

Next, the effect of the angle at exit from the rotor may be considered. According to Equation [26] the energy input will be greatest when α_2 is an acute angle, so that the exit vanes are turned forward. However, in this case there is another factor to be considered. The velocity diagrams for the fluid leaving a rotor with forward-curved blades, radial blades, and backward-curved blades are shown in Fig. 4. It is evident from these that the greater energy input to the fluid for the rotor with forward-curved blades occurs principally because of the increased value of the exit velocity V_2. The purpose of a compressor is to give an increased pressure, and the greater exit velocity obtained with forward-curved blades can be useful only if the passage of the fluid through the rotor is followed by a passage through an efficient diffuser. It is well known that diffusers are often inefficient, so that a large exit velocity from a rotor cannot always be used to best advantage in a compressor. In some fans or blowers, the purpose of which is principally to deliver a large quantity of fluid at a low pressure, a high exit velocity may be useful, and forward-curved blades may be used to advantage, but compressors with vanes turned forward at exit are rare.

If the blades of a blower or compressor rotor are turned backward at exit so that in Equation [26] cos α_2 is negative, the energy added to the fluid is decreased, principally because of the decrease in the value of V_2. In other words, a rotor with

blades turned backward at exit transfers less energy to the fluid passing through it than does a rotor with radial or forward-curved blades, and hence it produces a smaller pressure rise. Since V_2 is thus smaller, such a rotor gives the best efficiency in machines such as blowers, where there is no opportunity for conversion of $V_2^2/2g$ by a good diffuser.

However, the design of a rotor to be used with a diffuser must take account of the inefficient use of the high exit velocities produced by a rotor with forward-curved blades and the lower rotor energy produced by the use of backward-curved blades. As a compromise the rotor with radial blades is frequently used. This has the obvious advantage of being by far the simplest in construction and also the sturdiest. The equations for the rotor energy for this case have already been presented in Equations [22] and [23]. It may be recalled here that in this case the kinetic energy of the fluid at exit is roughly half of the total energy input, the rest of the energy input resulting in pressure rise in the rotor.

The theoretical effect of stationary inlet guide vanes and of bending the exit rotor blades is shown graphically in Figs. 5*a* and 5*b*. To do this the rotor energy of Equation [26] is compared with that of a rotor with no stationary inlet guide vanes and with radial blades at the rotor exit. For this case the rotor energy has already been found in Equation [23] to be

$$E = \frac{u_2^2}{g} \quad \ldots\ldots\ldots\ldots [23]$$

and this will be taken as a reference. The rotor energy when the effects of inlet guides and variable rotor exit angles are considered is given by Equation [26]. The value of K is defined so that this rotor energy is Ku_2^2/g, as in Equation [4]. Thus

$$\frac{Ku_2^2}{g} = \frac{1}{g}(u_2^2 + u_2v_2 \cos \alpha_2 - V_1u_1 \cos \beta_1) \quad \ldots [27]$$

or

$$K = 1 + \frac{v_2 \cos \alpha_2}{u_2} - \frac{V_1u_1 \cos \beta_1}{u_2^2} \quad \ldots\ldots [28]$$

Now, as the angles α_2 and β_1 may be supposed to change, it is convenient for purposes of comparison to keep the rotor speed and the flow constant. The flow at inlet to the rotor is normal to a surface which envelops the rotor blade inlet tips. We suppose that the area of this enveloping surface remains constant if inlet guides are used. The volume flow at entrance is this area multiplied by the component of velocity normal to this surface. This velocity component, as may be seen from Fig. 1, is $V_1 \sin \beta_1$, and this value is to remain constant as β_1 is varied. Thus the factor

$$x_1 = \frac{V_1 \sin \beta_1}{u_1} \quad \ldots\ldots\ldots\ldots [29]$$

is introduced, and the constancy of this at constant u_1 assures constant flow. Similarly at exit the factor

$$x_2 = \frac{V_2 \sin \beta_2}{u_2} = \frac{v_2 \sin \alpha_2}{u_2} \quad \ldots\ldots\ldots [30]$$

is used. The constancy of this likewise assures constant volume flow at exit at constant u_2, with constant enveloping surface of rotor blade exit tips. Thus x_1 and x_2 are factors constant with constant flow, constant rotor speed, and constant enveloping surfaces. If these factors are substituted in Equation [28], then

$$K = 1 + x_2 \cot \alpha_2 - x_1 \left(\frac{r_1}{r_2}\right)^2 \cot \beta_1 \quad \ldots\ldots [31]$$

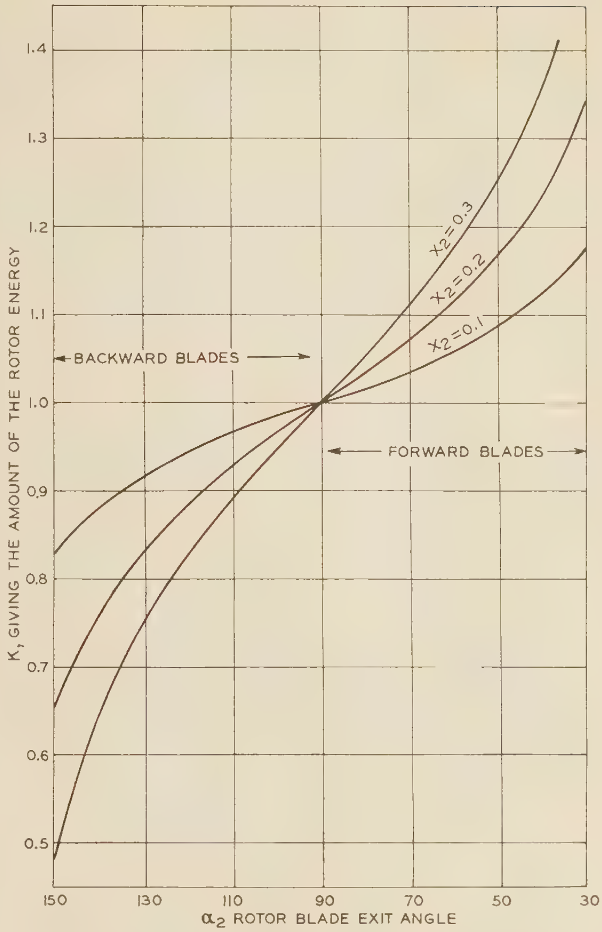

FIG. 5*a* EFFECT OF VARIATION OF EXIT BLADE ANGLES

(Values of $K = 1 + x_2 \cot \alpha_2$, with varying rotor blade exit angle, α_2, and no inlet guide vanes. $x_2 = \frac{V_2 \sin \beta_2}{u_2}$ is a factor constant with constant flow, constant rotor speed, and constant exit-tip enveloping surface.)

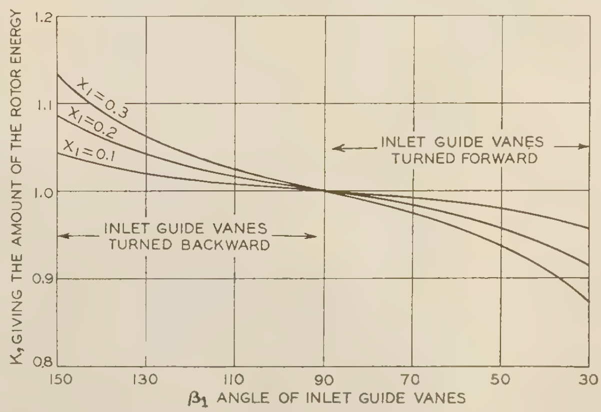

FIG. 5*b* EFFECT OF VARIATION OF INLET GUIDE VANES

(Values of $K = 1 - x_1 \left(\frac{r_1}{r_2}\right)^2 \cot \beta_1$ with varying inlet guide vanes, where the rotor blades at exit are radial and $\frac{r_1}{r_2} = 1/2$. $x_1 = \frac{V_1 \sin \beta_1}{u_1}$ is a factor constant with constant flow, constant rotor speed, and constant inlet-tip enveloping surface.)

This equation is plotted in Figs. 5*a* and 5*b* to show what gain is possible by variation of the angles. It is evident that the possible gain in rotor energy for a given u by the use of inlet guide vanes is less than that from bending the exit rotor blades forward.

Axial-Flow Fans, Blowers, and Compressors

Axial-flow fans, blowers, and compressors, Figs. 6 and 6*a*, are generally used for the movement of fluid rather than for the production of a large pressure rise. With axial flow the centrifugal effect for producing pressure rise is absent, but the change in kinetic energy and the velocity conversion effect are both present. Equation [15], without the centrifugal term, holds in this case. Hence, the rotor energy is

$$E = \frac{1}{2g}\left[(V_2^2 - V_1^2) + (v_1^2 - v_2^2)\right] \ldots\ldots\ldots [32]$$

Details of the transformation of this equation, and application to the actual case of the axial-flow compressor, are not further discussed.

In radial-flow compressors the centrifugal effect is quite important in producing pressure rise, and because of the absence of a centrifugal effect in axial-flow machines, these usually have a number of stages.

Stationary inlet guide vanes and diffusers can be used with axial-flow machines as with radial-flow machines but their use is less frequent. It can be shown that Equation [26] still holds for axial-flow machines so that for maximum rotor energy, inlet guide vanes should be turned backward, and the blade at exit from the rotor should be turned forward. However, blades with airfoil sections usually are used as these give the fluid a smooth passage through the rotor and result in a machine of high efficiency. Then it is not feasible to turn the rotor blades forward.

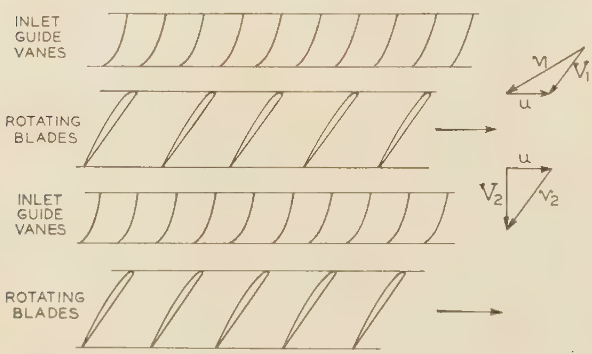

Fig. 6 Axial-Flow Fan, Blower, or Compressor

There is a feature of diffusers that should be mentioned. In radial-flow machines the diffuser takes fluid from the rotor exit through a passage at a greater radius. By the law of conservation of angular momentum it follows that any diffuser with radial flow, even an empty annular space, usually effects some pressure recovery. However, this is not the case with a diffuser on axial-flow machines, and it is possible for the entire kinetic energy associated with the tangential component of absolute velocity at exit from the fan to be lost in friction and eddying.

Some axial-flow machines present some practical deviations from the assumptions made that should be mentioned. These are made with so few blades that their characteristics can hardly be approximated by a rotor having an infinite number of blades. Furthermore, the blades may take up such a large portion of the face of the actual rotor that it would be hard to say at just what radius the various velocities and angles should be measured. Finally, the only cases that can be treated here are those in which the flow is uniform. Hence propellers such as may be used to drive airplanes or ships, Kaplan turbines, and propeller pumps must be excluded. In these applications the flow through the rotor must be determined from hydrodynamic considerations.

Radial-Flow Turbines—Francis Turbine

The subject of compressors, blowers, fans, and such machines in which the flow of energy is from the rotor to the fluid has been treated. Now machines will be discussed in which the flow of energy is from the fluid to the rotor, which is the general class of turbine machinery. Aside from the fact that turbines are the reverse of compressors there is one practical difference between the two which may be mentioned. In compressor machinery it is impractical to obtain a very great fluid velocity except at exit from the rotor, and a diffuser to convert velocity energy into pressure energy is comparatively inefficient. On the other hand, in turbine machinery an appreciable velocity may be obtained by passage of the fluid through a set of nozzles, which is an efficient process.

Because of the differences in properties of liquids and vapors, hydraulic and steam turbines are quite dissimilar. A vapor is highly compressible, and generally a number of stages are required to extract the energy from it efficiently. This staging is done in the simplest fashion in axial-flow machines. The Ljungström

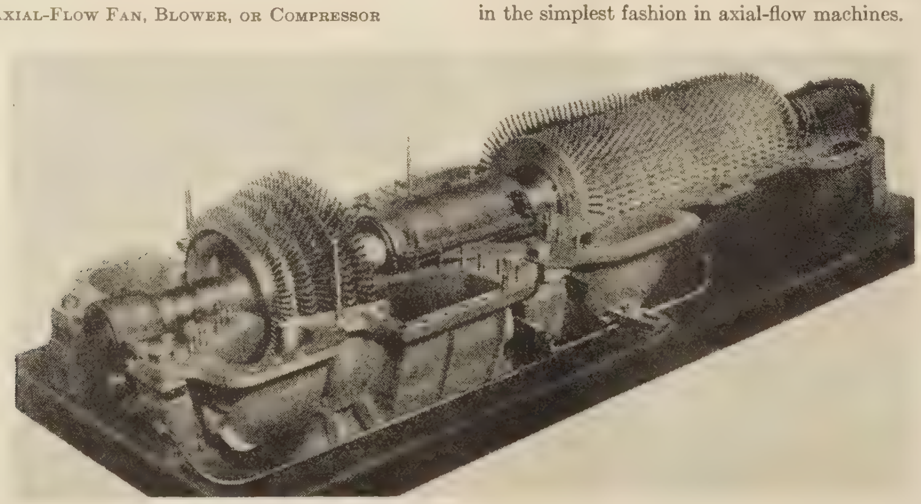

Fig. 6*a* Gas-Turbine Unit With Top Removed, Showing an Axial-Flow Turbine Driving an Axial-Flow Compressor
(Brown Boveri & Co., Ltd., Switzerland, and Allis-Chalmers Manufacturing Co., Milwaukee, Wis.)

turbine is the only well-known radial-flow steam turbine. In this the successive radial stages rotate in opposite directions. Flow is outward to allow for the expansion of the steam as it passes through the turbine. The general equations of energy transfer apply to each stage of the turbine, but since this turbine is rarely found in this country, nothing further will be said about it here.

Hydraulic turbines sometimes have a restriction not present in steam turbines. This is that at times the available heads are so small that angles and other conditions must be selected which give a small value of K. However, in some hydraulic and all steam turbines a large value of K is sought to lower the rotor speed.

The most common hydraulic turbine that has its flow primarily radial is the Francis water wheel. This is shown diagrammatically in Figs. 7 and 7*a*. Water flows radially inward

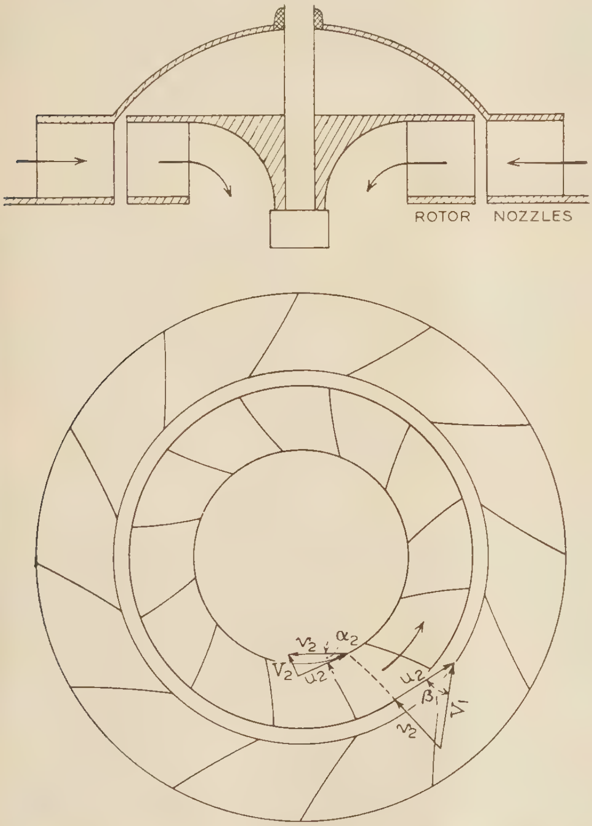

Fig. 7 Francis Turbine

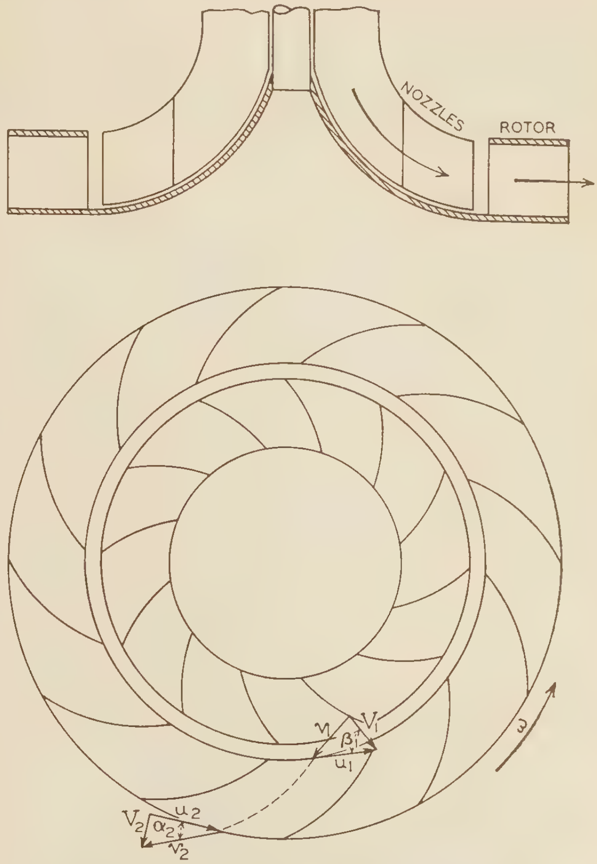

Fig. 8 Fourneyron Turbine

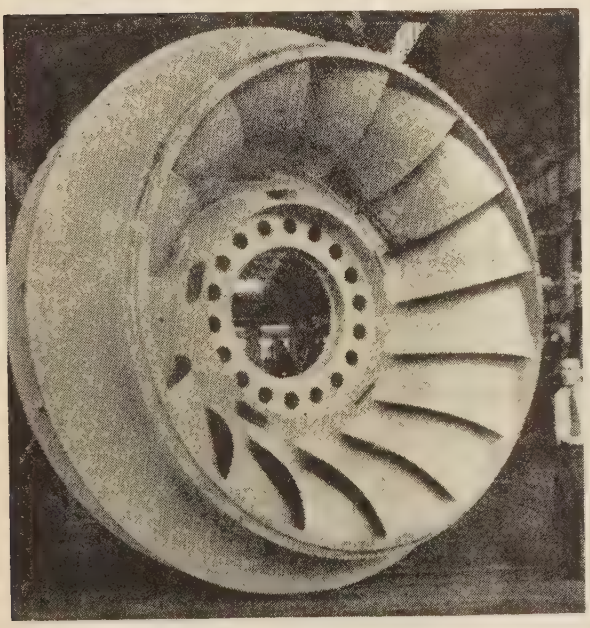

Fig. 7*a* Runner of Francis Turbine

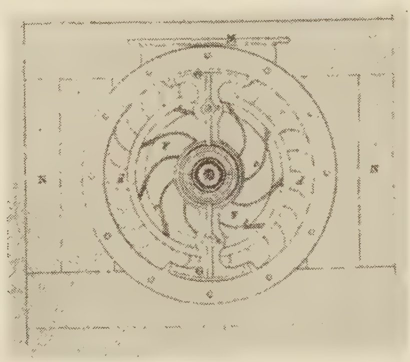

Fig. 8*a* Fourneyron Turbine of 1834

through nozzles or guide vanes at the outer periphery, passes through a rotor, called a runner, and leaves with as low a velocity as is practical. Thus the Francis water wheel is to some extent a centrifugal pump in reverse.

The general Equation [15] of energy transfer between fluid and rotor is applicable here. This is

$$-E = \frac{1}{2g}\left[(V_1^2 - V_2^2) + (u_1^2 - u_2^2) + (v_2^2 - v_1^2)\right] \quad [33]$$

where subscript $_1$ refers to entrance of the fluid, subscript $_2$ to exit, and E is negative, since energy transfer in this case is from the fluid to the rotor. The terms have the same physical meaning here as they do for pumps and compressors. The term $(V_1^2 - V_2^2)/2g$, arising from the change of absolute velocity of the fluid, represents the change in kinetic energy of the fluid. Likewise the term $(u_1^2 - u_2^2)/2g$ indicates a centrifugal effect. Since $u_1 = r_1\omega$ and $u_2 = r_2\omega$, it is readily seen that if this term is to represent energy transfer from the fluid to the rotor then $r_1 > r_2$. In other words, a radial turbine must have inward flow if it is to utilize the centrifugal effect, just as a centrifugal pump must have outward flow for the same reason. Finally, the term $(v_2^2 - v_1^2)/2g$ represents a reaction effect, or a drop in pressure due to the increased velocity relative to the rotor. The equivalent of this reaction effect in a centrifugal compressor is the velocity-conversion effect. This reaction will be discussed in greater detail in the treatment of axial-flow turbines.

In years past a hydraulic turbine, the Fourneyron turbine, Figs. 8 and 8*a*, was made with radial outward flow. This may be compared with the Francis turbine. It has already been shown that a Francis turbine with its inward flow takes advantage of each of the items of rotor energy as given in Equation [33]. On the other hand, it is obvious that in the Fourneyron turbine both the centrifugal effect and the reaction effect are negative and so reduce the rotor energy. Thus in the Francis turbine the rotor energy is comparatively high and these turbines are suitable for high heads. On the other hand, in the Fourneyron turbine the rotor energy is low, and these turbines are suitable for low heads and high speeds. In recent years the Kaplan turbine has been largely used for low heads.

The subject of inlet and exit angles for a radial-flow turbine may be treated briefly. Equation [26] may be shown to hold for this case as it does for a compressor

$$-E = \frac{1}{g}(V_1u_1 \cos\beta_1 - u_2^2 + v_2u_2\cos\alpha_2) \quad [34]$$

In this case the signs have been changed to take account of the present application. The angles have been chosen as acute when they are as shown in Fig. 7. The equation shows that the maximum energy is abstracted from the fluid when the inlet guide vanes direct the fluid forward and the rotor exit vane angle directs the fluid backward. The exit angle is such that the fluid leaves the rotor with as small an absolute velocity as is possible; for the Francis rotor shown this is a purely radial velocity. The actual form of the blades varies somewhat. Generally in hydraulic turbines the rotor velocity at inlet is as large or larger than the absolute fluid velocity. This gives a blade which varies from a radial entrance to the backward entrance that is shown in Fig. 7, rather than a blade with a large curvature as is commonly found in steam turbines. This condition arises from two reasons. First, the absolute velocity of the fluid at entrance to a Francis rotor is limited by the head available, which is often quite small, and it is desirable to make the rotor speed as high as possible to reduce the size of the turbine. Secondly, a blade with a large curvature causes large differences of velocity in the space between blades, and this gives rise to cavitation difficulties. For these reasons the backward blade is used.

With the aid of Equation [34] a value of K may be found similar to that found for centrifugal compressors. Only the case where the absolute velocity at exit is radial will be considered here. This represents the condition of minimum leaving loss. For this condition, as may be seen from the exit velocity triangle of Fig. 7

$$\cos\alpha_2 = \frac{u_2}{v_2} \quad [35]$$

Equation [34] becomes

$$-E = \frac{1}{g}(V_1u_1\cos\beta_1) \quad [36]$$

The value of K is defined in Equation [4], which for turbine apparatus becomes

$$-E = K\frac{u^2}{g} \quad [37]$$

Thus by comparison with Equation [36]

$$K = \frac{V_1\cos\beta_1}{u_1} \quad [38]$$

In other words K is determined by the ratio of the tangential component of the inlet velocity to the inlet rotor velocity.

It is possible to treat this case as the centrifugal compressors were treated and to find the variation of K with β_1 at constant speed and constant flow. However, for hydraulic turbines, such a treatment has little meaning. The velocity V_1 is limited by the available head, which is often small. The flow is also usually fixed for a particular application. It follows that the nozzle angle β_1 is fixed by the size of the rotor and the application to which the machine is to be put and is not a quantity the designer varies at will as is the case with the centrifugal compressors. The quantity that the designer does vary, however, is the rotor speed. The variation of K with rotor speed u is obvious.

Specific Speed

The use of the factor K in the discussion of hydraulic apparatus is an important item of the present paper. However, hydraulic rotors of different types often are distinguished by a quantity known as the specific speed. The specific speed is defined as the speed at which a rotor, similar to the given one and operating under conditions such that its velocity triangles are geometrically similar to those of the given rotor, would run if it takes one horsepower at a head of one foot, assuming that the influence of Reynolds' number can be neglected. In books on hydraulics (9, 10) the specific speed is given as

$$n_s = \frac{n\sqrt{P}}{H^{5/4}} \quad [39]$$

Here P is the horsepower. The quantity H is the energy of the fluid, and is numerically equal to w, discussed previously. Both P and H are usually measured at the condition of maximum efficiency.

Machines with geometrically similar dimensions operating under similar conditions (having similar velocity triangles) are said to have similarity. This similarity is with respect to both machine dimensions and velocity triangles. Effects of compressibility and Reynolds' number may be ignored. Machines with complete similarity, or with similar velocity triangles and therefore the same K but with dissimilar dimensions, or with geometrical similarity and different velocity triangles, may be

designated, compared with, and distinguished from each other by a factor known as the quantity constant. One expression for this is Q/nD^3 where Q is the volume flow and D is the rotor diameter.

If two rotors are similar and operate under similar conditions, they have the same K and the same quantity constant. They also have the same specific speed. A relation exists between the specific speed, the factor K, and the quantity constant. This may be found as follows. The horsepower required by a machine is

$$P = \frac{\rho Q E}{550} \quad \text{[40]}$$

The head delivered by a pump is

$$H = w = \eta E = \frac{\eta K u^2}{g} \quad \text{[41]}$$

For the rotor speed u there may be substituted the quantity $\pi n D/60$. Upon combining Equations [40] and [41] with the specific speed in Equation [39] there results

$$n_s^4 = 5.34 \times 10^6 \left(\frac{\rho^2}{\eta^5}\right)\left(\frac{1}{K^3}\right)\left(\frac{Q}{nD^3}\right)^2 \quad \text{[42a]}$$

Thus the specific speed for pump apparatus is found to be a function of two separate items, K and the quantity constant. In pump apparatus these two items are varied independently. Thus K is varied by change of angles on the rotor or guide vanes; and the quantity constant is varied by changing the flow, rotor speed, or rotor diameter. The specific speed shows the combined effect of variation of all of these items.

An expression similar to Equation [42a] can be found for turbine apparatus. Thus

$$n_s^4 = 5.34 \times 10^6 \rho^2 \eta^5 \left(\frac{1}{K^3}\right)\left(\frac{Q}{nD^3}\right)^2 \quad \text{[42b]}$$

However, in this case the angles are fixed by conditions under which the turbine is to operate, so that K is not a factor that the designer varies at will. Equation [42b] then shows that the specific speed depends primarily on the quantity constant.

Axial-Flow Turbines

The axial-flow turbines that are to be discussed here are the steam turbines in common use. Both the impulse and the reaction turbines will be treated. Figs. 9a and 6a show typical machines. Such turbines, especially those of large capacity, generally have a number of pressure stages; such turbines are made with axial flow because this makes the mechanical construction simpler. However, in spite of staging and its importance, only a single stage will be discussed here.

In general, the fluid passing through an axial-flow machine leaves the rotor at the same radius at which it entered. Hence the rotor velocities at inlet and exit are the same, and may be designated as u. Thus Equation [2] takes the form

$$-E = \frac{u}{g}(V_{1u} - V_{2u}) \quad \text{[43]}$$

This shows that the rotor energy depends only on the rotor velocity and the change in the tangential component of the fluid velocity. This equation is merely a statement of the fact that in this case the rotor energy is the force on the wheel multiplied by the rotor velocity, the force on the wheel being given by the change in tangential momentum. It is worth while to show the meaning of this equation on the velocity diagram, Fig. 9. The tangential component of the inlet velocity is AD. The tangen-

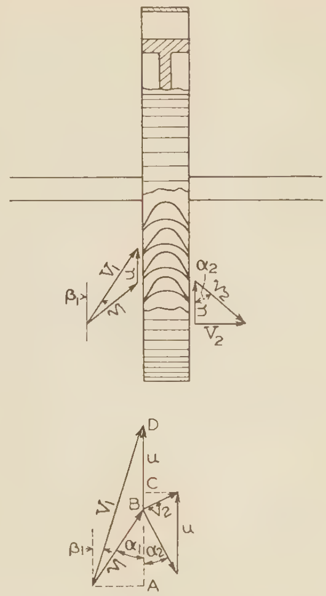

Fig. 9 Impulse Turbine

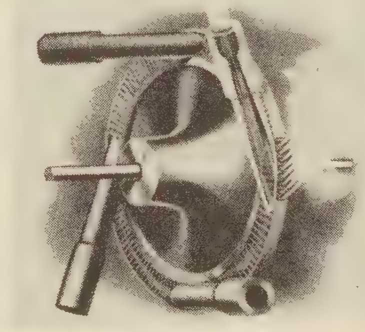

Fig. 9a Original Representation of an Impulse Turbine Used by the DeLaval Co.

tial component of the exit velocity is BC. The difference between AD and BC is the net change in tangential velocity, which gives the force on the wheel.

From the velocity diagram the following relations are apparent, in which β_1 is the nozzle angle and α_1 and α_2 are the blade angles at entrance and exit respectively

$$V_{1u} = V_1 \cos \beta_1 = v_1 \cos \alpha_1 + u \quad \text{[44]}$$
$$V_{2u} = -v_2 \cos \alpha_2 + u$$

By substitution of these relations in Equation [43] there results

$$-E = \frac{u}{g}[V_1 \cos \beta_1 + v_2 \cos \alpha_2 - u] \quad \text{[44a]}$$

$$-E = \frac{u}{g}[v_1 \cos \alpha_1 + v_2 \cos \alpha_2] \quad \text{[44b]}$$

Equation [44b] is interesting in regard to the velocity diagram. It shows that the change in the tangential velocity of the fluid in passing through the rotor is equal to the sum of the projections of the relative velocities.

A final form for the equation of rotor energy may be found from Equation [15], where the centrifugal effect may be neg-

lected since the entrance and exit are at the same radius. Then

$$-E = \frac{1}{2g}[(V_1^2 - V_2^2) + (v_2^2 - v_1^2)] \quad [45]$$

which shows that the energy change depends only on the change in kinetic energy and the reaction effect. In particular it shows that the exit velocity V_2 should be as small as possible unless it can be used efficiently in the following stage. Generally this is known as the leaving loss and is unavoidable at the last stage of the turbine.

The foregoing equations next will be applied to an impulse turbine, in which there is no pressure change across the rotor. Under ideal conditions this stipulation would mean that the relative velocity remains constant while the fluid passes through the rotor. However, because of friction and other losses the relative velocity decreases, and this may be taken account of conveniently by introducing a factor C_b, less than unity, such that

$$v_2 = C_b v_1 \quad [46]$$

If C_b is substituted in Equation [44a] there results

$$-E = \frac{u}{g}[V_1 \cos\beta_1 + C_b v_1 \cos\alpha_2 - u] \quad [47]$$

It is evident from this equation that the nozzle angle β_1 should be as small as possible for the greatest rotor energy.

Sometimes the bucket angles α_1 and α_2 are made equal, and any actual impulse buckets do not depart far from this condition. By making the assumption that the bucket angles are equal a number of relations can be found which are approximately true for all impulse buckets. Thus from Fig. 9 if $\alpha_1 = \alpha_2$ then

$$v_1 \cos\alpha_2 = v_1 \cos\alpha_1 = V_1 \cos\beta_1 - u \quad [48]$$

and Equation [47] may be written as

$$-E = \frac{u}{g}(1 + C_b)(V_1 \cos\beta_1 - u) \quad [49]$$

This expression may be differentiated with respect to u, and the speed at which the rotor energy is a maximum is found to be

$$u = \frac{V_1 \cos\beta_1}{2} \quad [50]$$

Since β_1 is usually rather small, it can be seen that for the maximum rotor energy the rotor velocity is about half the steam velocity. The factor is about $^3/_8$ in some cases.

The fact that the rotor speed for maximum rotor energy is half the tangential component of the entrance velocity can be given a physical explanation for the ideal case where there are no losses in the bucket. Referring to Fig. 9, it can be seen that under these conditions the tangential component AB of the inlet relative velocity is equal to the rotor speed. Since v_1 is assumed equal to v_2, the same is true at exit. It follows that the velocity V_2 is purely axial and hence is a minimum. Thus with no bucket losses, Equation [50] gives the rotor speed such that the leaving loss is a minimum.

The efficiency may now be treated. The input to the wheel is the kinetic energy $V_1^2/2g$, since there is no pressure drop across the rotor. However, this kinetic energy is produced by a drop in pressure through the nozzles, and this is accompanied by a friction loss. Thus the velocity V_1 is less than the ideal velocity V_0 that would be produced by an isentropic pressure drop, and this may be taken account of by introducing a factor C_n such that

$$V_1 = C_n V_0 \quad [51]$$

Thus the input to the stage is $\frac{V_0^2}{2g}$. The output is given by Equation [49] which, with the introduction of the factor C_n, reduces to

$$-E = \frac{u}{g}(1 + C_b)(C_n V_0 \cos\beta_1 - u)$$

The efficiency of the stage is the ratio of this quantity to the input, or

$$\eta = 2\left(\frac{u}{V_0}\right)(1 + C_b)\left(C_n \cos\beta_1 - \frac{u}{V_0}\right) \quad [52]$$

This efficiency is known as the nozzle and bucket efficiency. It is a function of the velocity ratio u/V_0, and is so plotted in Fig. 10 for the representative values $C_b = 0.85$, $C_n = 0.97$, and $\beta_1 = 12$ deg.

In this discussion, nozzle coefficients and bucket coefficients

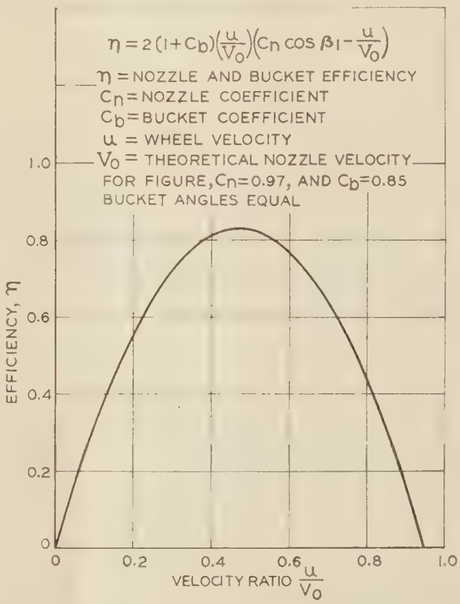

Fig. 10 Efficiency of Impulse Stage of Turbine

have been introduced to find the nozzle and bucket efficiency. It is found that such coefficients are useful in drawing velocity diagrams and finding nozzle and bucket angles. However, the nozzle and bucket efficiency of Equation [52] is of somewhat limited utility. The action between nozzle and bucket is quite complex, and some degree of reaction may be present. For these reasons the nozzle and bucket efficiency may be determined from experiment; the rotor energy is then

$$-E = \eta w$$

where w is the isentropic drop in enthalpy. Such a procedure often results in greater accuracy.

Finally, if a factor K is desired, this may be found from Equation [49] by comparing this quantity with Ku^2/g. Thus

$$K = (1 + C_b)\left(\frac{C_n V_0}{u}\cos\beta_1 - 1\right) \quad [53]$$

The effort is usually made to make the nozzle angle β_1 as small as possible. Thus K is determined by the ratio u/V_0. For the condition of best efficiency as given in Equation [50]

$$K = (1 + C_b) \quad [54]$$

which is close to the value 2. Thus the ideal rotor energy for an impulse stage is close to

$$-E = 2u^2/g \quad [55]$$

The impulse stage just discussed is characterized by the pressure equality across the rotor. Ideally the entire drop in enthalpy occurs across the stator nozzles, with no drop across the rotor. On the other hand, a reaction stage has a drop in enthalpy across the rotor with a corresponding drop in pressure. Fig. 6a shows on the left a reaction turbine driven by combustion gases. A reaction steam turbine is similar. Stages may be designated by the proportion of the drop in enthalpy which takes place across the rotor. Thus a turbine with 0 per cent drop in rotor would be one in which there is no drop in enthalpy across the rotor—in other words an impulse turbine. A turbine with 50 per cent drop in rotor would be one in which the drop in enthalpy across the rotor is equal to that across the stator. A turbine with 100 per cent drop in rotor would be one in which the entire drop in enthalpy takes place across the rotor. In this case the stator would merely change the direction of the velocity of the fluid coming from the preceding stage without causing any increase of its velocity.

Fig. 11 Reaction Turbine

A drop in enthalpy across the rotor of a turbine causes an increase of the relative velocity of the fluid. The acceleration of the fluid requires a force from the rotor, and the reaction or recoil of this is the force which drives the rotor.

For a 50 per cent drop in the rotor the use of stator blade and rotor blade with the same angles is common. The velocity diagram for this case is shown in Fig. 11, and it can be seen from this that the stator blade section is the same as the rotor section. Such a construction has obvious advantages in manufacture.

With the aid of Fig. 11, it may be shown that in the absence of friction losses the equal angle arrangement has 50 per cent drop in rotor, assuming the blade height varies directly as the specific volume of the fluid. The converse is also true. The stator angle, β_1, is equal to the rotor angle α_2. The velocity V_{2p} is the velocity of the fluid coming from the previous stage. From Fig. 11 the following relations are apparent

$$V_1 = v_2 \quad [56]$$

$$v_1 = V_2 = V_{2p} \quad [57]$$

The fluid velocity is obtained by a drop in enthalpy. Thus if subscript $_s$ denotes the stator and subscript $_r$ the rotor, the following equations may be written

$$\Delta h_s = \frac{1}{2gJ}(V_1^2 - V_{2p}^2) = \frac{1}{2gJ}(V_1^2 - V_2^2) \quad [58]$$

$$\Delta h_r = \frac{1}{2gJ}(v_2^2 - v_1^2) = \frac{1}{2gJ}(V_1^2 - V_2^2) \quad [59]$$

Thus half of the total drop in enthalpy takes place in the rotor so that the stage has 50 per cent drop in rotor.

Because of the various degrees of reaction that can be used and the compressibility of the fluid, no ideal analysis of a reaction stage, such as was made for an impulse stage, is given here, since in general the exit conditions are not defined by the inlet conditions. However, a few features may be pointed out. In many reaction turbines the rotor angle at inlet is close to 90 deg rather than the small angle found in impulse stages. This 90-deg rotor inlet angle corresponds to the condition

$$u = V_1 \cos \beta_1 \quad [60]$$

which is found to be approximately the velocity at which maximum efficiency occurs. If this is combined with the condition that the absolute exit velocity from the bucket is axial then the maximum energy transfer for a reaction stage with 90-deg bucket inlet angle can be found from Equation [43] as

$$-E = \frac{u^2}{g} \quad [61]$$

In this case, the inlet angles of the stator and rotor are the same, although exit angles may be different. However, if exit angles also are the same this becomes a particular case of the 50 per cent drop in the rotor.

There may be made some rough comparisons between the ideal impulse stage and the reaction stage in which nearly all the pressure drop takes place across the rotor. Upon comparing Equations [50] and [60] it is apparent that for a given fluid velocity, the stage with usual reaction has a rotor velocity twice that of the impulse stage. In other words, a reaction machine is inherently a higher-speed machine than the impulse machine. Upon comparing Equations [55] and [61] it is apparent that the ideal impulse stage extracts twice as much energy as the stage with usual reaction. Put in another way, in order to extract equal amounts of energy the usual reaction stage must have a rotor speed equal to $\sqrt{2}$ times the speed of the impulse stage, or about 40 per cent greater. However, both of these comparisons may be changed somewhat in practice.

Comparison of Axial- and Radial-Flow Turbines

In the study of centrifugal compressors it was emphasized that there were three important divisions of the energy transfer from the rotor to the fluid. These were the change in kinetic energy of the fluid passing through the rotor, the centrifugal effect due to the fluid's leaving the rotor at a radius different from that at which it entered, and a diffusion effect due to a reduction of the relative velocity of the fluid as it passes through the rotor. The centrifugal effect is of the greatest importance, since a diffuser to convert velocity energy into pressure energy is in practice a comparatively inefficient device, and a rotary compressor which does not make use of the centrifugal effect would be impractical. On the other hand, the turbines studied have been chiefly axial-flow machines in which there is no centrifugal effect. It is thus of interest to compare axial turbines and radial turbines with inward and outward flow and to obtain mathematically relations that are well known from experience.

To compare radial- and axial-flow turbines all losses will be neglected and it will be assumed that the fluid enters the rotor tangentially, i.e., with zero entrance angle, and that it leaves at zero absolute velocity. In other words the turbines will be compared at 100 per cent efficiency. It is, of course, impossible to satisfy these conditions and still have fluid flow through the rotor, but the expressions for energy are simplified by these assumptions without being radically changed in value. Under these conditions the rotor energy as found from Equation [2] is

$$-E = u_1 V_1/g \quad [62]$$

Two new variables are introduced. One is V_0, which is the velocity the fluid would have at the entrance to the rotor if the

entire pressure drop that takes place across the machine took place in the stator blades. Thus the definition of V_0 is

$$-E = V_0^2/2g \qquad [63]$$

The quantity V_0 is the nozzle velocity of the ideal impulse turbine. Thus $(V_0^2 - V_1^2)/2g$ is the energy that is derived from a drop in pressure across the rotor. Of this energy a portion

$$\frac{C}{2g}(V_0^2 - V_1^2) = \frac{1}{2g}(u_1^2 - u_2^2) \qquad [64]$$

may be attributed to the centrifugal effect if present. Thus $C = 1$ represents a radial-flow turbine with no reaction effect and $C = 0$ represents an axial-flow turbine in which there is no centrifugal effect.

By combining Equations [62] and [63] with [64] there results

$$\left(\frac{u_2}{V_0}\right)^2 = C\left[\frac{1}{4\left(\frac{u_1}{V_0}\right)^2} - 1\right] + \left(\frac{u_1}{V_0}\right)^2 \qquad [65]$$

In this equation u_1 and u_2 are the rotor velocities, and these depend upon the inlet and exit radii. Thus the dimensionless

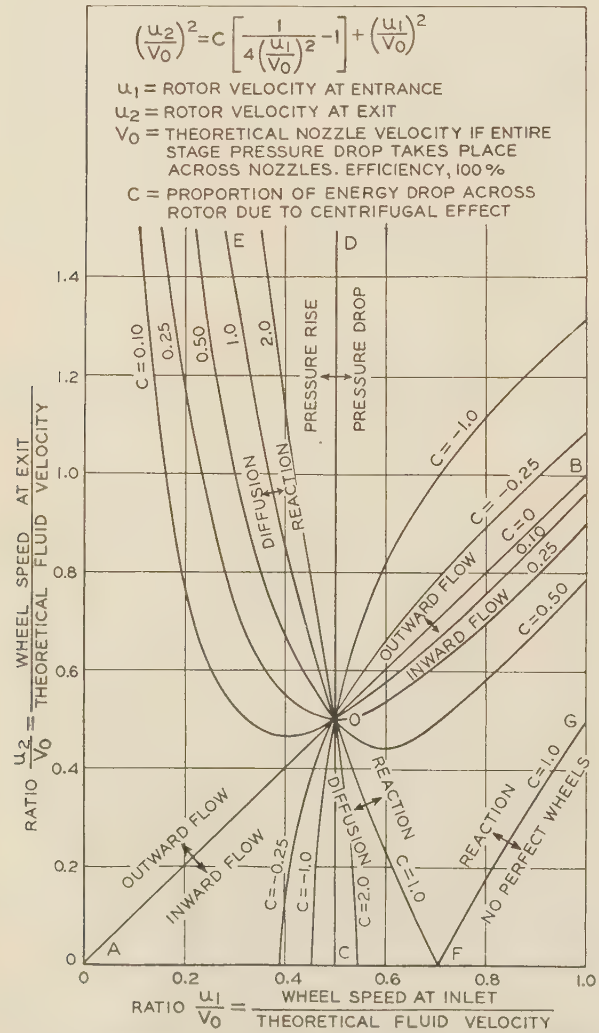

FIG. 12 COMPARISON OF AXIAL- AND RADIAL-FLOW TURBINES

factors u_2/V_0 and u_1/V_0 form convenient measures of these radii. These quantities may be used as co-ordinates on which to plot lines of constant C as in Fig. 12, and on the basis of this figure, various types of turbines may be compared. The co-ordinates chosen seem particularly appropriate, since they are dimensionless and V_0 is a measure of the total energy transfer that takes place in a stage.

In Fig. 12 the diagonal line AB represents axial-flow turbines. To the right of AB are inward-flow turbines, and to the left are outward-flow turbines. On this line $C = 0$, since there is no centrifugal effect.

On the line CD are found rotors with no pressure change, or $V_1 = V_0$. In other words, either the reaction effect and the centrifugal effect balance each other or each is zero. At the point 0 is the axial-flow impulse turbine. To the right of CD are represented rotors for which $V_1 < V_0$; this indicates a pressure drop across the rotor. On the other hand, in the region to the left of CD are represented rotors for which $V_1 > V_0$; this means that the fluid is overexpanded in the nozzles and there is a pressure rise across the rotor.

Finally, the broken line $EOFG$ is the plot of $C = 1$, or the locus of turbines in which there is no velocity-conversion effect or reaction. Along this line the entire pressure change across the rotor is utilized in producing the centrifugal effect. In the region to the right of EOF are located rotors with reaction effect, and to the left of EOF are located rotors with diffuser effect, i.e., the relative velocity at exit from the rotor is less than the relative velocity at entrance. In the region to the right of FG there are no perfect turbine rotors.

By means of Fig. 12 an investigation may be made as to which type of rotor gives the smallest outside diameter. All of the rotors which lie in the region $V_1 < V_0$, i.e., to the right of the line CD, have their larger diameter greater than that of a pure impulse rotor. The inward-flow rotors of this region with C between $^1/_4$ and 1 have their inner diameters first decrease and then increase as V_1/V_0 decreases. The rotors in the region COF have diminishing inner diameters as V_1/V_0 decreases. These are diffuser rotors. The reduction of the inner diameter causes such an excess of centrifugal action that the relative velocity has to decrease along the rotor in order to counterbalance it. All other rotors in the region $V_1/V_0 < 1$ have an increasing exit diameter as V_1/V_0 diminishes. Moreover, they call for a considerable expansion, especially in the outward-flow type, because in this case the pressure difference between inlet and outlet has to balance not only the reaction effect, but the centrifugal effect as well. The investigation so far indicates that none of the rotors working under the condition $V_1/V_0 < 1$ has characteristics that would make them preferable to pure impulse rotors.

The rotors represented along the line CO have their greater diameter the same as that of a pure impulse rotor. The nearer alike the inlet and exit diameters are, the less is the diffuser action required in them. The rotors along OD are outward flow, but have their exit diameter greater than that of an impulse rotor. Hence, none of these rotors is desirable.

Finally, the region to the left of CD may be considered. For this region $V_1/V_0 > 1$, and the rotors have a pressure rise across them. This makes them of particular interest, as they have not yet been used in practice. The following rotors have their large diameter less than that of a pure impulse rotor: The inward-flow rotor in the space AOC; the axial-flow wheels along the line AO; and the outward-flow wheels on the space between AO and the curve $C = {}^1/_4$. Of these three possibilities for a given value of V_1/V_0 the outward-flow wheel has its larger diameter greater than that of an axial-flow rotor, but with less diffusion; the inward-flow rotor has its larger diameter equal to that of an axial-flow, but with more diffusion. The rest of the

rotors in the region $V_1/V_0 > 1$ have their larger diameter greater than that of an impulse wheel.

Of all the types of rotors discussed it is only those with outward flow and with $C < 1/4$ that seem to offer any advantage over the impulse rotor. All of these have a diffusion effect. They have not yet been made in practice and it may be that the diffusion may counterbalance the inherent advantage they seem to have.

Before leaving this discussion it would be well to recall the assumptions under which it was made. In the first place it was assumed that the fluid entered the rotor with its absolute velocity tangential. This is approximately true for an impulse turbine, but less so for a reaction stage. However, for a turbine like the Francis water wheel this is even further from the truth.

The other assumption made was that the fluid leaves the rotor at zero velocity. This was done for simplicity. However, in multistage machines an effort is made in practice to utilize as much as possible of the leaving velocity from one stage in the following stage of the turbine. If this is done, the condition of zero leaving loss is closely approximated.

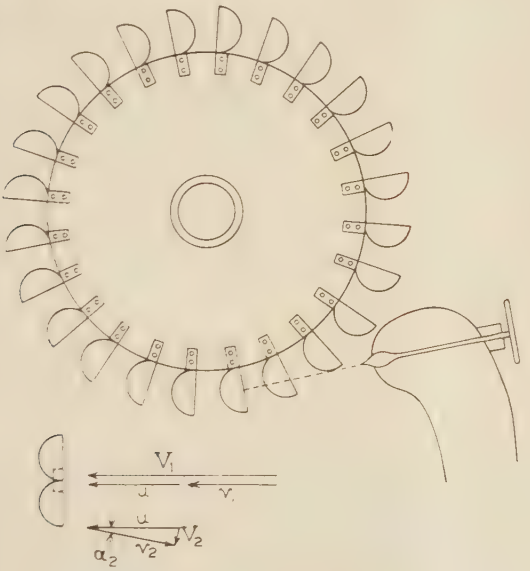

Fig. 13 Pelton Water Wheel

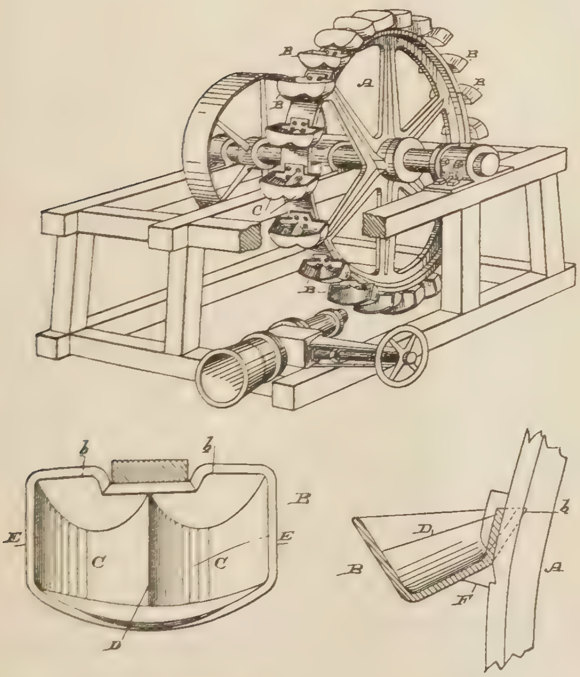

Fig. 13a Pelton Water Wheel, as Given in Pelton's Patent of 1889, but Typical of All Pelton Wheels

The Pelton Water Wheel

The Pelton water wheel was one of the earliest impulse machines used. This differs from the machines already discussed since the fluid does not completely fill the flow passages. For this reason greater outputs from a rotor of this kind may be obtained by increasing the flow without causing much change in efficiency. In fact the Pelton water wheel maintains its efficiency under changing flow better than most other turbine machines.

A Pelton wheel is shown schematically in Figs. 13 and 13a The flow is quite different from that in the other machines considered. So far, a continuous flow around an entire circumference has been considered. As opposed to this the flow at entrance to a Pelton rotor is through one or more nozzles, resulting in a few jets impinging on the rotor. However, each filament of fluid in the jet has approximately similar paths as regards velocities and directions, so that the flow may be regarded as uniform. There is a periodic change as the jet changes from one bucket to the next, but the slight effect of this will be disregarded.

As shown in Fig. 13 the flow of fluid enters the buckets essentially tangentially. The rotor is usually designed so that this is possible without the buckets greatly interfering with the flow into adjacent buckets. During passage through the buckets the direction of flow is practically reversed. The relative velocity of flow at exit is at a small angle α_2 with the direction of the bucket velocity so that the leaving fluid is cleared out of the way without interfering with the following buckets.

The fundamental Equation [2] is applied to this case as well as to the other cases considered.

$$-E = \frac{1}{g}(u_1V_{1u} - u_2V_{2u}) \quad \ldots\ldots [2]$$

In this case the rotor velocities u_1 and u_2 are equal and may be designated by u. The inlet velocity triangle degenerates into a straight line so that

$$V_1 = v_1 + u \quad \ldots\ldots [66]$$

At exit evidently

$$-V_{2u} = v_2 \cos \alpha_2 - u \quad \ldots\ldots [67]$$

Hence

$$-E = \frac{u}{g}(v_1 + v_2 \cos \alpha_2) \quad \ldots\ldots [68]$$

This equation is true regardless of the losses that take place while the fluid is passing through the rotor. A Pelton wheel by nature is an impulse machine. Because of the open passageways, it is impossible to maintain any pressure drop between entrance to the rotor and exit. Hence in an ideal rotor in which there are no losses v_1 and v_2 are equal. If this condition together with [66] be substituted in [68], there results

$$-E = \frac{u}{g}(V_1 - u)(1 + \cos \alpha_2) \quad \ldots\ldots [69]$$

This may readily be shown to be a maximum if

$$u = \frac{1}{2} V_1 \qquad [70]$$

and in this case the maximum rotor energy is

$$-E = \frac{V_1^2}{4g} (1 + \cos \alpha_2) \qquad [71]$$

The physical reason behind the existence of this condition for maximum energy transfer is similar to that for the impulse turbine. In Fig. 13, if the rotor velocity is half the fluid absolute velocity, then the relative velocity of the fluid at entrance and the velocity of the rotor are equal. If there are no losses as the fluid passes through the bucket, then at exit likewise the relative velocity of the fluid and the velocity of the rotor are equal. If the exit angle were zero, then the absolute fluid velocity at exit would be zero, and it is clear that this would be the condition for maximum energy transfer between the fluid and the rotor. Since the exit angle of the rotor α_2 is not zero, there is a small exit velocity, but the same condition for maximum energy transfer holds.

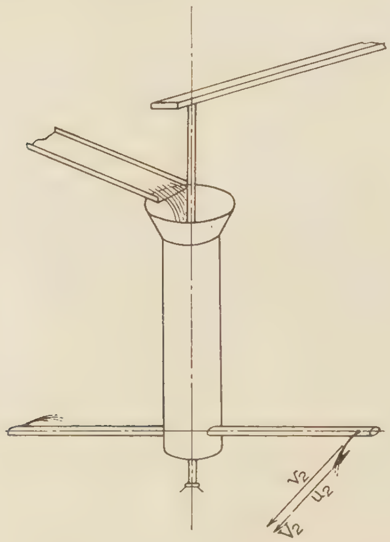

Fig. 14 Barker's Mill

Equation [71] also throws light on another matter. The Pelton wheel bends the fluid, and at times this bending may be practically 180 deg. The impulse turbine also bends the fluid, but not as much as this. For this reason, the Pelton wheel can effect a greater energy transfer than the impulse turbine.

The action of the fluid on the buckets of a Pelton wheel is fairly complicated and further mathematical work on this subject is useless. The development of the Pelton wheel has been advanced more by systematic experimentation than by mathematical analysis.

Barker's Mill

As a final machine for discussion, Barker's mill will be treated. This machine is no longer of much practical importance, but it was one of the early reaction machines and gives another illustration of the application of the fundamental equations for the rotor energy. Moreover, unlike the axial-flow reaction turbine, some ideal conditions may be assumed for Barker's mill so that at least an approximate value of the best speed may be found.

Barker's mill is shown schematically in Fig. 14. It will be seen that this is similar to a common form of lawn sprinkler. The fluid, generally water, enters at the axis of rotation, from which it proceeds out along the arms of the mill. At the far radius of the arms the flow is bent practically to the tangential direction. Thus at the outer radius it follows that

$$V_{2u} = V_2 = v_2 - u_2 \qquad [72]$$

The fluid enters at the axis so that $u_1 = 0$. Hence by Equation [2] the rotor energy may be found as

$$-E = \frac{u_2 (v_2 - u_2)}{g} \qquad [73]$$

Now assume an ideal mill. In this case the only loss is the kinetic energy of the fluid at exit. This kinetic energy is

$$\frac{V_2^2}{2g} = \frac{(v_2 - u_2)^2}{2g} \qquad [74]$$

The total energy input is

$$-E + \frac{V_2^2}{2g} = \frac{1}{2g} (v_2^2 - u_2^2) \qquad [75]$$

Thus the ideal efficiency is

$$\eta' = \frac{\dfrac{u_2}{g} (v_2 - u_2)}{\dfrac{1}{2g} (v_2^2 - u_2^2)} = \frac{2u_2}{v_2 + u_2} \qquad [76]$$

According to Equation [73] the relative velocity v_2 must be greater than the rotor velocity u_2 if the mill is to deliver energy. Hence it follows from Equation [76] that the efficiency increases as the rotor speed increases and can only reach unity at infinite speed. Practically, of course, this effect is offset by frictional losses at the greater rotor speeds. However, this ideal maximum efficiency of Barker's mill contrasts with that of the impulse turbine which has its maximum efficiency when the rotor velocity is half the fluid jet velocity.

Nomenclature

A = area for flow, sq ft
Q = flow, cu ft per sec
E = rotor energy, ft-lb per lb of fluid
V = absolute velocity of fluid, ft per sec
v = relative velocity of fluid
u = absolute tangential velocity of rotor, ft per sec
ω = angular velocity of rotor, radians per sec
r = radius, ft
g = acceleration due to gravity, ft per sec^2
J = mechanical equivalent of heat, ft-lb per Btu
c_p = specific heat at constant pressure, Btu per lb per deg F
c_v = specific heat at constant volume, Btu per lb per deg F
k = c_p/c_v = specific-heat ratio
T = temperature, deg abs F
h = enthalpy or total heat, Btu per lb
Z = vertical height of fluid, ft
ρ = density, lb per cu ft
R = gas constant, ft-lb per lb per deg F
n = hyperadiabatic constant in $pv^n = c$
p = static pressure, lb per sq ft
p_t = total pressure, lb per sq ft
α = angle between rotor blade and tangential direction
β = angle between absolute velocity of fluid and the tangential direction
K = constant by which u_2^2/g is multiplied to obtain the rotor energy for rotors with different angles

$x_1 = \dfrac{V_1 \sin \beta_1}{u_1}$ introduced in Equation [29]

$x_2 = \dfrac{V_2 \sin \beta_2}{u_2}$ introduced in Equation [30]

w = energy received per pound of fluid as it passes through a machine—the fluid energy

w_n = theoretical work of hyperadiabatic compression; $dw_n = vdp$ if $pv^n = c$ where v is specific volume

w_k = theoretical work of isentropic compression

η = hydraulic efficiency, $w = \eta(Ku_2^2/g)$ in Equation [9]

η' = ideal efficiency, where the only loss considered is the leaving loss

V_0 = defined by Equation [63]

C = defined by Equation [64]

M = torque exerted by rotor on fluid, ft-lb

P = power transferred from rotor to fluid, ft-lb per sec

W = total quantity of matter passing through rotor, lb

n = speed of rotation, rpm

n_s = specific speed

D = diameter, ft

Subscripts

1 indicates rotor entrance

2 indicates rotor exit

0 indicates machine entrance

3 indicates machine exit

u indicates tangential direction

r indicates radial direction

n indicates axial direction

APPENDIX 1

Derivation of the Equations for Rotor Energy

The general equations for the rotor energy have been given and discussed for various applications in this paper. This rotor energy is the theoretical energy that the rotor transfers to the fluid as determined kinematically. The derivation of these relations will now be given.

The assumptions and conditions for the validity of the expressions for the rotor energy have already been given. They involve principally a steady-state flow of fluid to and from a rotor which is turning about a fixed axis at constant angular velocity. The fluid enters and leaves the rotor at any radius, at any velocity, and in any direction, provided only that the flow is uniform. The meaning of the assumption of uniformity is that all filaments of fluid enter the rotor with the same velocity in the same direction with respect to the radius vector, and likewise all filaments of fluid leave the rotor with the same velocity and similar directions.

The physical principle involved in the derivation comes from Newton's laws of motion. These state that the time rate of change of angular momentum of a particle about an axis is equal to the moment of the applied force. Consider the rotor during a short time dt. A quantity of fluid dW at radius r_1 and velocity V_1 is taken into the rotor. The angular momentum of this fluid is $dW(r_1V_{1u})/g$. In the same short time dt an equal quantity of fluid dW leaves the rotor radius r_2 with velocity V_2. Its angular momentum is $dW(r_2V_{2u})/g$. Since the flow is steady the quantity discharged is equal to the quantity taken in. Hence the change in angular momentum in time dt is

$$\frac{dW}{g}(r_2V_{2u} - r_1V_{1u})$$

and

$$M = \frac{1}{g}\frac{dW}{dt}(r_2V_{2u} - r_1V_{1u}) \ldots\ldots\ldots\ldots [77]$$

where dW/dt is the quantity of matter flowing per unit of time. Thus the power is

$$P = M\omega = \frac{\omega}{g}\frac{dW}{dt}(r_2V_{2u} - r_1V_{1u}) \ldots\ldots\ldots [78]$$

The energy transfer per pound of fluid is

$$E = \frac{\omega}{g}(r_2V_{2u} - r_1V_{1u}) \ldots\ldots\ldots\ldots [79]$$

By use of the relations $u_2 = \omega r_2$ and $u_1 = \omega r_1$ it follows that

$$E = \frac{1}{g}(u_2V_{2u} - u_1V_{1u}) \ldots\ldots\ldots\ldots [80]$$

Equations [80] and [79] are identical with Equations [2] and [3] for the rotor energy.

Fig. 1 will be referred to now. In general, the entrance flow is a conical sheet. The rotor velocity, the absolute fluid velocity, and the relative fluid velocity may be shown by vectors in any plane tangent to this cone. As shown in the velocity diagram β_1 is the angle between the absolute fluid velocity and the rotor velocity and hence is the angle at which stationary inlet guide vanes direct the fluid against the rotor. Likewise α_1 is the angle between the relative fluid velocity and the rotor velocity and hence is the angle the rotor blades should have at entrance if the fluid is to enter the rotor without shock. The exit velocity diagram may be explained similarly. Thus

$$V_{1u} = V_1 \cos \beta_1 \ldots\ldots\ldots\ldots [81]$$

$$V_{2u} = u_2 + v_2 \cos \alpha_2 \ldots\ldots\ldots\ldots [82]$$

From the law of cosines

$$v_1^2 = u_1^2 + V_1^2 - 2u_1(V_1 \cos \beta_1) = u_1^2 + V_1^2 - 2u_1V_{1u}$$

so that

$$-u_1V_{1u} = \frac{1}{2}(-V_1^2 - u_1^2 + v_1^2) \ldots\ldots\ldots [83]$$

Also

$$V_2^2 = v_2^2 + u_2^2 + 2u_2v_2 \cos \alpha_2$$
$$V_2^2 = v_2^2 - u_2^2 + 2u_2(u_2 + v_2 \cos \alpha_2)$$
$$V_2^2 = v_2^2 - u_2^2 + 2u_2V_{2u}$$

whence

$$u_2V_{2u} = \frac{1}{2}(V_2^2 + u_2^2 - v_2^2) \ldots\ldots\ldots\ldots [84]$$

By the substitution of Equation [83] and [84] in Equation [80] there results Equation [15]

$$E = \frac{1}{2g}[(V_2^2 - V_1^2) + (u_2^2 - u_1^2) + (v_1^2 - v_2^2)] \ldots [15]$$

Also, by the substitution of Equation [81] and [82] in [80], there results Equation [26]

$$E = \frac{1}{g}(u_2^2 + u_2v_2 \cos \alpha_2 - V_1u_1 \cos \beta_1) \ldots\ldots [26]$$

The derivation of the other equations is indicated at the place where they are discussed.

Discussion

C. H. Berry.[4] The authors have presented an informative discussion of an important detail of fluid engineering and have done the profession a service in emphasizing the generality of the fundamental equation for the work transfer between fluid and impeller, and in bringing together a well-chosen set of examples.

On several points the writer has communicated his comments to the authors privately. He wishes to mention here a few points that seem to have general interest.

At several points, the paper asserts that the equations apply only to an incompressible fluid. The writer believes that this supports a widespread misconception that the Bernoulli equation in the form given in Equation [5] of the paper is inapplicable to the flow of gaseous fluids. This is not the case. The criterion is not whether the fluid might be compressed, but whether it is in fact compressed in the process considered. It would, he believes, be better to say "uncompressed" instead of "incompressible."

The physical interpretation of the Euler equation in terms of three parts, into which it can be broken down, is illuminating, as the writer can testify from his experience in attempting to make the situation clear to students, who find that this breakdown somewhat dispels the seeming abstraction of the simple Euler equation.

The Euler equation, which appears as Equation [3] of the paper, asserts that the work transfer between fluid and impeller is determined by the change in value of the product of radius multiplied by the tangential component of the absolute velocity of the fluid, together with the rotative speed of the impeller.

This equation is easy enough to accept as applied to impellers that receive fluid at one radius and discharge it at another, especially if the fluid passages through the impeller lie in a plane perpendicular to the shaft. We can readily picture the fluid as rotating within the impeller, and it is no shock to think of the rotational velocity of the fluid as changing, as in centrifugal pumps, or some types of water wheels.

But there is a large class of so-called "axial-flow impellers," such as ship or airplane propellers, the propeller type of fan, the screw type of pump, or the Kaplan water wheel. For these, the conclusion seems far from evident. Some people stoutly deny its validity. We picture each streamline of fluid entering and leaving such an impeller at the same radial distance from the shaft. For this situation, our mathematics tells us that there can be no transfer of work between fluid and impeller unless the rotational velocity of the fluid is changed. The fluid must receive a twist to receive work, and must receive a negative twist to develop work.

[4] Gordon McKay Professor of Mechanical Engineering, The Graduate School of Engineering, Harvard University, Pierce Hall, Cambridge, Mass. Mem. A.S.M.E.

Moreover, the work transfer is computed in terms of this change in rotational velocity. In the case of an airplane or ship propeller, this seems artificial. One has a feeling that the real work is done by the thrust force. If, however, we look at the impeller from the standpoint of the driving engine or motor, this objection seems less serious.

It may be helpful to consider the situation in connection with a common analogy that is sometimes cited to prove (so it is alleged) that a change in rotational velocity is not necessary. The analogy pictures the screw impeller driving a fluid stream much as a screw would drive a nut. Certainly a screw can drive a nonrotating nut. Why cannot a propeller drive a nonrotating stream of fluid? Let us consider this screw analogy in some detail.

First, consider a vertical shaft fitted with a shoulder upon which rests a collar, Fig. 15 of this discussion. The contact is frictionless. Everything is at rest. Now start rotating the shaft. What does the collar do? Nothing. No force acts on the collar, wherefore it remains at rest. In particular, it does not rotate.

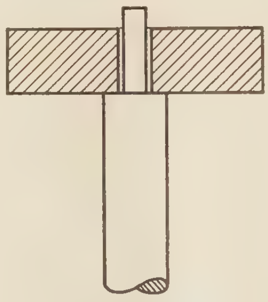

Fig. 15

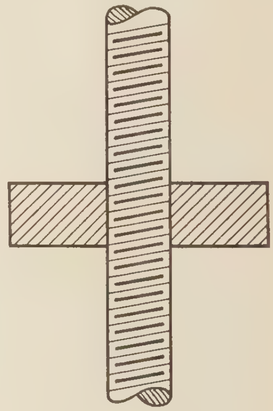

Fig. 16 (Right)

Now consider a screw fitted with a nut, Fig. 16. Again the contact is frictionless. Starting from a position of rest, set the screw rotating. Offhand, it appears that, like the previous collar, the nut will not rotate, because friction is absent, whereupon the nonrotating nut will be driven upward by the rotating screw. But this is not correct. We assume the nut free to rotate.

If the nut does not rotate, there can be no torque acting on the nut. If no torque acts upon the nut, there can be no torque resisting the rotation of the screw. Accordingly, no work is expended in driving the screw. But the nut is lifted, so that work is done against gravity. This is then a machine that gives a finite work output for zero input. Impossible!

Look more carefully at the screw. Friction being absent, the force acting between the nut and the thread of the screw must be normal to the thread. It is not parallel to the axis. This force has two components, Fig. 17, one axial, one tangential. The axial component tends to lift the nut and imposes a thrust upon the screw. The tangential component tends to rotate the nut and imposes a torque on the screw.

The axial force does work on the nut, lifting it, but merely imposes thrust on the

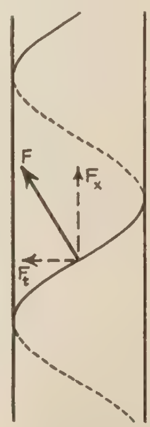

Fig. 17

screw, entailing no work transfer (friction being absent). The torque alone involves a work transfer to the screw, and yet all that the torque does to the nut is to give it a useless rotational acceleration.

What really happens then is somewhat as follows: As the screw is put into rotation, the nut is subject to a lifting force and to a torque. The nut moves upward and also rotates in the same direction as the screw. Moreover since torque is continuously imposed on the nut, its rotation is accelerating continuously (variable acceleration, to be sure, but nonetheless continuously applied). The rotational velocity of the nut increases unremittingly. At the same time, of course, the nut moves upward with a variable vertical velocity.

Ultimately the rotational velocity of the nut will rise to equal the rotational velocity of the screw (which is assumed to be constant), when the nut will cease rising. But the rotational torque and the rotational acceleration continue, so that the nut thereafter rotates faster than the screw, and hence moves downward. At last it will reach a steady state of downward motion, characterized by constant accelerations, vertical and rotational. It is not our present purpose to analyze this analogy beyond the immediate application. Accordingly, we shall confine our attention to the nut during its upward motion.

At any instant, the screw is rotating with velocity ω_s = constant, and the nut is rotating with velocity $\omega_n < \omega_s$.

The rate of rise of the nut is equal to the relative rotational velocity of the screw in the nut $(\omega_s - \omega_n)$ multiplied by the advance of the screw thread per radian of rotation, which is the pitch p of the screw (the advance per revolution), divided by 2π. If V_n denotes the vertical velocity of the nut

$$V_n = (\omega_s - \omega_n)\frac{p}{2\pi}$$

The vertical acceleration of the nut is found by differentiation.

$$\frac{dV_n}{dt} = -\frac{d\omega_n}{dt}\frac{p}{2\pi}$$

since ω_s and p are constants.

The torque acting upon the nut is the product of its angular acceleration and its moment of inertia, J. It also equals the tangential force component multiplied by the pitch radius of the screw.

$$T = \frac{J d\omega_n}{dt} = F_t r$$

whence the tangential force component can be formulated as

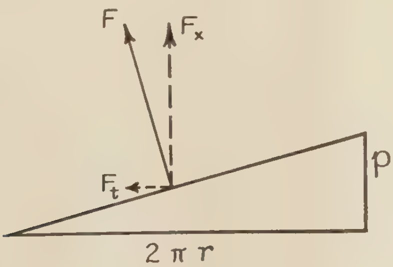

FIG. 18

$$F_t = \frac{J}{r}\frac{d\omega_n}{dt}$$

From the geometry of the screw thread, Fig. 18, the axial force component must be

$$F_x = F_t\frac{2\pi r}{p} = \frac{J}{r}\frac{d\omega_n}{dt}\frac{2\pi r}{p} = \frac{2\pi J}{p}\frac{d\omega_n}{dt}$$

The rate at which work is done upon the nut by the axial force component and by the torque can now be formulated.

$$\frac{dW_x}{dt} = V_n F_x = (\omega_s - \omega_n)\frac{p}{2\pi}\frac{2\pi J}{p}\frac{d\omega_n}{dt} = J(\omega_s - \omega_n)\frac{d\omega_n}{dt}$$

$$\frac{dW_t}{dt} = T\omega_n = J\omega_n\frac{d\omega_n}{dt}$$

Adding these two work rates, we find the total rate at which work is being done upon the nut

$$\frac{dW_n}{dt} = J\omega_s\frac{d\omega_n}{dt}$$

This equation, it will be observed, is closely analogous to the work Equation [3] of the paper. (In that equation, let the two radii be equal and note that $V_t = r\omega_f$, where ω_f is the rotational velocity of the fluid.)

The total power delivered to the nut depends upon the moment of inertia of the nut, the rotational acceleration of the nut, and the rotational velocity of the screw. If the nut has no rotational acceleration, it can receive no work.

Now consider the power required to drive the screw. By the axial component of the force, F_x, no work is done. This force merely produces a thrust in the screw.

By the torque work is done equal to the torque multiplied by the angular velocity of the screw.

$$\frac{dW_s}{dt} = T\omega_s = J\omega_s\frac{d\omega_n}{dt}$$

This is the total rate of work delivery to the screw; it equals the total rate of work delivery to the nut.

$\frac{dW_s}{dt} = J\omega_s\frac{d\omega_n}{dt}$ The power delivered to the screw has two ultimate destinations:

$\frac{dW_t}{dt} = J\omega_n\frac{d\omega_n}{dt}$ part of it is devoted to accelerating the nut rotationally. If the primary object is to lift the nut, this power is wasted, save in the sense that without it the lifting could not occur.

$\frac{dW_x}{dt} = J\omega_s\frac{d\omega_n}{dt} - \frac{dW_t}{dt}$ part of it is devoted to lifting the nut vertically (with a negative acceleration).

The total power required to drive the screw is the product of the moment of inertia of the nut, times the rotational acceleration of the nut, times the rotational velocity of the screw. Not a word about the upward velocity of the nut, notwithstanding the principal purpose of this mechanism is presumably to lift the nut.

The nut must have rotational acceleration if the screw is to absorb any work from the driving mechanism.

This study of the screw analogy may somewhat allay the incredulity with which some receive the statement that the work required to drive a propeller can be formulated in terms of the rotational velocity of the propeller and the change in the product of radius times rotational velocity of the fluid.

It would be interesting to study further the screw and nut, but it would be irrelevant to the present purpose and must be left to those interested in mechanics. A few aspects will be mentioned.

Consider the process of starting from rest, with the nut at the

lower end of the screw. The screw is abruptly set into rotation. Obviously a case of impact.

Consider the nut partially restrained from rotation by a frictional drag. This may perhaps be analogous to a propeller driving a viscous fluid through a duct.

Let the nut be positively restrained from rotating by frictionless guides.

Friction in the screw thread, between screw and nut, will introduce an additional torque and alter the allocation of power.

Finally, it is interesting to study the downward course of the nut after it has reached a rotational velocity exceeding that of the screw, and to formulate the final constant accelerations of the nut, vertical and angular.

Examination of the power allocation just developed indicates how the effectiveness of this screw mechanism can be improved. It is desired to increase the power devoted to lifting without increasing that devoted to rotational acceleration of the nut. Clearly, the one thing that will do this is to drive the screw at a high rotational speed, ω_s.

For analogous reasons, a propeller fan must operate at high rotational speed.

D. J. Bloomberg.[5] Those of us who are actively participating in developmental design work on turbines for different types of applications appreciate the need of this analytical treatment of the transfer of energy between a working fluid and a rotor, as presented by the authors.

Any practical turbine design for a given application embodies compromises in respect to the ideal turbine design because of the limitation of the designer's knowledge of the art, the manufacturing methods and facilities, and also the economic considerations.

When a new turbine design is called for to meet new operating requirements or new manufacturing methods, it is highly essential, in order to avoid pyramiding the compromises required on previous designs with those required by the new conditions, to go back to fundamentals in choosing the proper design combination to meet the new conditions.

The more thoroughly this procedure is followed, the shorter will be the developmental time period in arriving at a satisfactory design.

As pointed out in the paper, the transfer of energy between the fluid and the rotor is a function of the fluid and rotor velocities at the rotor entrance and exit.

The performance of any type of turbine design can be calculated by means of the velocity diagram with a reasonable degree of precision.

If this were more generally known, a considerable amount of well-intentioned but wasted efforts in designing and developing some new types of turbine could be avoided by a few comparatively simple calculations.

In other words, the first test any turbine design should be subjected to is that of a rational calculation system, based on the velocity diagram.

That portion of the paper covering the relation between rotor and fluid velocities for ideal energy transfer between fluid and rotor is of particular interest in respect to choosing a design combination to fit specific application requirements.

The number of design combinations for the hypothetical ideal energy transfer between the fluid and rotor, as shown in Fig. 12 of the paper, are innumerable, but certain portions of the field can be eliminated at the start as impractical.

For given ranges of fluid flow volume the problems involved in the size of the flow-path parts, stresses, rotation losses, etc., will still further narrow down the field of possible combinations. Even then, as is indicated by the different types of turbines being manufactured for the same general field of application, the choice of combinations is comparatively large.

In general practice, practical considerations, such as the desire to specialize on one general type of design and manufacturing facilities, usually are predominant.

In this connection, a comparatively small percentage of the effort normally spent on developmental work could be well spent on graphical analysis similar to that shown in Fig. 12, covering theoretical velocity-diagram performance data for definite ranges of fluid flow volume.

However, under the present world conditions, with the rapid development of new manufacturing methods, materials, etc., and with the newer fields of applications for which the turbine drives are suitable, it is well to re-examine the field of design combinations in order to reduce to a minimum that costly development period usually devoted to new design applications.

In the paper a brief mention is made of the opposed-rotation type of turbine; the comparison data for the ideal turbine-fluid and rotor-velocity relations, as shown in Fig. 12, do not include this type of turbine.

Although this type of turbine has not been widely adopted in this country, there is still the possibility that new fields of turbine applications and new manufacturing methods may offer a place for this turbine type.

K. A. Browne.[6] The authors have presented the complete basic theory of rotating machines in a remarkably clear and concise manner. The use of a simple general expression for energy transfer for all the various types of fluid flow creates a truly enlightened viewpoint on the fundamental operation of pumps and turbines.

Aircraft-engine supercharging is being accomplished solely by the radial-vane impeller, shown in Fig. 2 of the paper, and the writer's comments will be confined to this design. Vaned diffusers are used primarily to reduce the diameter of the compressor, a factor becoming more critical with every step forward in engine performance. In the last 10 years, aircraft engines have quadrupled in power output for the same diameter or head area; compressor design has kept in step by not requiring more than its same proportion of space. Now the emphasis is on altitude performance, up to 40,000 ft, where the volume to handle is 4 times that at sea level and the total pressure ratio around 8. Based on conventional practice, the size and weight of the necessary compressors increase prohibitively.

In spite of the basic advantages of the centrifugal type, serious consideration is being given the axial-flow compressor primarily because of its high Q/nD^3 and secondarily, because of its high efficiency, even though its capacity range is severely limited. There appears to be nothing in the theory of the radial type which penalizes the use of an entrance diameter equal to the rim diameter, yet practice shows that restrictive losses develop when the entrance substantially exceeds one half the rim diameter, because effective velocity conversion does not take place in the conventional rotor inlet. If we disallow any theoretical inlet diffusion ($v_1^2 = 0$, in Equation [25] of the paper) yet maintain the assumption of uniform V_1, an obviously incompatible condition, the portion of rotor energy theoretically available for conversion to pressure

$$= 1 - \frac{(r_1/r_2)^2 + (r_h/r_2)^2}{2}$$

With a hub radius r_h of $0.22\ r_2$, this factor is as follows:

[5] Research Engineer, Steam Turbines, General Electric Company, River Works, Lynn, Mass. Mem. A.S.M.E.

[6] Research Engineer, Wright Aeronautical Corporation, Paterson, N. J.

0.85 for inlet to rotor diam ratio of 0.5, avg optimum Q/nD^3 of 0.13
0.73 for inlet to rotor diam ratio of 0.7, avg optimum Q/nD^3 of 0.286
0.65 for inlet to rotor diam ratio of 0.8, avg optimum Q/nD^3 of 0.383
0.57 for inlet to rotor diam ratio of 0.9, avg optimum Q/nD^3 of 0.495

It is obvious that high volume capacity is obtained at the expense of efficiency, unless effective velocity conversion is obtained at the entrance. No one would consider making the diffuser vanes as short and sharply bent as the entry hooks on the usual supercharger blades, yet the diffusion problem is very similar for both parts. The authors call attention to the relative inefficiency of the diffusion process for creating pressure, yet actual tests do not show the impeller part of a compressor substantially better than the diffuser, thus indicating a large entry loss. Mr. Planiol has used airfoil-blade fans in the entrance with some degree of success toward improving efficiency. Further development on the impeller entrance is essential to allow higher specific capacity called for by high-altitude conditions.

Steady-flow tests of compressor-diffuser passages indicate a very high recovery, therefore, the poor recovery during operation must result from nonuniformity of flow, or departure from the theoretical assumptions. Good velocity conversion at the entrance will materially improve the axial-flow distribution. Incidentally, the slight gain in pressure, mentioned as desirable in the expanding impeller passage, can well be expended in choking the exit to obtain more uniform radial flow in both axial and tangential directions, but real gains in performance will not be forthcoming until efficient velocity conversion is obtained at the impeller entrance.

Kenneth Campbell.[7] Of general interest these years is the application of rotor fluid energy-transfer relations to the supercharging of aircraft engines. In this great field of application, the position of Dr. Moss of the General Electric Company is unique. During the last 7 years, the activities of the engine companies and the larger laboratories of the country on supercharger research have increased until today there is a great flood of effort in this direction. Dozens of engineers with scores of thousands of dollars worth of equipment are investigating the field in detail. All this follows as a logical result of the foresight, enthusiasm, and contribution of Dr. Moss's work, extending continuously from the last war to the present day.

Referring to Equation [15] of the paper, the authors have made a simplified and most effective explanation of the three important components of energy imparted to the fluid by the rotor of a centrifugal compressor. A few years ago, our investigations indicated that, in the case of radial-blade centrifugal superchargers to meet the modern requirements of high pressure ratio, there is a substantial net advantage in foregoing much of the pressure regain offered by the third component of the equation. This component represents the reduction of velocity and the resulting conversion to pressure within the impeller itself.

At the high angular velocities (up to 26,000 rpm) necessary to obtain high tip speeds with impellers of limited diameter, the eddy losses in the expanding impeller passages reduce the efficiency to a low value, which defeats the purpose of the high speed. Therefore, we have been designing our impeller passages so that the expansion ratio is in the neighborhood of 1. Of course, there is still a considerable velocity reduction because of increasing density along the path; nevertheless, by this design, the radial component at the impeller exit is made appreciable, rather than zero as assumed for simplicity in the paper, and more than one half of the rotor energy, instead of exactly one half, is represented by total velocity imparted to the fluid. This in turn places a premium on diffuser efficiency in aircraft-engine superchargers.

[7] Project Engineer, Wright Aeronautical Corporation, Paterson, N. J.

With regard to the design of vaneless diffusers, fewer velocity changes are encountered by keeping up the value of the radial component in the impeller rather than increasing it again in the diffuser after it has been reduced in the impeller. As the authors point out, however, the vaned diffuser provides the same diffusion in a smaller space and, as space is paramount in an aircraft engine, at least some form of vaning is necessary.

Rational design of vaned diffusers for comparative testing is accomplished by assuming that, as the fluid moves outward from the tips, the fronts of equal pressure across the diffuser path lie approximately on circles concentric about the main supercharger axis, as in the case of a vaneless diffuser. This conception fits in with pressure-gradient surveys which show most of the velocity-pressure conversion occurring before the so-called throat, normal to the path at the tip of the following vane.

R. Eksergian.[8] This paper is of value in the presentation of over-all generalizations that hold for all types of turbines and pumps. While a considerable part of the analysis is a recapitulation of well-known theory, such a presentation is useful in showing the applications of first principles, namely, those of momentum and energy, to a variety of equipments.

The term "rotor energy" appears somewhat misleading. This would imply the kinetic energy stored up in the rotor, whereas, the authors mean the energy transfer between the fluid and rotor. This energy transfer has two aspects. When considering the fluid flow, it is the work of the moving blades reacting on the flow. When considering the rotor, it is the work on the rotor due to the reaction of the fluid. The rate of this energy transfer is measured either by the tangential reaction component, due to the interaction between fluid and rotor, times the peripheral velocity of the rotor, or more generally by the torque times the angular velocity of the rotor.

The torque interaction between fluid and rotor is equal to the rate of change of the angular momentum of the fluid due to this interaction and is, therefore, the change in angular momentum of the fluid from the entrance to the exit sides or vice versa. The entrance angular momentum is determined by the tangential velocity from the stationary blades, whereas, the exit angular momentum is determined by the absolute whirl velocity from the moving blades. When the entrance angular momentum to the moving blades exceeds the exit angular momentum, the torque reaction of the rotor opposes the flow, while the action on the rotor drives the rotor, and the energy transfer corresponds to that of a turbine. When the exit angular momentum exceeds the entrance, work is done on the flow, with a corresponding resistance to the motion of the rotor. In this case we have a pump.

Using the authors' nomenclature and referring to Fig. 9 of the paper, the torque reaction Φ and the rate of energy transfer E between fluid and rotor are

$$\Phi_{\text{turbine}} = \frac{1}{g}\left[V_1 \cos\ \beta_1 \cdot r_1 - (u_2 - v_2 \cos \alpha_2) r_2\right] \text{(per pound of flow)}$$

and since $E = \Phi\, \omega,$ where $\omega = \dfrac{u_1}{r_1} = \dfrac{u_2}{r_2}$

$$E_{\text{turbine}} = \frac{1}{g}\left[V_1 u_1 \cos \beta_1 - u_2^2 + u_2 v_2 \cos \alpha_2\right] \text{(per pound of flow)}$$

while the terms are interchanged for a pump. The latter is the authors' Equation [26].

It is important to note, however, that Equation [26] of the paper represents only the energy transferred between the rotor and the fluid. It does not represent the change in energy between

[8] Edward G. Budd Manufacturing Company, Philadelphia, Pa. Fellow A.S.M.E.

the entrance and exit sections to the rotor (as was the case in considering the change in angular momentum), because entrance-shock losses occur as well as friction losses through the rotor itself.

Now in general the relative velocity at entrance, i.e., the vector difference $\bar{V}_1 - \bar{u}_1$ does not coincide with the blade angle α_1. Therefore, Equations [44] and [44*b*] hold only for one specific speed. The same objections apply to Equations [46] to [49]. If C_b is to cover all losses, when $\alpha_1 = \alpha_2 = \alpha$ it would be preferable to replace Equation [46] by $v_2 \cos \alpha = C_b \; [V_1 \cos \beta_1 - u_1]$ and then Equation [49] retains its previous form. This interpretation of Equation [49] is necessary since the authors use it to discuss the form of the efficiency curve with speed, which, therefore, includes the very shock losses just discussed.

Referring to the alternate form for the energy transfer, given in Equation [15] of the paper, it is again important to note that the entrance relative velocity v_1 is obtained from the vector relation $\bar{v}_1 = \bar{V}_1 - \bar{u}_1$, which is not the authors' relative velocity.

It is difficult to concur with the authors' thermodynamic treatment of the fluid-energy relations through the turbine. The authors' statement cannot be sustained, i. e., that the energy that the fluid gains or loses is in the form of change of pressure and temperature, and that only pressure is of interest, since this is the only useful portion of the energy. The authors mean that only the energy changes, expressed in terms of pressure and temperature, are of interest. Neglecting kinetic energy and head as small, the energy per pound of fluid, associated with a given pressure and temperature at any section of the flow, is given by the relation

$$h = Apv + u - u_0$$

where $A = 1/J$, v = specific volume, u = intrinsic energy per pound of fluid, and h = the total heat, or better, the enthalpy of the fluid.

The authors' Equations [7] to [12] can be regarded as a specialized case, applicable to the flow of gases, whereas, a more generalized relation should be stated.

Therefore the fundamental energy equation of the fluid across the turbine is

$$Q_{12} - AP + H_1 - H_2 = \frac{AW}{2g} (V_2^2 - V_1^2)$$

$$\text{and } E = \Phi\, \omega \qquad J = 1/A = 778$$

where

P = rate of energy transfer between fluid and rotor, (ft-lb/sec)
W = fluid flowing across a section, lb per sec
(This W is not W as used in Appendix 1)
V_1 and V_2 = terminal absolute velocities, (ft/sec)
$H_1 - H_2 = W\,[A(p_1v_1 - p_2v_2) + u_1 - u_2]$ = total heat drop
Q_{12} = total external heat transmitted to fluid per sec, (Btu/sec).

While the kinetic-energy term across the entire turbine can usually be neglected, on the other hand, it cannot be neglected when considering the flow across the rotor. When $Q_{12} = 0$, we have an adiabatic change in the flow.

In the case of a pump, the energy transfer to the fluid across the rotor E increases the enthalpy at section 2 over that at section 1, so that

$$AP - Q_{12} = H_2 - H_1 + \frac{AW}{2g} (V_2^2 - V_1^2)$$

where Q_{12} is now the external heat lost by the fluid. Since the change in intrinsic energy of a gas from state 1 to state 2 is

$$u_2 - u_1 = A \left[\frac{p_2v_2 - p_1v_1}{k - 1} \right]$$

then, for an adiabatic compression $Q_{12} = 0$; and since $h = Apv + u$, and $H = Wh$

$$P = \frac{kW}{k-1} [p_2v_2 - p_1v_1] + \frac{W}{2g} (V_2^2 - V_1^2)$$

It is important to point out the fact that this relation holds irrespective of friction, shock, and throttling losses and is equal to the energy-transfer rate between fluid and rotor.

In the case of an ideal adiabatic isentropic (constant entropy) compression $pv^k = C$ then

$$P = \frac{kWRT_1}{k-1} \left[\left(\frac{p_2}{p_1}\right)^{(k-1)/k} - 1 \right] + \frac{W}{2g} (V_2^2 - V_1^2)$$

This is an ideal adiabatic reversible compression. Actually, however, the compression is irreversible with external heat transfer, and $pv^n = C$ is assumed for the pressure–volume relation in the compression. In this case, the expression for the energy relation is

$$P - J\,Q_{12} = \frac{kWRT_1}{k-1} \left[\left(\frac{p_2}{p_1}\right)^{(n-1)/n} - 1 \right] + \frac{W}{2g} (V_2^2 - V_1^2)$$

so that, knowing the pressure limits, measuring P and Q_{12} through the jacket water, n can be calculated.

Relative to Equation [14] of the paper, the interpretation is somewhat confusing. If the authors mean the actual change in enthalpy from the initial to the final conditions, the change is not isentropic, due to the internal losses. In this case, we should write $P = J\,(H_3 - H_0)$, since E is the actual energy-transfer rate across the rotor and H_3 and H_0 are the terminal-section enthalpies. With this interpretation, the losses do not have to be taken care of by an efficiency factor. If an efficiency factor is used, i.e., $P' = \frac{1}{\eta} P = J(H_3 - H_0')$, then we may assume an ideal isentropic adiabatic heat drop for the same pressure and temperature limits but H'_0 is not the actual enthalpy at the lower terminal section.

It is just this point that requires the statement of an additional relation which the authors have not included in their flow analysis. This is the heat equation, which gives the thermodynamic relation for the changes of state of the fluid at the terminal sections. We can always measure the actual changes of state which occur through an irreversible process, by a reversible path. The heat transferred to the fluid for the reversible path is the total heat, both externally and internally transferred to the fluid between the terminal sections. The internal-heat component is due to the various mechanical losses, regenerated within the fluid into heat. If Q_{12} and Q_R are the external and internal heat transferred to the fluid, then

$$Q_r = Q_{12} + Q_R = W\,[u_2 - u_1 + 1/J \int_1^2 pdv]$$
$$= H_2 - H_1 - W/J \int_1^2 vdp$$

where the corresponding change in entropy (per pound of fluid) is

$$\phi_2 - \phi_1 = \frac{1}{W} \int_1^2 \frac{d(Q_{12} + Q_R)}{T}$$

For an adiabatic flow, $\phi_2 - \phi_1 = \dfrac{1}{W} \displaystyle\int_1^2 \frac{dQ_R}{T}$

We may write the adiabatic-energy equation for the fluid, as

$$(H_1 - WT_0\,\phi_1) - (H_2 - WT_0\,\phi_2) - WT_0\,(\phi_2 - \phi_1) = \frac{1}{J} P$$

which reduces to

$$H_1 - H_2' - WT_0\,(\phi_2 - \phi_1) = \frac{1}{J}\,P$$

where T_0 = the lowest available temperature of the system; in this case $T_0 = T_2$ and $H_2' = H_2 - WT_2\,(\phi_2 - \phi_1)$ = the enthalpy, assuming an isentropic heat drop, at the lower terminal section. We note, $H_1 - H_2'$ = the isentropic adiabatic heat drop, and

$$WT_2\,(\phi_2 - \phi_1) = T_2 \int_1^2 \frac{dQ_R}{T} = \text{increase of unavailable energy}$$

due to throttling, etc.

In other words, the isentropic heat drop minus the increase of unavailable energy, resulting from throttling, etc., and measured by the increase of entropy, is equal to the work performed. In this case, the turbine efficiency referred to in the authors' Equation [14] is

$$\eta = \frac{P}{J(H_3 - H_0')}$$

where

$$H_0' = H_0 - WT_0\,(\phi_0 - \phi_3)$$

J. H. Marchant.[9] In this paper, the authors have attempted to generalize the very complicated field of jet-and-vane machinery, probably with the idea of giving the reader a better perspective of this whole problem. Such an objective is certainly praiseworthy, but it seems as though the many simplifying assumptions, which the authors have been forced to make, tend to promote intangibility.

Regarding the centrifugal supercharger itself, the writer would like to comment more specifically. This piece of equipment, like other jet and vane machinery handling compressible fluids, is not susceptible to the simple analysis given by the authors. In this case, hyperadiabatic work has little significance, except possibly to mask the complication of its internal workings. Furthermore, is it not impractical for the authors to assume that one half of the pressure rise occurs in the impeller? Generally speaking, none of these simple relations stated by the authors have actual significance unless they may have in mind being able to alter the machine to fit their formulas; and, judging from the performance of the most modern centrifugal aircraft-engine superchargers, this cannot be done quite yet.

A look at what actually may be taking place in the modern centrifugal aircraft-engine supercharger will serve to illustrate the limitations of any such generalizations. Suppose that it has an axial inlet with no inlet guide vanes, as the authors assume; the air enters axially for no particular theoretical reason (as the authors state) except that, among others, it is trying to obey Newton's first law. It enters the impeller generally with rather large impact losses, except probably over one very narrow range of $Q/(ND^3)$, at which it seldom is operated in practice. Immediately, flow separation develops in the impeller, generally beginning at the inlet-vane tips, and by the time the air leaves the impeller that passage is running perhaps not over one third full. The circumferential velocity traverse of the air in any one passage is probably a weird-looking thing, with air flowing radially outward near the high-pressure side of the blade and radially inward near the low-pressure side of the next adjacent blade. Besides all of this, most of the air crowds to the back wall of the impeller. What now will the authors use for A (area) or V (velocity) in their Equation [1]? Next, the air leaves the impeller with the usual large leaving losses, the vortices, which are produced by each blade tip, being dragged around in the clearance space between the impeller and the diffuser at the rate of approximately 25,000 rpm.

It is obvious that no simple steady-flow equation applies here, since the flow is probably about as unsteady as it could be made conveniently. Then the air enters the diffuser, with unknown impact losses, with a stream velocity which is probably supersonic, and the diffuser vanes, which are curved airfoil sections usually cast and rough, stall; flow separation occurs, and compression shock may develop from each rough spot; and no one knows what comes out of it into the collector case.

Generally speaking, the air stream is so completely garbled that it would be difficult to interpret the significance of readings of the instruments which might be installed to measure component performance. There is also some question in the writer's mind as to whether or not the instruments themselves even would know what to indicate, due to induced instabilities.

Thus, the supercharger is no simple piece of equipment. Even the authors, competent as they are, would find it difficult to make it conform to the simple laws which they would like to have us believe it obeys.

The bibliography of this paper is high-lighted by the absence of the name of Prof. A. Stodola, who some time ago pointed out the practical limitations of the Euler equations, the generality of which the authors have undertaken to expound.

In closing, the writer wishes to commend the authors on their purpose in presenting this paper. The useful information in this field is scattered and in some cases certainly difficult to ferret out. Such a general compilation as the authors have undertaken is needed and could be very useful. Unfortunately, however, any such comprehensive survey is difficult and vulnerable to all sorts of criticisms; since generalities inevitably lead to exceptions.

R. D. Madison.[10] Without detracting in any way from the valuable aspects of this paper, the writer wishes to comment on certain parts that may be of special interest. The paper as a whole brings to the reader a very clear picture of the energy transfer between a fluid and a rotor. However, one should be on the alert to remember that in many cases the chief purpose is not to effect the greatest energy transfer. Frequently, a smaller energy transfer can be effected under more favorable conditions of efficiency.

In this connection, in discussing inlet guide vanes, the authors say: "The inevitable increase of friction with increased V_1 and inlet guides would further reduce the rotor energy. Since this is undesirable, inlet guide vanes turned forward are rarely, if ever, used." Stationary inlet guide vanes have been used on both high-speed high-duty centrifugal fans, as well as on ventilating fans for many years, and in ever-increasing quantities. It is true that there is an increase in V_1 and a decrease in v_1 and to obtain the same pressure and air delivery, the fan must be operated at somewhat higher speeds. In doing so $(u_2^2 - u_1^2)$ becomes greater and there is a larger percentage of static-pressure rise across the rotor, a form of pressure development more efficient than is possible in velocity-pressure conversion in the usual commercial-fan volutes.

Then the authors admit that in the case of inlet guide vanes turned backward (against wheel rotation) an increase of v_1 increases the shock loss at entrance to the rotor. By the same reasoning, a decrease of v_1 (in the case of the forward inlet vane) reduces the shock loss and, in many cases, this is more desirable than increase of energy transfer.

In the most approved form of the stationary inlet guide vane,

[9] Engineer, Pratt & Whitney Aircraft, East Hartford, Conn. Mem. A.S.M.E.

[10] Research Engineer, Buffalo Forge Company, Buffalo, N. Y. Mem. A.S.M.E.

the curvature varies from the center of the inlet outward, that is, the air is guided forward in the direction of wheel rotation, but the amount of spin is small near the shaft center and large near the outer diameter of the fan inlet. In terms of the values in the paper, β_1 near the shaft center is substantially 90 deg, but at the largest radius, β_1 becomes as small as 30 or even 20 deg. It is also interesting to observe the flow between the vane and rotor inlet. The fluid near the shaft center takes a long sweeping curve to meet the rotor entrance. The air passing through the guide vane farthest from the shaft center is first curved forward in the direction of wheel rotation and then outward through the rotor vane with an absolute velocity approximately at right angles to the initial flow. The latter type of flow is very much less power-consuming than would appear at first thought. Tests[11] on compound elbows with turns in planes at 90 deg have shown this to be the case.

The advantages of inlet guide vanes turned forward may be summarized as follows:

1 Fan efficiency is increased when the rotor-blade shape is backward-curved at the exit.

2 A self-limiting horsepower curve is produced which greatly facilitates good motor selection without danger of overloading.

3 Fan noise is reduced for a given amount of air and pressure, in spite of higher rotative speeds. This lowered noise is observable both in the space surrounding the fan housing, as well as in the air stream itself as measured near the duct outlet.

The disadvantage lies solely in the fact that for very high pressures the extra speed required may be beyond the strength of materials of construction, and other expedients must be employed.

The use of variable-inlet vanes (forward-curved) is another example having wide present-day acceptance as a means of throttling fan capacity and lowering the power transfer between rotor and fluid. In this case, over-all fan efficiency may not be high at part load, but it can be made appreciably higher than by straight dampering at the fan outlet and, hence, its usefulness.

An interesting use may be made of Equation [15] of the paper, in plotting characteristic horsepower curves of fans with forward-, radial, and backward-curved rotor blades at their tip. These will show curves concave upward, straight inclined, and concave downward, respectively, for the cases mentioned. Obviously, these are somewhat modified by friction on the outside of the rotor surface and therefore the actual curves do not pass through the origin. However, the characteristic shape of the horsepower curve remains and is valuable in the study of fan types.

In conclusion, the writer wishes to emphasize the value of this paper and to urge its study by all interested in the subject. The authors have repeatedly warned against assumptions based on nonuniform continuous flow. Many complications are thus introduced and sometimes it is difficult to know of their presence. In spite of this, many present-day misconceptions of what transpires when a fluid passes through a rotor can be cleared up by applying the fundamental principles, as outlined in the paper.

A. F. Sherzer.[12] Early in the paper, the authors state: "In pump machinery, because of losses, the fluid energy is less than the rotor energy. Thus a practical coefficient, called the hydraulic efficiency is defined by $\eta = W/E$." It should be pointed out that the value of η thus obtained is usually less than the actual work efficiency of the pump or $\dfrac{\text{output horsepower}}{\text{input horsepower}}$. If this is true, it must be clear that η is not the real hydraulic efficiency. The actual efficiency of a pump is the product of two other efficiencies, one mechanical and the other hydraulic, and either must, of course, be greater than the actual efficiency since all values are less than 100 per cent. This is frequently pointed out in texts, and a more accurate term such as "manometric constant," etc., is used.

In the writer's opinion, the reason for this numerical discrepancy can be traced to a misunderstanding of the fundamental theory involved.

Later it is stated: "Generally, it is only the pressure that is of interest, since this is the useful portion of the energy. Then the fluid energy will be defined as the energy required for the pressure change of the fluid, with conventions on signs as given for Equation [2]." When this statement is applied to a centrifugal pump through which is passing a fluid whose compressibility is neglected, it just does not make sense. The writer hopes the authors in their closure will fully explain just how energy may be stored in a fluid by changing the pressure without a resulting change in volume.

An inelastic vessel filled with an incompressible fluid contains no energy no matter what the internal pressure may be, in so far as the pressure itself is concerned. The term "pressure energy" is incorrect when referring to a substance so slightly compressible as water.

Pressure may be used to measure potential or kinetic energy, but when so doing it should be kept in mind that the pressure is only a convenient means of measuring other forms of energy and is not energy of itself, so long as no change in volume takes place.

If an inelastic vessel were to be lowered 231 ft below the surface of a lake, it could be filled with water at a pressure of 100 psi. If the vessel be closed and raised to the surface, there would be water contained in it at a pressure of 100 psi, but, of course, little or no energy due to that pressure. It should be clear that the pressure of 100 psi was only the measure of the potential energy of 231 ft of water column above it.

Would the authors claim that there was an energy equivalent of $H = 231$ ft + ($P/\gamma = 100$ lb $= 231$ ft) or a total of 462 ft available head? That claim seems to be repeated several times in their paper. For example, refer to statement at the beginning of page 6.

"However, the derivation of Equation [15] shows that this centrifugal effect exists with the other effects of flow superposed upon it, and the energy involved in this effect is additive to the energy involved in the effects of flow."

The substance of much of the paper is to the effect that, when the equations are applied to a centrifugal pump, the pressure produced by centrifugal force is added to the velocity which produced it. Expressed in terms of energy, the pressure produced by centrifugal force is approximately $u_2^2/2g$, and the kinetic energy of the water discharged $V_2^2/2g$ is also approximately $u_2^2/2g$ for small rates of flow, regardless of the vane angles. Hence, the total energy $= E$ is claimed to be $\dfrac{V_2^2}{2g} + \dfrac{V_2^2}{2g} = \dfrac{V_2^2}{g}$ or nearly that. This is only approximately true but it is close enough to illustrate the point.

The fallacy of this is not hard to show as follows: Suppose a known mass were revolved at the end of a string of known radius and at a known angular velocity. From these data, using the well-known formula for centrifugal force, it is possible to compute the tension in the string, as well as the kinetic energy of the mass. Consider now the fundamentals of the problem. What is the energy of the rotating mass? Clearly, it is only the kinetic

[11] "Pressure Losses in Rectangular Elbows," by R. D. Madison and J. R. Parker, Trans. A.S.M.E., vol. 58, 1936, paper AER-58-2, p. 175.

[12] Professor of Mechanical Engineering, University of Michigan, Ann Arbor, Mich.

energy of the mass ($^1/_2\, MU^2$) (neglecting the mass of the string). Would the authors suggest that to this should be added the tension in the string? Probably not in this case, yet that is exactly what has been done several times in their paper.

The tension developed in the string and the pressure developed in a rotating impeller are both manifestations of the same centrifugal force, and both are computed by the same general law. Whether the mass extends to the center or nearly so, or is located at the end of the string, is only a numerical difference and does not in any way affect the principles involved.

Centrifugal force is not and never was kinetic energy, or any other kind of energy when dealing with incompressible fluids; although it may be used to measure the kinetic energy present if sufficient data are available.

The writer would take exception to the authors' statement that a diffuser is needed to convert the velocity into pressure. This is surely not borne out by present-day designs. Velocity can more efficiently be converted into pressure through the action of centrifugal force, in which case the efficiency is nearly if not 100 per cent. In the case of a revolving water paraboloid $H = U_2^2/2g$ with mathematical accuracy.

However, to add the pressure head, so produced by the velocity, to the velocity which produced it would be like eating your cake and having it too. Most centrifugal pumps give a shutoff head of $U_2^2/2g$ for the reason that that is all the head there is. If there is no flow, there can be no losses, and what would become of the other $U_2^2/2g$? Careful power measurements will account for only $U_2^2/2g$ and, if more were put in, the dynamometer would have to show it, which it does not.

It is quite possible to build a form of pump which will give a total E of U_2^2/g, or even $2U_2^2/g$ and the writer has done so, but no one would call it the equivalent of a modern centrifugal pump.

The authors claim that, in a radial inward flow (Fourneyron) turbine, the rotor energy is reduced by the effect of centrifugal force. This is the same old fallacy and leads to the idea that this is an inefficient form of turbine, which is not the case. The idea regarding the effect of head on the application of the Fourneyron turbine is most unusual. One of the early, if not the first, installations of turbines at Niagara Falls was of that type, and surely that would not be called a low-head plant. There were other reasons for not using the Fourneyron turbines on either high or low heads.

Equation [41] states: The head delivered by a pump is $H = \eta KU^2/g$.

Assuming that this refers to a centrifugal pump, it should be known that the head developed by such a pump varies with the rate of flow and is by no means the fixed value that Equation [41] would imply. This equation could be applied to a rotating impeller without a casing, in which case the head and rate of flow would both be fixed, but at present centrifugal pumps are not built that way.

Finally, it was stated that the physical meaning of Equation [15] had never before been explained. Equation [15] is the usual one found in texts. The writer gave substantially the same explanation as the authors in a paper[13] presented in 1926 and was criticized for it. This explanation was commonly used by some European writers and is not claimed to be original by the writer, but it has often been given before.

R. B. Smith.[14] The authors are to be commended for their broad exposition of the application of Euler's equation, or perhaps more rigorously of Newton's laws, to rotating power machinery. Expositions of this type have been presented to the Society before, notably by Spannhake (11),[15] but in view of the grandeur such a fundamental treatment discloses, repetition is healthy.

The Euler equation is a powerful basic tool, but it is not entirely free of shortcomings. For instance the authors' Equation [2], while correct, cannot be solved until one is able to ascertain the magnitude of V_2u and of V_1u. These quantities depend upon the angles at which the fluid enters and leaves the rotor; they are not the geometric angles of the blading or of the impeller. The difference between average geometric and actual angles depends upon the nature of the flow and the strength of the circulation around the impeller or turbine blades.

For turbines, the flow in the channel is generally an accelerated one with contact losses at the walls minimized, and the fluid follows reasonably well the geometric contour of the passage, providing the blades are closely spaced and the lift is not abnormally large. Compressors, where the flow is taking place in such a way that the velocity of the fluid is being decelerated, are subject to very serious contact losses at the walls. Furthermore, the lift desired per blade in most centrifugal blowers is large in relation to the blade pitch, with the result that a divergence between the geometric and the actual angle of efflux exists.

It has often been said that Euler's law applies only to those cases in which perfect guidance of the stream is possible, i.e., to impellers with an infinite number of blades. Actually Euler's equation is always applicable, but in order to effect its solution one must know something of the character of the flow and particularly of the circulation. Stodola (12) was one of the first to consider the effect circulation within the impeller passage might have on the flow; and the work has been taken up and extended more recently by Eck (13), Pfleiderer (14) and Kearton (15). The effect of circulation is not minor; in a centrifugal impeller it diminishes the exit whirl component V_2u by from 10 to 25 per cent, depending upon the number of blades and the wheel configuration; it accounts for the fact that at reduced flow the stream breaks away from the back side of the impeller blade and not the front side as was long supposed; and further, it precludes the possibility of a flow, as stated by the authors, which is "normal to the enveloping surface" at the inlet, although at this point, the effect of circulation is slight.

In the authors' Equation [4], the value of K cannot be determined from the geometric angles of the impeller, unless account is taken of the magnitude of the circulation and the number of blades. While it may seem convenient to accept K as a function of the geometric angles and incorporate the circulation effect as an efficiency correction after the fashion of Equation [9], it frequently leads to erroneous conclusions. The fact that K is diminished by the circulation is not an indication of an energy loss, it means instead that less energy was transferred to the fluid from the rotor, and is in no way a reflection on the efficiency of the machine. Experimental determination of the values of K are possible on a well-insulated blower through temperature measurements at the inlet and discharge.

Generally the internal efficiency of a well-designed supercharger, with tip velocities in the region of 60 per cent of the acoustic velocity, can be between 80 and 85 per cent. For higher tip speeds, the efficiency will fall, largely as a result of acoustic-shock waves created at localized points. Analysis of the losses in the blower confirm the authors' conclusion that the diffuser losses are generally the largest single item. The diffuser design has a marked effect upon the performance of the machine in that one may achieve by suitable changes either a pronounced

[13] "New Theory for the Centrifugal Pump," by A. F. Sherzer, Trans. A.S.C.E., vol. 93, 1929, pp. 1–29.

[15] Numbers in parentheses from (11) to (16), inclusive, refer to the Bibliography at the end of this discussion.

sloping or a very flat performance characteristic. Vaneless diffusers are the most attractive from the standpoint of efficiency and surging characteristic, but least attractive in view of their size. The authors' reference to the advantages of the Moss-Robinson diffuser is slightly obscure. A diverging-wall vaneless diffuser would seem to offer little that is desirable, since the tangential-velocity component, which is much greater than the radial, is unaffected by the divergence. In general, the object of a vaned diffuser is to reduce in the minimum length the tangential-velocity component.

In discussing typical applications of Euler's theorem, it may be of interest to mention the Schict (16) axial-flow blower. This machine is designed for a constant velocity in the blade passages and with all the pressure increase developed in the diffuser. The most attractive feature of this design is that values of K approaching 2 can be achieved in a single stage. This is about 3 times as great a coefficient as a conventional airfoil stage produces.

The authors have discussed the basic operation of an impulse steam-turbine stage and have represented the result by the simple expression of Equation [52]. An equally simple relation is possible for the 50 per cent reaction-turbine stage. Assuming that the reaction blades are so proportioned that the velocity triangles from row to row are identical and that each stage utilizes the leaving velocity from the preceding stage, then the work done per rotating row is, with the notation of Fig. 11 of the paper

$$\text{Work} = 2\frac{v_1^2}{2g}\left(2\frac{u}{v_1}\cos\beta_1 - \frac{u^2}{v_1^2}\right)$$

The term in parentheses is frequently called the diagram factor and is defined as

$$\epsilon = \frac{u}{v_1}\left(2\cos\beta_1 - \frac{u}{v_1}\right)$$

Since, under these conditions, the enthalpy drop per stage is

$$A\,\Delta H = \frac{v_1^2}{g}\left(\frac{1}{C_n^2} - (1-\epsilon)\right)$$

the efficiency of the stage is

$$\eta = C_n^2\left(\frac{\epsilon}{1 - C_n^2(1-\epsilon)}\right)$$

For reasonably high value of C_n, as all reaction blades possess, the parenthetical term may be neglected, and the efficiency of the stage at its ideal velocity ratio is thus equal to the square of the nozzle-velocity coefficient. For the usual value of $C_n = 0.96$ to 0.97 the result is a stage efficiency in excess of 92 per cent.

Authors' Closure

The authors wish to express their thanks and appreciation to those who have discussed the paper. There is evidence that a number of people have thought it worth while to spend a great deal of time on the study of the details presented. A number of discussers point out that some of the individual fundamental principles presented in the paper can be found at various places in previous publications. However, the discussion indicates that the present paper may serve a worth-while purpose in gathering and generalizing the facts and in showing their meaning and application in a way useful to modern designers.

We emphasize the meaning of the term "rotor energy" because of the remarks of Mr. Eksergian and others. We do not mean the kinetic energy of the rotor as a revolving body but do mean the flow of energy between rotor and fluid. A graphical summary of all the mathematics connected with rotor energy is given in Figs. 19, 20, and 21, which are self-explanatory.

The senior author of the paper has been working on standardization of symbols for many years, and his face is therefore very red because Professor Daugherty has privately pointed out that the velocity diagrams in the paper reverse α and β of the American Standard Letter Symbols for Hydraulics, ASA Z-10.2–1942, where α is the angle between the tangent to the rotor and the absolute fluid velocity, and β is the angle between the tangent to the rotor and the relative fluid velocity. Obviously all authors, including the authors of the present paper, need to be very careful to see that they use standard symbols.

Professor Berry's analogies are both instructive and amusing. He gives some fundamental reasons why rotors with few blades—such as airplane propellers or Kaplan water wheels—are covered by the principal equations of the paper. However, the paper considers primarily rotors with so many blades that all fluid filaments at entrance and exit theoretically have uniform velocity. This does not occur with rotors having few blades, and additional items which are not within the scope of the paper must be brought in. The details of "lift" with blades of airfoil shape also are outside the scope of the present paper.

We agree with Professor Berry that it would have been more accurate if we had used the term "uncompressed" rather than "incompressible."

Mr. Bloomberg has given some practical comments. The authors believe, with him, that the theoretical possibilities and limitations of a new turbine design should be investigated before much work of a practical nature is attempted.

In connection with the discussion of Mr. Browne, it is to be remarked that one of the mathematical purposes of the paper is fulfilled when it is pointed out that for a centrifugal pump or compressor there is usually a rather high relative inlet velocity, v_1, which is decreased along the rotor to a lower relative exit velocity, v_2. So far as mathematics is concerned, there is a conversion of velocity into pressure energy corresponding to $(v_1^2 - v_2^2)/2g$. But we agree with Mr. Browne that the mathematical assumption of this conversion and its accomplishment on an actual rotor are two quite different things. As Mr. Browne remarks, "entry hooks on the usual supercharger blades" do not make a very good diffuser for converting $(v_1^2 - v_2^2)/2g$ into pressure energy. The practical achievement of some better conversion passage along the rotor is therefore highly desirable. The alternative mentioned both by Mr. Browne and Mr. Campbell, of maintaining the high relative rotor velocity from inlet to exit, has a disadvantage of large friction loss. However, a supercharger engineer can take some comfort from the fact that these "entrance hooks," crude diffuser though they may be, do result in a perceptible gain as compared with having no bend at all at the entrance, which is periodically proposed as a method of reducing impeller costs.

Mr. Browne talks about steady flow tests of diffuser passages, and possibly he means tests of a straight passage such as a Venturi meter tail. In such a test there would be practically uniform conditions in a plane perpendicular to the passage axis. On the

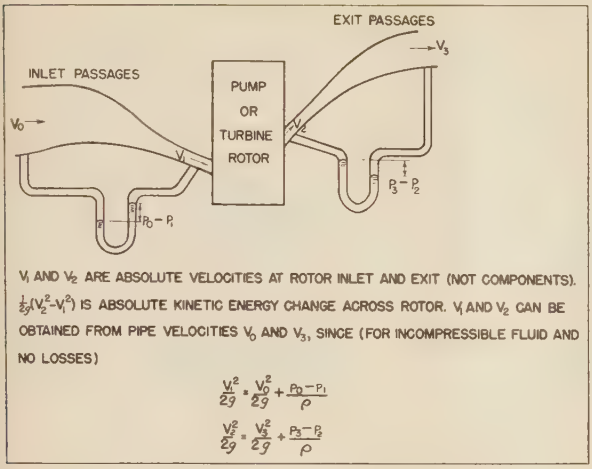

Fig. 19 Diagram of Kinetic Energy Effect

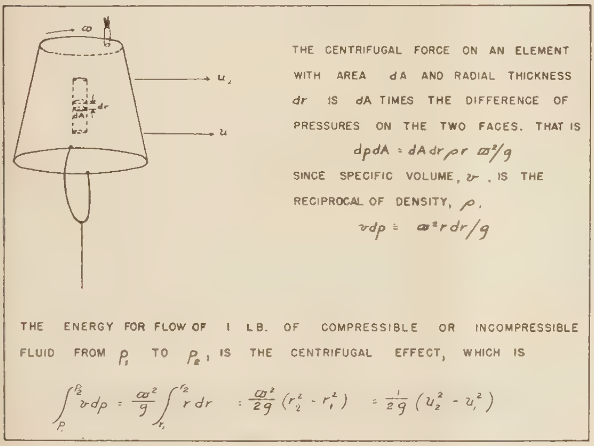

Fig. 20 Diagram of Centrifugal Effect

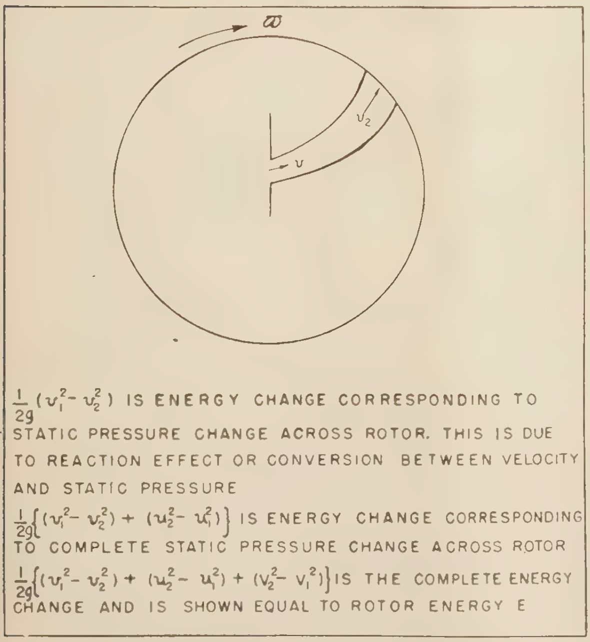

Fig. 21 Diagram of Rotor Velocity Conversion Effect

other hand, Mr. Campbell assumes that fronts of equal pressure are approximately concentric with the axis. Finally, Dr. Marchant talks about the "weird-looking" results of an impeller passage velocity traverse where, instead of the simple steady state, "the flow is probably about as unsteady as it could be made." Probably the velocities in an actual diffuser passage are just as weird and unsteady. Therefore, as Dr. Marchant rightly points out, the actual occurrences in any practical machine differ from the simplified ones given by Messrs. Browne or Campbell or by the equations of the paper. But we have to start somewhere, and one of the purposes of the paper is to propose that this start be made with the particular mathematical methods given. These must be corrected either by purely empirical coefficients or by theoretical corrections such as the effect of circulation which Mr. Smith mentions. We certainly are not going to say that the actual actions are so weird-looking and unsteady that we can't at least start their analysis by the ideal equations of the paper. And we do not understand that Dr. Marchant proposes any other method of attack.

The reference to Professor Stodola that Dr. Marchant mentions is (12) in the bibliographical references added by Mr. Smith.

Mr. Eksergian speaks of "change in energy between entrance and exit sections to the rotor" and "entrance shock losses." We reiterate the statement, made in the second paragraph of the paper, that the fluid velocity and direction just preceding entrance to the rotor and following exit from the rotor, together with the rotor velocities, give the energy transferred between the rotor and fluid. Shock losses at entrance and exit occur on the rotor so far as this fundamental principle is concerned, and the C_b of Equations [46] to [53] is on this basis. C_b is found to vary but little with usual changes in the velocity ratio, u/V_0. Mr. Eksergian's substituted equations do not change this situation.

Mr. Eksergian calls attention to the fact that the fluid angle at entrance to any blade may not be the same as the angle of the blade itself. If the blade inlet angle, or better still, the angle corresponding to the effective passage between the blades, does not match the fluid angle at any given speed, there is a shock loss.

In spite of Mr. Eksergian's remarks about external heat transfer, we do not think his equations differ from ours in any essential particular. His group of equations has a kinetic-energy term. If this is appreciable, it is equivalent to the use in our own equations of total pressure, such as would be given by an impact tube.

With regard to heat transfer mentioned by Mr. Eksergian, we did not propose to give expressions for fluid energy for every possible case. Each one of the expressions we do give is for an explicit case, and each such case implies a thermodynamic process which the inlet temperature and the change of pressure completely measure. In our equations for a liquid or uncompressed fluid, changes in total pressure give the entire fluid energy. The losses are taken care of by the hydraulic efficiency, η, whether they appear wholly as liquid temperature rise, or with the usual very small percentage of external heat transfer. In the case of compression or expansion of a gas with exponent n, as stated in bibliographical reference (5), n takes full account of the temperature changes, even if rotor losses and rotation losses are added, and whether or not there is external heat transfer by radiation from the casing or by means of a water jacket.

With regard to our Equation [14], given as a general expression for the fluid energy of a single turbine stage, we are following usual practice. That is, the efficiency of the stage is based on isentropic drop of enthalpy as a standard. On this conventional basis, the efficiency multiplied by the isentropic drop gives the rotor energy. In all turbines of appreciable size and with the usual casing lagging, the external heat loss is negligible. It is true that a precise analysis will take account of the fact that the

enthalpy drop is not isentropic because of the losses which occur.

The final equations which Mr. Eksergian gives no doubt theoretically take care of all the heat transfer, but they are not in form useful to designers. The actual values of the external and internal heat transfer seldom are known, whereas for every kind of actual machine there are experimentally determined coefficients which enable the fluid energy to be calculated from the pressures involved.

In connection with the discussion of Mr. Madison, the authors have overlooked the special uses of inlet guides and agree with all of the points he has made. A complete mathematical analysis based on the fundamental equations of the paper and the particular cases which Mr. Madison mentions would be a useful contribution.

Referring to the discussion of Professor Sherzer, the authors

FIG. 22 EULER'S FIRST PAPER ON ENERGY TRANSFER, 1750

agree with him that the existence of a given quantity of compressed or uncompressed fluid at a given pressure involves no energy transfer. But a flow of fluid from a place of low pressure to a place of high pressure does involve energy transfer. In Fig. 20, the fluid in the rotating bucket is at a high pressure because of centrifugal force. As Professor Sherzer points out, the mere existence of this fluid at the centrifugal pressure is no evidence of energy transfer. So long as the bucket rotates at the end of the string with the same quantity of fluid in it, no power is required to keep the bucket rotating (except, of course, for atmospheric friction). But if fluid is passing from atmospheric pressure through the bucket, so that there is continuous flow from its outer radius at a pressure corresponding to the centrifugal pressure, then an energy transfer is involved. If the fluid is a

FIG. 24 ZEUNER'S BOOK GIVING ENERGY TRANSFER

liquid, this energy transfer is equal to $(p_1 - p_0)/\rho$ foot-pounds per pound of liquid flowing. In the general case, it is equal to $\int vdp$, where v is the specific volume of the fluid. Our interest is always with machines operating at normal flow, and not with the abnormal condition of no load, where the equations of the paper do not apply. Bibliographical reference number (7) indicates a fundamental disagreement between Professor Sherzer and other writers on this subject, including the present authors. As Professor Sherzer points out, the physical interpretation of Equation [15] is not original with the authors.

We quite agree with Mr. Smith that the equations of the paper are concerned with actual fluid angles, and that these are not necessarily the same as the blade angles. Any theories of circulation, lift, and the like, which permit a better knowledge of actual angles of fluid flow, would be important additions to the general theory.

The brilliant scientist Euler, in the course of his scientific work in Berlin at the court of Frederick the Great, seems to have been the first to expound the mathematical theories enlarged upon in this paper. Figs. 22 and 23 show excerpts from his contribution to the Transactions of the Prussian Royal Academy, 1750. Fig. 24 shows the title page of Zeuner's book of 1899, which has been used frequently in the engineering careers of the senior authors. But Euler, the Prussian Royal Academy, and Zeuner probably did not have the faintest conception of the kinds of pumps and turbines to which these theories are applied in modern times. Steam and water turbines of 100,000 to 200,000 kilowatts capacity could not have been imagined in their wildest dreams. And they had no idea that the mathematics which they originated would lead to machines like the turbosupercharger, operating at 1500 F and 25,000 rpm in the *Flying Fortress* and other high-altitude airplanes.

Comparative Characteristics of Fixed- and Adjustable-Blade Axial-Flow Pumps

By J. D. SCOVILLE,[1] YORK, PA.

This paper compares the hydraulic characteristics of the fixed- and adjustable-blade type of pump. Certain advantages of the adjustable-blade design are enumerated. In it is described a large unit installed in the Traicao pumping plant of the Sao Paulo Tramway, Light and Power Company. The method used in making model cavitation tests is outlined.

THE comparison between the adjustable-blade pump and the fixed-blade axial-flow type is quite similar to the comparison between the Kaplan and the propeller turbines. The Kaplan turbine can deliver power at high efficiency over a range of discharge at normal heads; while at low heads, its output can be substantially increased over that of the propeller turbine by opening its blades. The propeller unit is at a considerable disadvantage in efficiency at variable flow. With the adjustable-blade pump operating at constant head, its discharge may be reduced by decreasing the blade pitch, maintaining high efficiency, and proportionately reducing the power input and, at low head, increased discharge is possible up to the motor capacity by an opposite change in blade angle. With a fixed-vane constant-speed propeller pump, a variable quantity at constant head can be delivered only by means of throttling on the discharge side, with the result that the horsepower input is no less than at full discharge, and often is substantially more. At reduced head, the discharge of the fixed-blade pump is determined by its inherent characteristics and cannot be increased as can that of the adjustable-blade type.

Blade Adjusting Mechanism

The mechanism by which the blades are adjusted is identical with that of the Kaplan turbine. Trunnions on which the blades rotate are a part of the vane castings. The bearings in which they turn are a part of the impeller hub. Levers are keyed to the trunnions and are connected by links to a common crosshead. Axial motion of the crosshead thereby changes the pitch of the impeller blades. This axial motion may be produced by a hand wheel mounted on top of the motor, through a thrust bearing to a draw rod passing through the hollow motor and pump shaft to the crosshead. This method is suitable only for small pumps. For medium-sized pumps, the same purpose can be accomplished by a motor in the shaft which produces axial motion of the draw rod by reducing gear and a slowly rotating nut. On large pumps, it is advantageous to use a servomotor in the pump shaft, actuated by means of oil under pressure which is admitted through the hollow motor shaft and controlled by a valve located on top of the motor. This valve may be moved manually or may be float-operated, so as to keep a constant suction level with varying flow. Fig. 1 illustrates the scheme of operation, using an oil servomotor in the shaft.

[1] Assistant Chief Engineer, S. Morgan Smith Company. Mem. A.S.M.E.

Contributed by the Hydraulic Division and presented at the Annual Meeting, New York, N. Y., December 1–5, 1941, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

Fig. 2 shows the comparative performance of a fixed- and an adjustable-blade impeller of the same diameter and speed. Their specific speed is 14,000 on a gpm basis. This curve illustrates that, for a constant head, the power requirement for the adjustable-blade design decreases as the flow diminishes. In order to pump less than rated capacity with the fixed-blade pump, the discharge must be throttled, thereby increasing the head on the pump as, for instance to 295 per cent, at 20 per cent Q. The motor horsepower goes up to about 220 per cent. If a mixed-flow pump of about one half the specific speed were used, the head at 20 per cent Q would be about 160 per cent, and the horsepower requirement 105 per cent. The adjustable-blade pump has a decided advantage at low flow over both types, about 25 per cent horsepower being required at 20 per cent Q.

At low heads, it is possible to obtain higher discharge than with the fixed-blade design, as indicated, 19 per cent more at 25 per cent head, and yet keep within the motor rating. At normal head, more than rated discharge is possible temporarily, by overloading the motor.

Pumps of this new type have been used in handling pulp stock

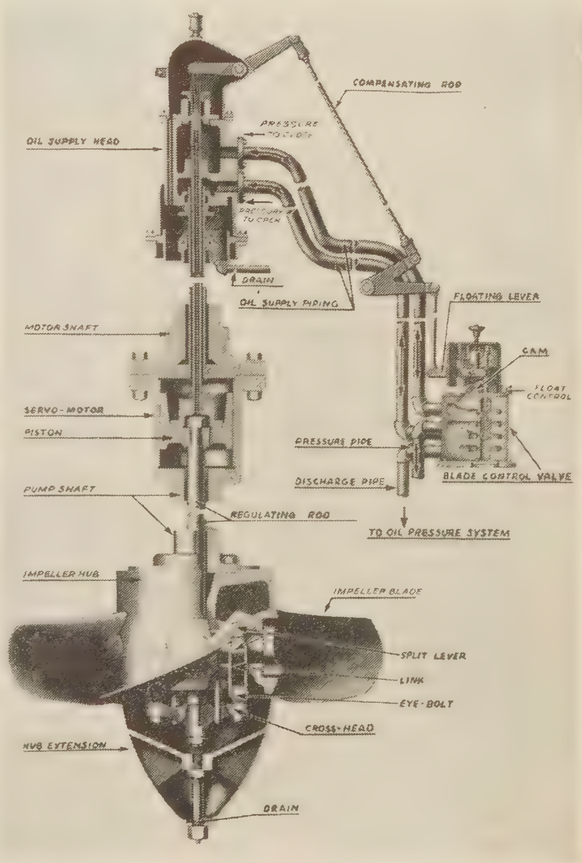

Fig. 1 Arrangement of Adjustable-Blade-Pump Mechanism

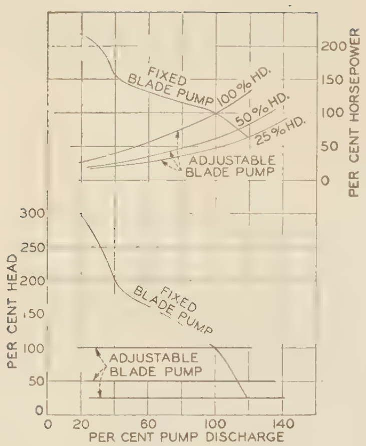

Fig. 2 Comparison of Fixed and Adjustable-Blade Pumps of 14,000 N_S at 100 Per Cent Q and H

in paper mills, pumping condenser cooling water for steam turbines, and for flood-control work. Of special interest is a unit built for the Traicao plant of the Sao Paulo Tramway, Light and Power Company in Brazil.

Pump Unit at Traicao Plant

This plant is located on the outskirts of the City of Sao Paulo. It was designed and the machinery purchased by the Canadian and General Finance Company, Limited, of Toronto, Ontario. It is one of two plants in series, with a total lift of about 100 ft. Their purpose is to impound additional water for the Serra power plant, a large high-head station having a number of impulse turbines operating at about 2400 ft head; and further to provide flood control by transferring water from one shed to another.

The Traicao plant now has one unit, but will ultimately have four. The pump installed is of the adjustable-blade axial-flow type, having a guaranteed capacity of 50 cu m per sec discharge under 7 m maximum head at 150 rpm. The head variation is from 7 down to 4.5 m. The blades are controlled manually by means of a valve on top of the motor which admits oil under pressure to the servomotor in the pump shaft, thereby moving the blades to the desired pitch.

The general arrangement of the pump is shown in Fig. 3. The water enters the suction tube, passes through the impeller, and through a set of warped guide vanes to the discharge tube. Figs. 4 and 5 are shop views of the assembled impeller and shaft, and of the warped guide-case section, together with part of the hollow tube which surrounds the shaft. The impeller and the guide-vane assembly are removable through the motor stator. It will be seen that the discharge tube acts as a siphon, the lower part of the invert being slightly above the maximum-discharge water level. Two air valves are provided to break the siphon automatically when the pump shuts down.

This pump is driven by a 6600-hp, 3-phase, 60-cycle, 150-rpm synchronous motor with a pressure-lubricated thrust bearing for easy starting.

Model Test of Pump

The size and the required service of the pump were such that it was deemed necessary to make a complete model test to determine its hydraulic characteristics. The prototype size is 138 in., and the model was made 10 in. diam. Tests were conducted in the laboratory to determine the efficiency variation with pitch change and head, cavitation limits under varying head and tail-water level, discharge, hydraulic thrust, torque variation during the starting cycle, and the maximum reverse speed in case of power failure.

Curves A, B, and C, Fig. 6 show the model efficiency plotted against prototype discharge in English units with the quantity in cubic feet per second, and the head in feet, corresponding to 7.5, 6, and 4.5 m net head. Curves A', B', and C' show the discharge horsepower and the expected discharge-efficiency performance of the prototype, the latter stepped up in accordance with the well-known Moody formula. In computing this efficiency differential, an exponent of 0.20 was used for the diameter ratio in the formula, as suggested by W. S. Pardoe in his discussion (1)[2] of a paper by L. M. Davis.

Of special interest is the large capacity of this unit, namely, 2780 cfs at 24.6 ft head, and 3070 cfs at 14.8 ft head. These figures correspond to 15,000 specific speed at the high head and 23,000 at the low head. However, the horsepower capacity of the motor limits the available output of the pump. Herein is one of the advantages of the adjustable-blade design. Due to possible casting variation, a fixed-blade impeller could not safely be made for more than 6400 hp or 1910 cfs at 24.6 ft head for a 6600-hp motor. At 14.8 ft head, the discharge would be about 2190 cfs. With an adjustable-blade impeller, the pump can be operated within the motor capacity of 6600 hp at both heads and deliver 1960 cfs and 2560 cfs,

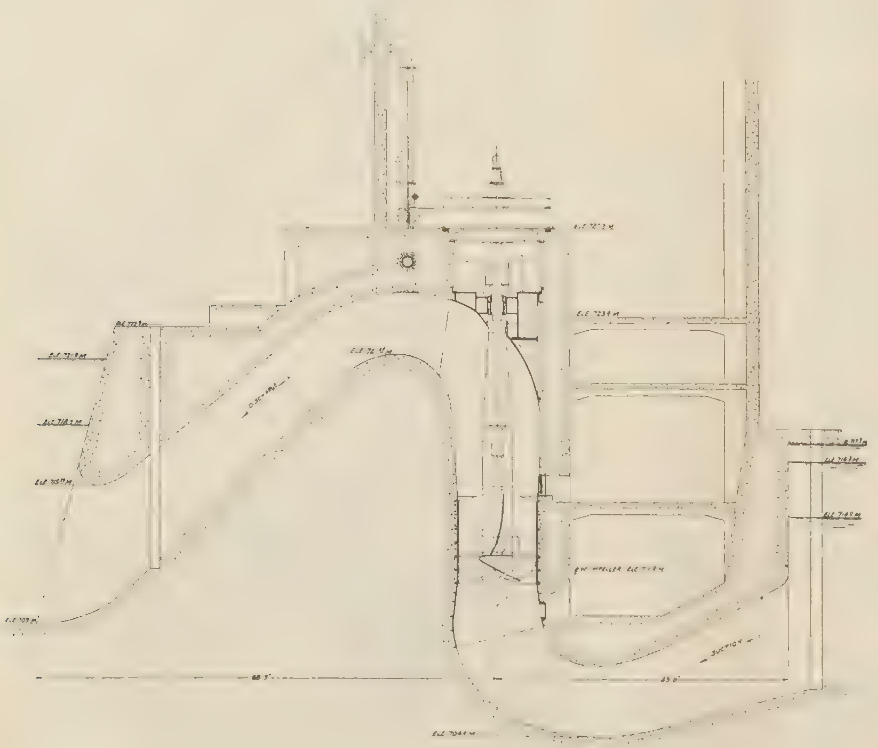

Fig. 3 General Arrangement of Adjustable-Blade Axial-Flow Pump at Traicao Plant, Sao Paulo

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

respectively. The latter is an increase in discharge of 17 per cent, as compared with the fixed-blade design. It will be noted that the cavitation-limit curve, shown in Fig. 6, is well above the 6600-hp motor capacity.

Fig. 7 shows the head-speed relationship, and also the torque variation during the starting cycle, neglecting the torque required for acceleration. Characteristic curves for both fixed- and adjustable-blade impellers are indicated. They show that, with this particular design of pump, if the blades are fixed at such an angle as to give the required discharge, the impeller produces its rated head at about one-half speed, the torque having risen rapidly up to this point. Beyond this, discharge starts and the torque rises more slowly. At synchronous speed, the full-load torque of the motor is reached. During the starting period of the adjustable-blade pump, the blades are held in the flat position. At synchronous speed, maximum head has not been reached and the maximum torque is only about 19 per cent of the fixed-blade-impeller torque at normal speed. After the circuit breaker has been closed, the blades may be opened slowly to the required setting. This results in less shock to the system and permits a somewhat cheaper motor, having less pull-in torque than for the fixed-blade design. Full-voltage starting is used.

Fig. 4 Shop View of Traicao Unit Impeller-and-Shaft Assembly

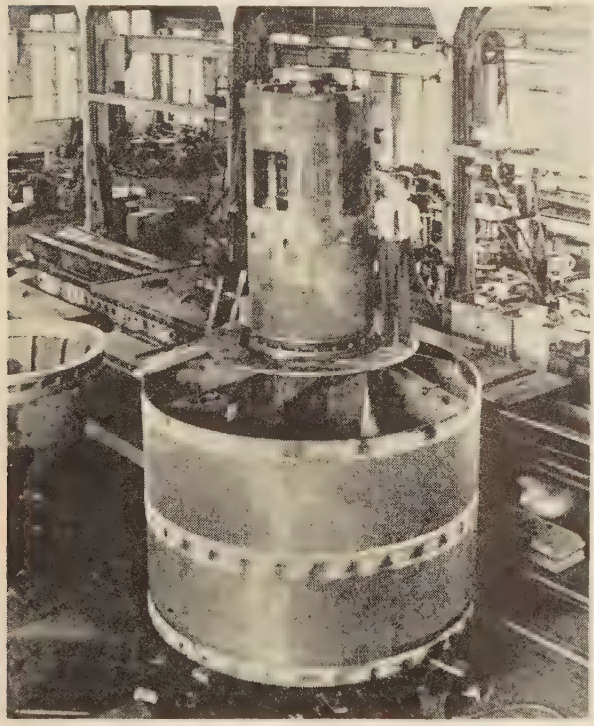

Fig. 5 Warped Guide-Case Section of Traicao Unit Set Up in the Shop

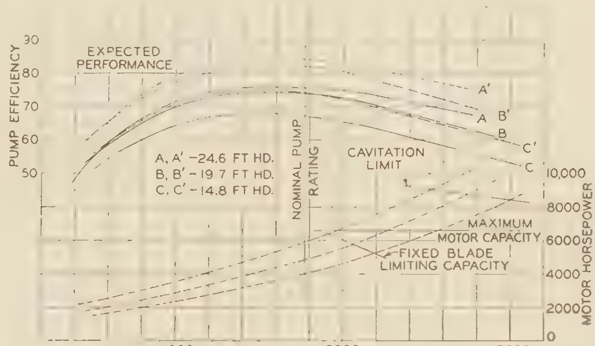

Fig. 6 Efficiency Curves of Model Pump and Curves of Expected Performance of Prototype

The behavior of the pump during shutdown is of interest. The blades may be slowly closed and the breaker opened when the load on the motor is a minimum. At this time, the solenoid-operated air valves at the top of the invert of the discharge tube open and break the vacuum, thus pre-

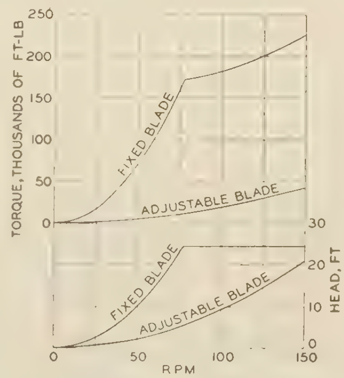

Fig. 7 Torque-Speed Relationship of Fixed-Blade and Adjustable-Blade Pumps

venting backflow. In the event of power failure during full load, the air-valve capacity is sufficient to break the vacuum and bring the speed to zero. Tests made in the field show that 7 sec were required for the pump to reverse its direction, 13 sec to reach its maximum runaway speed of 225 rpm, and 7 sec to reach normal speed again after opening the air valves manually. When the air valves are operated automatically at the opening of the circuit breaker, the unit comes to rest in about 5 sec.

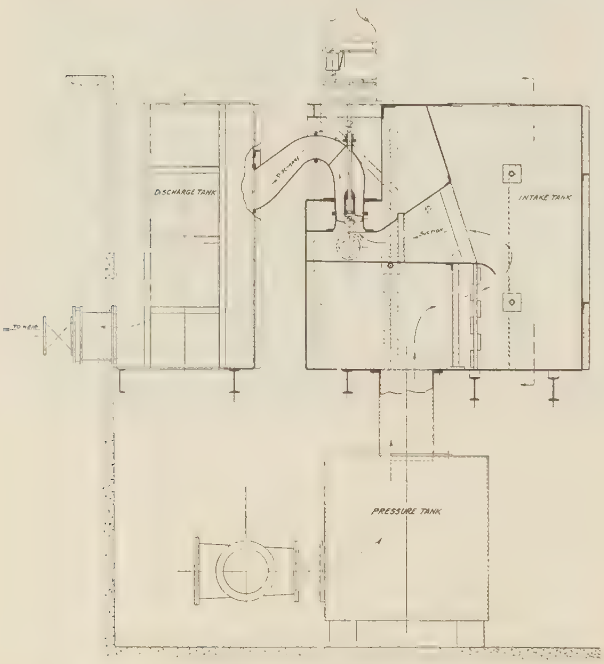

Fig 8 Laboratory Arrangement for Pump Cavitation Testing

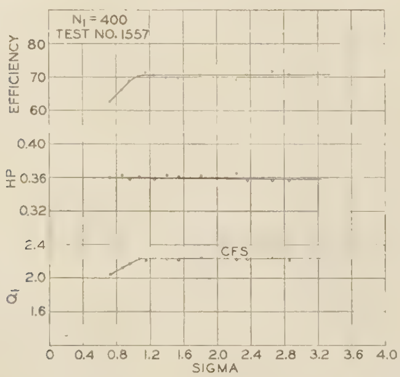

Fig. 9 Typical Cavitation Test for One N_1 and Blade Angle

The pump has been in operation in the field, but as yet to a very limited extent, and not over the entire range of head it was intended for. Its showing so far, however, has been satisfactory.

Problem of Cavitation

As with the Kaplan turbine, the high specific speed and unit discharge introduce special problems with regard to cavitation. In order to attack a problem involving adjustable-blade pumps, cavitation tests are required.

The method of obtaining cavitation limits in the laboratory for hydraulic turbines has been described recently by L. M. Davis (2) and R. E. B. Sharp (3). The same system is used for pumps. Fig. 8 shows the laboratory setup for this type of test. The pump is operated at constant speed and head, but with variable intake and discharge pressures. The discharge and suction heads are decreased equally until cavitation progressively reduces the efficiency. Fig. 9 shows a typical test for one N_1 and blade angle.

$$\sigma = \frac{H_B - V_P - H_S}{H}$$

N_1 = rpm of model under 1 ft head
H_B = barometric pressure
V_P = vapor pressure
H_S = suction lift
H = total head

The term σ is the ratio of velocity head at some point within the impeller plus the remaining pressure safety, to the total head. Critical σ is reached when this remaining pressure safety is reduced to zero, thus starting cavitation.

It is this cavitation which causes the loss in efficiency shown in Fig. 9. The critical σ values must be determined experimentally for the entire range of N_1 (or head) and blade angle of a given design of pump, in order properly to locate the impeller with reference to the suction level, and predict a safe value of pump discharge. During cavitation tests, observations made through windows in the suction tube, with a stroboscope, gave valuable information on the location of critical parts of the impeller blade and the magnitude of the cavitation.

Conclusion

In this paper, the author has endeavored to point out certain advantages of the adjustable-blade type of pump, which are:

1 High speed combined with a flat efficiency curve.

2 Extra capacity in an emergency and at low heads.

3 Easy starting characteristics and the elimination of a valve to control discharge.

4 Possible operation of pump under abnormal suction conditions by adjusting the blade position to eliminate cavitation.

5 Flexibility; not available in a fixed-blade design.

It has the disadvantage of increased cost, but as with the Kaplan turbine, this can be offset by the use of fewer and larger pumps. It is perhaps significant that most low-head-turbine installations suitable for high-speed propellers are now being made with the Kaplan type of runner.

Possibly many installations involving the pumping of a variable quantity under low heads can use the adjustable-blade type of pump at a net saving in cost.

Acknowledgment

Acknowledgment is made to Mr. Rolfe Sahle who was in charge of the pump tests conducted in the S. Morgan Smith Company's laboratory, and to the Canadian and General Finance Company, Toronto, Ontario, with whose permission the information on the Traicao pumping plant has been released.

Discussion

R. W. Angus.[3] If for no other reason than its flexibility, the pump referred to in this paper has a very definite field of service. Many years ago when the writer was in Germany, he visited an outdoor river-flow laboratory near Berlin, in which the water used was supplied by this type of pump. Running at constant speed the discharge could be varied from a mere trickle to a very large volume by adjusting the impeller blades by hand. For low heads, the axial-flow pump permits the use of a high-speed motor which usually may be direct-connected without gears.

A pump with fixed impeller blades, however, has the unfortunate characteristic that maximum driving power is required for minimum flow, and this power decreases as the flow increases, as has been pointed out by the author.

The mechanism for operating the blades is fairly costly, and it would be instructive if the author could give some indication of the minimum capacity for which this type of unit is economical. When so much expense has been put into adjusting the impeller blades, it would seem that considerable efficiency is being sacrificed by leaving the guide-ring vanes stationary. The writer wishes to ask if any development work has been done on variable guide vanes, and what success has been achieved.

The quarter turn in the suction pipe, Fig. 3 of the paper, is not generally approved in centrifugal-pump work, as it has a general tendency to reduce the capacity. Some of the earlier axial-flow pumps used entry guides in front of the impeller. Has the author had any experience with these?

Only one view of the author's laboratory is given in Fig. 8, and in it there is an apparent difference between the suction arrangement and that shown in Fig. 3, already referred to. The laboratory setup indicates more nearly axial entry to the suction pipe with slight tendency for whirling and probably with less danger of cavitation. It would be interesting to know what the effect of the quarter turn in the suction pipe would be on the limiting sigma, as found from the setup of Fig. 8.

The value of the paper would be greatly increased if actual test curves from the model were shown. The writer hopes that the author may yet be able to add test curves from the actual Traicao pump.

W. S. Pardoe.[4] The author has used Professor Moody's step-up formula for turbines, adopting the writer's suggestion of 0.2 as exponent of the model scale. It might be well to bear in mind the source of this exponent, coming as it does from the following expression for the coefficients of 56 cast-iron Herschel-type Venturi meters with finished bronze throats

$$C = \sqrt{\frac{1 - \left(\frac{d_2}{d_1}\right)^4}{1 - \left(\frac{d_2}{d_1}\right)^4 + \frac{0.045}{d_2^{0.23}}}}$$

$\frac{0.045}{d_2^{0.23}}$ is a coefficient of $\frac{V_2^2}{2g}$ giving the lost head, including such change as takes place in the pipe factors. The writer reduced this exponent to 0.2 as some of the turbine losses vary as V^2. Note that the Venturi meters were all of the same physical roughness. Hence, both model and prototype turbines should have surfaces of the same physical roughness. No attempt should be made to get the same proportional roughness (whatever that means). It would seem reasonable, if both model and prototype were very smooth, for the exponent to approach Professor Moody's 0.25. If model and prototype have the physical roughness of sand-cast pipe, the exponent might approach 0.15 as in the Williams and Hazen formula

$$V = cd^{0.63}S^{0.54} \text{ or } h = \left(\frac{V}{c}\right)^{1.85}\frac{L}{d} \times \frac{1}{d^{0.15}} \alpha \frac{1}{d^{0.15}}$$

The writer's suggestion of 0.2 was a mean between these values and was intended for the step up of turbine efficiencies. The author and others have used it for centrifugal pumps—unwisely, the writer believes. He uses it for the upstream section of the Venturi meter with its converging boundaries, but would hesitate to use it to step down the loss in the downstream section with its diverging boundaries, where losses vary as V^2.

If the model centrifugal pump is very smooth and the prototype pump rough, we may get no step up and a probable step down in efficiency.

C. B. Spellman.[5] This paper is of particular interest to the Baldwin-Southwark division of Baldwin Locomotive Works. The I. P. Morris department of this division, in its capacity of builders of large hydraulic machinery, has conducted numerous and extensive tests on models of turbines and pumps. During 1940, I. P. Morris tested a four-bladed axial-flow propeller-type pump, of approximately 11 in. throat diam and having adjustable impeller blades. The results obtained, if stepped up to 138 in. diam and 150 rpm, would essentially duplicate the performance data shown in the author's Fig. 6. The maximum efficiency obtained from this model was 77.5 per cent, when tested at a speed of approximately 1350 rpm, under a normal head of about $10^1/_2$ ft, measured from suction water level to discharge water level. As in the case of the S. Morgan Smith model, the pump was placed in a cavitation-laboratory setting.

The writer realizes the manifold advantages of the usual adjustable-blade axial-flow pump. Nevertheless, it is believed that there is a possibility, not generally recognized, of still further improvement which might prove to be advantageous in cases where operating economy is of prime importance. In such cases, it would be highly desirable to operate on the envelope of the efficiency curves for the various blade positions. That this cannot be done with the usual adjustable-blade axial-flow pump against a constant head can be seen by a brief study of a typical characteristic chart for such a pump.

In Fig. 10 of this discussion, the *H-Q* curves represent pump-performance curves of head versus quantity at constant speed for various fixed positions of the adjustable-blade pump. Points of equal efficiency are shown by the customary contour lines. The characteristics of this type of pump are such that the locus of the best efficiency for the various blade angles is a sloping line, as L_E. This is the *H-Q* curve on which the pump must operate in order to attain its maximum efficiency. In other words, this line corresponds to the envelope efficiency curve E_E. Now, since L_E is a sloping line, it follows that pump operation against a constant head, denoted by the horizontal line H_C, can be on the envelope curve only at the point of intersection E_M. At any other point on the line H_C, the efficiency will be below the envelope of maximum efficiency. Hence the maximum efficiency actually obtainable for constant-head operation becomes a curve, such as shown by the dotted line E_A, tangent to the envelope at one point only.

It is the writer's opinion that the envelope shown by the test could be more nearly approached, for any given head, if the pump

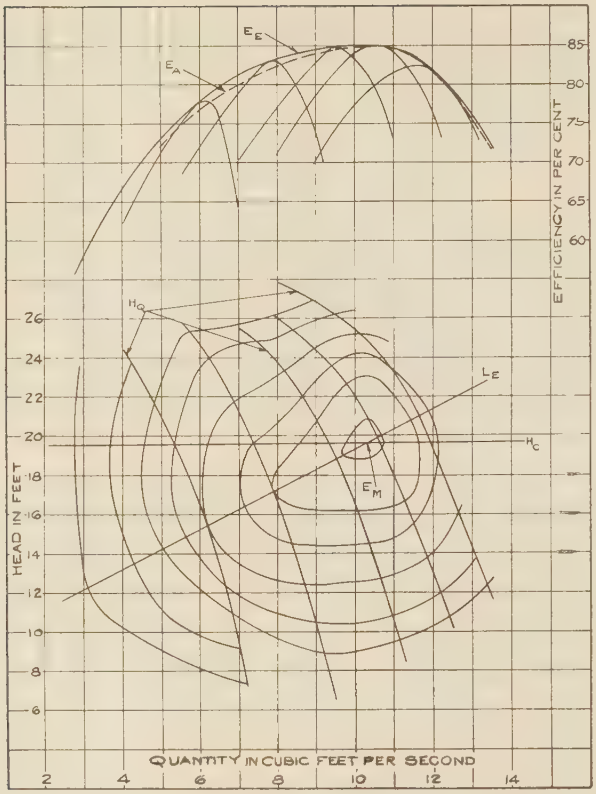

Fig. 10 Typical Characteristic Chart for Adjustable-Blade Axial-Flow Pump

were supplied with movable guide vanes, instead of fixed guide vanes at the discharge side of the impeller. Such vanes should be positioned in relation to the impeller-blade position, to minimize the hydraulic losses as the water enters the guide case. Thus, instead of attaining performance analogous to that of an adjustable-blade turbine with fixed guide vanes, it would be logical to expect performance analogous to that of the full Kaplan turbine, where the guide vanes and runner blades are both adjusted to their proper relative positions. However, the gain in efficiency which could be realized by the use of such movable guide vanes at the entrance to the guide case might be too small to warrant the increase in cost.

The author also mentions the runaway speed of the Traicao pump in the reverse direction. It is not clear from the context whether this speed was obtained with the pump blades in the full-open position. It is the writer's thought that the maximum speed in the reverse direction would probably be attained with the impeller blades in an intermediate position. It would be interesting to know whether the S. Morgan Smith tests over the full range of blade positions have been such as to confirm this thought.

Author's Closure

As stated by Professor Angus, the adjustable-blade pump has considerable merit because of its flexibility. It is this feature which has justified the construction of pumps having a capacity as low as 5000 gpm for handling pulp stock for paper mills.

Professor Angus points out that the adjusting mechanism is costly. True, but there are certain types of installations where the extra cost is more than compensated for by other savings. For instance, a dry-dock pump must operate over a 100 per cent head range. For such an installation, an adjustable-blade pump permits a smaller size, running at higher speed, requiring a smaller motor of a cheaper design than for a fixed-blade design. The starting characteristics of the adjustable-blade pump allow the use of a synchronous motor at a considerable saving in cost, as compared with the induction motor which is customarily used on the fixed-blade design.

Both Professor Angus and Mr. Spellman suggest the desirability of using movable guide vanes above the impeller. Because of practical limitations, it is questionable whether this would result in better efficiency. A rather expensive construction would be required. It is possible that fixed axial vanes below the impeller, and the elimination of vanes above, with the substitution of a volute casing at the discharge, would accomplish equal improvement.

It is felt that the use of an accelerating velocity elbow suction tube is preferable to the common bellmouth. However, comparative efficiency and cavitation tests made recently on the two types of intake tubes showed no difference in performance, at least for that particular pump.

The curves A, B, and C in Fig. 6 of the paper are the actual model performance stepped up mathematically to prototype size and head with no efficiency correction. There is no field test available for the Traicao installation.

The author appreciates Professor Pardoe's discussion of the Moody formula. It is regrettable that there is not more information on the efficiency step up for size on pumps. In Table 4 of a paper[6] before this Society, Professor Angus supplies tests on four pumps for the City of Toronto and shows that on the average the efficiencies check with those computed from the model test using an exponent of 0.25.

The author cannot present any confirming data on pumps but can do so on Kaplan turbines. Fig. 11 of this closure shows the

[6] "An Improved Technique for Centrifugal Pumps—Efficiency Measurements," by R. W. Angus, Trans. A.S.M.E., vol. 63, 1941, pp. 13–19.

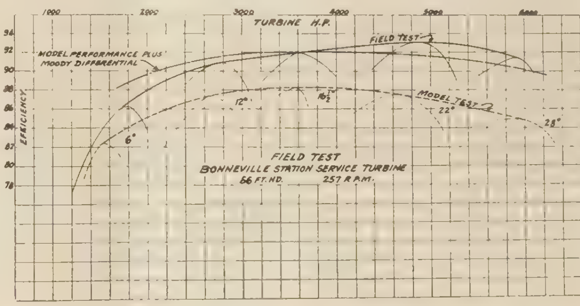

Fig. 11 Field Test on Bonneville Station Service Turbine (56-ft head; 257 rpm.)

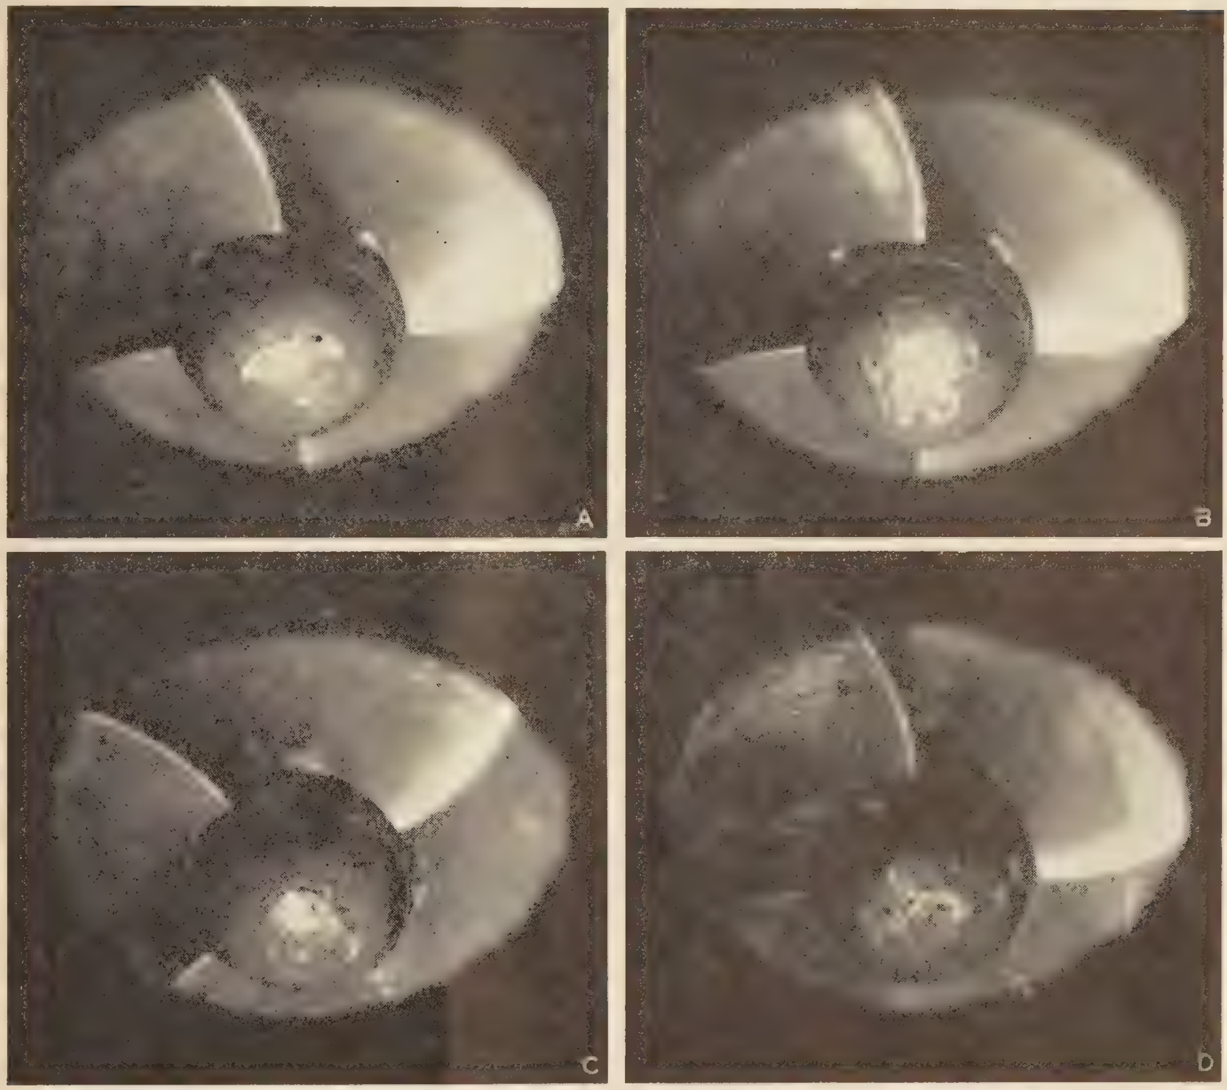

Fig. 12 High-Speed Studies of Cavitation

field test of the Bonneville service unit compared with the model test and the computed performance using the Moody efficiency step up. The model diameter was 16 in. and the prototype 81 in. It is logical that the efficiency displacement is upward and to the right, indicating that the efficiency increase resulted in larger output. This shift is confirmed by about 25 or more index tests on Kaplan turbines where relative efficiency was obtained without making an actual water measurement. Therefore, it would be reasonable to expect the increased efficiency in a pump to result in larger discharge from the same horsepower input.

The S. Morgan Smith tests on the Traicao model show that the maximum reverse speed on the adjustable-blade pump occurs when the blades are about half open. This answers Mr. Spellman's question.

Fig. 12 (*A* to *D*) of this closure shows cavitation on the lower side of the runner blades at various stages. The original photographs were taken under the direction of Rolfe Sahle using a 4 × 5 Graphic View camera having a Zeiss Tessar 4.5 lens. The pump speed was 1200 rpm, and the motion was stopped by the use of a Speedotron lamp with a flash duration of about 0.00003 sec.

Fig. 13 shows the sigma-break curve of the pump, the points *A* to *D* corresponding to the views *A* to *D* of Fig. 12. The illustrations show progressive increase of cavitation as sigma is lowered, and there is a change in efficiency corresponding to the progression in cavitation.

Some Problems in the Selection and Operation of Centrifugal Pumps for Oil and Gasoline Pipe Lines

By A. HOLLANDER,[1] LOS ANGELES, CALIF.

During the 15 years since they were first introduced, high-pressure motor-driven centrifugal pumps have been adopted to an ever greater extent in crude-oil trunk lines. Since the inception of gasoline trunk lines six years ago, centrifugal pumps have been exclusively used in this service. This paper deals with the basic principles of developing pumping stations of suitable capacity under present conditions and mentions future improvements contemplated. Today, trunk-line centrifugal pumps include units having capacities from 5000 to 125,000 bbl per day, working against pressures of 300 to 1100 psi, driven by two-pole induction motors of 200 to 900 hp. Units proposed for the National Defense Pipe Line will have 250,000 bbl per day capacity against 775 psi, operating three single-stage pumps in series, each driven by a 1300-hp motor. The procedure followed by the pump designer in developing units to meet given requirements is outlined, together with details of the resulting characteristics. Discussion of trunk-line operating schedules is included, and finally a method is given for solving pipe-line-pumping problems.

SINCE their first introduction some 15 years ago in pipe-line service (1),[2] high-pressure centrifugal pumps have found ever wider acceptance for crude-oil trunk lines, until today reciprocating pumps are considered only in exceptional cases. The lower viscosity of gasoline served as a further factor in favor of centrifugal pumps, and for gasoline trunk lines starting about six years later (2), centrifugal units were initially employed and have been used exclusively ever since.

With low-cost and reliable electric power supplied from great interconnected networks close to the pumping stations, the high-speed, two-pole induction motors, direct-connected to light multi-stage centrifugal pumps, constitute an irreducible minimum in pumping machinery and material, with the least building and foundation requirement.

Even though oil is available at low cost from the pipe line, the more expensive oil engines, driving centrifugal pumps through speed-increasing gears, are seldom used today in preference to the direct-connected electric-motor drives. The use of electric-motor-drive centrifugal pumps was further advanced by automatic, or at least semiautomatic operation, which practice is becoming more and more general.

It is fortunate that the electric-centrifugal pipe-line station can be considered as proved and economically sound. Otherwise, the great defense trunk-line projects, now under consideration, or in process of construction, would not have been feasible.

The engineering staffs of the pipe-line and oil companies design the pipe-line systems. These staffs are fully conversant with all the numerous elements involved and in close touch with the manufacturers thereof. Based on some assumed loading of the line, the staff determines by successive approximations, among a great many other details, the final specifications of the pipe, its size, thickness, and material, the number and location of stations, and of their pumping units, which call for definite capacities, pressures, and horsepower, arrived at through some previous consultations with the manufacturers of the equipment. It is this last phase of the problem, describing the main factors determining the pump design and its implications for future developments, which is the subject of this paper, with some operating possibilities and diagrams that might be of interest.

Present Practice and Future Improvements

The trunk-line centrifugal pumps include units having capacities of 5000 to 125,000 bbl per day, working against pressures of 300 to 1100 psi and driven by two-pole motors of 200 to 900 hp. The final pressure is obtained either with a single multi-stage pump or by operating two units in series. The pumps are built in two to eight stages, three to six stages being the most common. Gathering pumps are similar but smaller, coming down in capacity to about 1000 bbl per day.

It is noted that the units proposed for the National Defense Pipe Line are quite exceptional, as the requirements indicate pumps of 250,000 bbl per day capacity against 775 psi, operating three single-stage units in series, each driven by a 1300-hp motor. The pump designer uses as the unit of the flow rate or capacity q gallons per minute, and as the unit of the head per stage h feet; with these units, he defines the pump type of one stage by the specific speed n_s.

$$n_s = \frac{q^{1/2}\ \text{rpm}}{h^{3/4}} \qquad [1]$$

This varies for pipe-line pumps from about 500 to 2000, and, within this range, the optimum efficiency is reasonably well established (3). Optimum efficiency is defined as the best obtainable efficiency under the most favorable suction conditions of a single-stage pump, pumping cold water and built in a sufficiently large size, so that any further increase in its size will make only a negligible improvement.

The second factor which will have a major effect on the pipe-line-pump efficiency is the pump size, which is determined by the flow rate of the pump divided by a characteristic velocity, e.g., $\sqrt{2gh}$, of which every velocity through the pump is a function.

As the flow rate divided by a velocity gives an area, to get a linear dimension, the square root of this figure is taken. Omitting constants, the characteristic size s is defined

$$s = \sqrt{\frac{q}{\sqrt{h}}} = q^{1/2}/h^{1/4} \qquad [2]$$

---

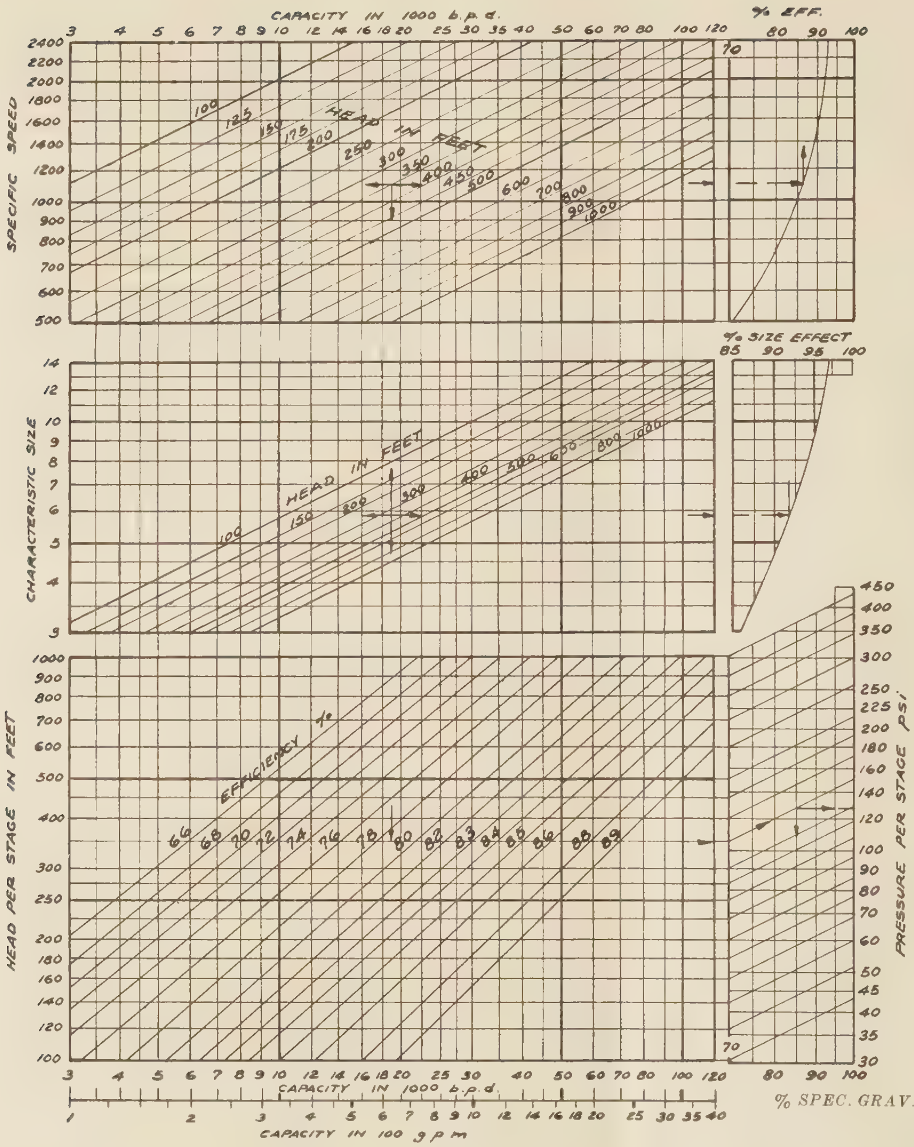

Fig. 1 Determination of Ideal Efficiency for Pipe-Line Pumps

This varies from about 3 to 14, and the efficiency variation, due to this size factor, is also fairly well established.

It is noted, that using these two factors, the affinity law, according to which the efficiency e remains substantially constant for different speeds for a constant value of the characteristic size, is fully complied with, so that this term is more suitable for the size definition than the capacity. This conception is not novel in so far as it is the application of the model law (4) for units of the same type and different size, but it limits the range of types and sets the absolute value of the characteristic sizes.

The approach, however, is just the opposite in so far as it starts from an optimum and reduces this with the size decrease; the very assumption of an optimum is contradictory to the turbine-model laws which assume that the losses in per cent $(1 - e)$ will decrease *ad infinitum* the same way, i.e., if the doubling of the model diameter reduces the losses 13 per cent, a similar percentile reduction will take place by doubling the size of the units, e.g., from 20 to 40 times that of the model. This means an efficiency increase of an 80 per cent model to 82.6 or 2.6 points for a double-sized model; a 20 times to 40 times model size will give efficiencies of 87.8 per cent and 89.4 per cent, respectively, or show a 1.6 point increase with a model law, according to which the losses are proportional to the fifth root of the size ratio.

For the small sizes and narrow range of types, experience with the pipe-line pumps indicates that the change of efficiency with size is rather independent of the type, and this is how Fig. 1 is laid out. It is noted that the values indicated are only estimates and in some cases economically impractical.

The great effect of viscosity, particularly for heavy crude, is not considered in this paper, but it should not be neglected when the absolute maximum of obtainable efficiency is to be determined for oils of different viscosities. This effect is subject to further exploration, some of which is being carried through at present. The reduction of efficiency, due to viscosity, is greater for the lower specific speeds; therefore any conclusions which call for

higher-specific-speed types are even more valid for viscous than for nonviscous oils.

The important factor of cavitation may be overlooked for the newer pipe-line systems, because they are designed to give ample positive suction head to avoid cavitation even at the starting station, while for the successive stations pressure regulators on the suctions provide sufficient inlet pressure. On the first station, or in those with tank farms, if the static head provided is insufficient, auxiliary pumps furnish the required suction pressure. Furthermore, the pumps being multistage, only the first stage would have to be changed to reduce cavitation tendencies so that the total effect would be rather small.

Secondary effects, due to the larger shaft required by a great many stages or higher or lower stuffing-box pressures, also may be taken into account, but the general picture developed in this paper will not change materially if they are neglected.

Operating at a single given speed of 3550 rpm, a nomogram, Fig. 1, was constructed from which the best efficiency for a given capacity and head per stage may be determined. The nomogram consists of three sections, the abscissa showing the capacity in barrels per day and gallons per minute being the same for all of them.

In the uppermost section, from the capacity and the slanting head lines, the type or the specific speed, shown as an ordinate, is determined, and at the right the corresponding optimum efficiency is given.

Similarly in the middle section, the characteristic size, as defined by Equation [2], is determined, and at the right the corresponding size effect or the reduction of efficiency is given. By multiplying the optimum efficiency with the size effect, for a given capacity and head per stage, the best efficiency for the unit may be figured.

While the values of the specific speed and size are designated, they could be omitted and only the corresponding efficiencies marked, thus avoiding these terms altogether; however, they are given because, by their continued use, a certain "feel" of the pumps may be obtained, e.g., the ratio of impeller width to its diameter by the specific-speed term, or linear dimension of the volute outlet within the pump, by the size term. The discharge-nozzle diameter, which is used in the trade to differentiate pump sizes, is far from being a characteristic figure and was adopted because it is an easily measurable dimension.

In the third and lowest section, the ordinate is the head per stage and the constant-efficiency lines, obtained from the two upper sections, are shown. This section alone gives the final values directly, so that the others could have been omitted. On the other hand, further developments and later modifications to include such important effects as viscosity should be made by alterations of either or both of the first two steps, thus making such changes easily comparable with the data herein outlined.

Looking over the optimum-efficiency curve, it is found to be going up with the specific speed toward a maximum for the full range. On the other hand, for a given capacity, higher specific speed means less head per stage, or more stages for a given pressure; it is evident that the gain beyond $n_s = 1500$, with an optimum efficiency of 90 per cent, is very slight and slow, so that there is not much reason to go beyond this point. Contrasted with this, at a lower range of specific speeds, there is a gain of 10 points or 13 per cent from 500 to about 800, which is certainly worth while.

Similar statements can be made of the change of efficiency as a function of size, which also shows much greater effect at its lower end, although it is less pronounced.

It should also be noted that by doubling the number of stages the specific speed or type number is increased to 168 per cent of its former value, there being simultaneous increase in the characteristic-size term, which increases to 119 per cent of its former value; both are advantageous from an efficiency standpoint, and particularly effective for low capacities.

The efficiencies, obtained in the third section from the two sections above it, are straight lines for constant efficiency; the equation of the uppermost, 66 per cent efficiency line, is $q = 0.04\ h^{1.25}$ and that of the lowest, 89 per cent efficiency line, is $q = 0.2h$.

These compared with the constant specific-speed lines, the equation of which is $q/h^{1.5}$ = constant (not shown), indicate that the greatest deviation from them is at small sizes and low specific speeds, as expected.

The head per stage is also given in psi with a specific-gravity correction scale to get it from the foot per stage on which the diagram is based.

Pipe-line pumps of today are proved and satisfactory machines. For capacities of 10,000 bbl per day and over, they are built as horizontal machines. They are axially and radially well-balanced units, as illustrated in Figs. 2, 3, and 4.

The pump cases are of the volute type without diffusers and with external crossovers from stage to stage. Cases are axially split, bolted together with heavy bolts, permitting the assembling of the complete rotating element and mounting it in the case as a unit.

For different conditions, two complete rotating elements can be furnished for any one pump. By initially furnishing large-diameter runners and later reducing such diameters, lower volumes and pressures are obtained. Lately this practice has been extended by suitable design to provide for a change in impellers to secure larger volumes and increased pressures. Optimum efficiencies with full- and reduced-diameter impellers are practically unimpaired.

As an example of this practice, the Plantation Pipe Line Company (5) pumps are to be started with a capacity of 60,000 bbl per day which later on is to be extended to 90,000 bbl per day, doubling the resistance of the line and the number of stations. The first pumps are provided with low-capacity impellers, but have also been tested with the future high-capacity impellers, so that all the units can be used for the final conditions, requiring only that the impellers be changed. Fig. 5 shows the performances, which indicate only a slight sacrifice for the starting conditions. The explosion-proof motors at the start will have fans for 600 hp, later to be changed to fans of greater volume for 900 hp, which is the electrical design load of the units.

The electric motors for centrifugal pipe-line pumps are of high efficiency and lately, as a rule, of explosion-proof type. If explosion-proof motors are not used, the pump and motor are usually separated by a fire wall. The motor drives the pump by means of a shaft operating in a stuffing box in the fire wall. The stuffing box prevents the passage of flame from one room to the other. In both cases the motor is air-cooled.

Precautions are taken to minimize dust entering the motor room, even though considerable air is needed for cooling the large motors. It seems that cooling by the pumped liquid would be more rational. Pumping units called by their inventors the Rannett type, with the motor cooled by the pumped liquid, were built for one gasoline line and were quite successful Their price is high because of various special structural features, including a fluid jacket, which surrounds the stator of the motor, to take away the heat, and which jacket has to stand the full line pressure. Such a unit is illustrated in Fig. 6.

To obtain good efficiency with small-capacity pumps, the specific speed and the characteristic size have to be increased, which means low head per stage and many stages. The first objection to many stages is the critical speed. This was serious until pumps were made to run below the first critical; however,

today they are made to run between the first and second critical, so that the unit has to be quite long to come near to the latter. This requirement in most cases is not a serious limitation. The initial bending, due to the weight of the rotating element, for small horizontal units can be eliminated by making them vertical. Such a vertical unit is illustrated in Figs. 7 and 8. These vertical units have a single stuffing box and a solid coupling between pump and motor, which latter carries any slight thrust of the pump. While horizontal units are as a rule limited to eight stages, vertical units have practically no limitations, but there is no object in going above the specific speed of about 1200, as for small capacities the head would become impractically low.

Special consideration must be given to the stuffing-box pressures in selecting centrifugal pumps for pipe-line duty. When centrifugal pumps were first used in pipe-line work, frequently two separate pumps were operated in series. This meant that the second-unit stuffing boxes were subjected to high pressures. Generally, the crude oils handled were reasonably good lubricants and wear on the well-lubricated packing was satisfactorily low.

Stuffing boxes are made with or without pressure-breakdown bushings and bleeder lantern rings. Pressures on the external packing may be reduced by providing a leak-off to the first suction.

Gasoline pumps, from which leakage constitutes an important loss and because gasoline is a rather poor lubricant, were first made in a single unit for the whole pressure, so that there were only two stuffing boxes, both of which were under low pressure. Later on, with improved shaft-sleeve materials, such as stellited chrome steel, and increased size of the pumps, the gasoline as well as the crude-oil pumps were separated into two units operated in series, the second unit having high pressure on the stuffing boxes, the leakage being bled back to points of lower pressure. Like all stuffing boxes, they are a nuisance, as special pumps have to be provided to pump the leakage back to the line from an underground tank, which stores this leakage until it is repumped.

No matter how good the stuffing box, it is an anomaly and the final solution of the pipe-line pump stuffing box will be its complete elimination. While this goal is not yet fully attained, there are a number of units of the so-called stuffing-boxless type in service, pumping light fractions and gasoline, where both the pump and motor are submerged in the liquid pumped. The stuffing-boxless units now in the field are using an oil-filled motor. The oil in the motor and the pumped liquid are separated by a mercury seal with a balance line equalizing the pressure on both sides of the seal. This unit, which is built in a vertical type and has no stuffing box, is independent of the system pressure, so that a combination of units for any pressure or volume is easily possible. The advantages, of course, are a much greater variation in capacity with good efficiency for the line, the good efficiency being obtained because of the lack of throttling which is possible with the use of a number of units.

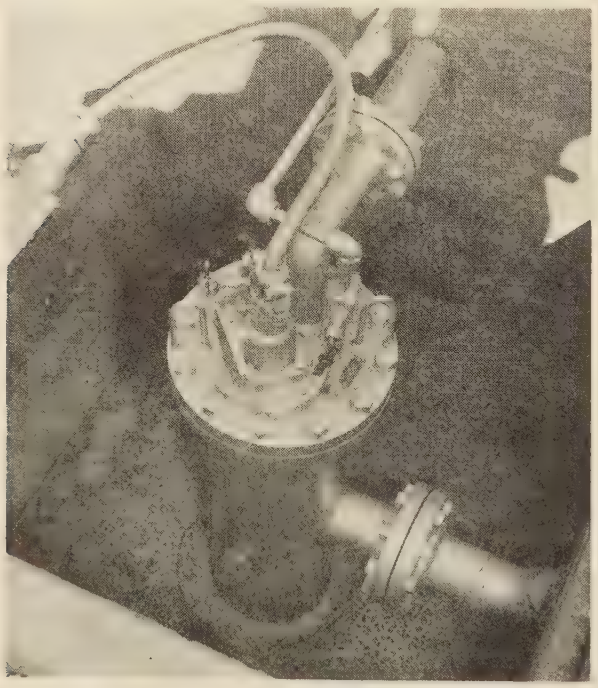

Fig. 9 Typical Stuffing-Boxless Installation

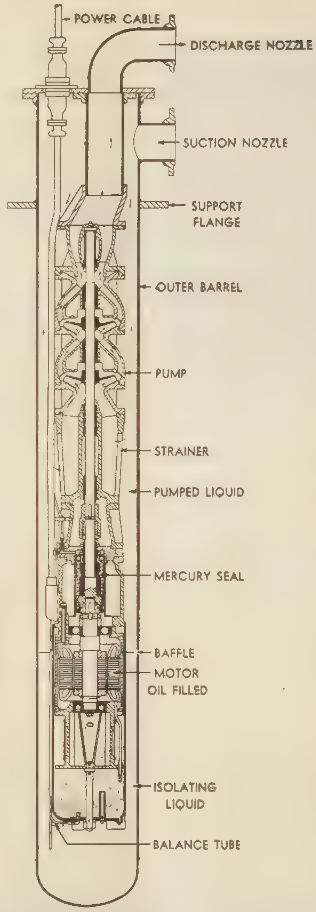

Fig. 10 Sectional Elevation of Stuffing-Boxless Pump Reveals Construction Principle and Working Elements

The automatic or semi-automatic stations which are becoming more and more general would become very simple with the use of stuffing-boxless units, inasmuch as the pump house would be eliminated, and only a control chamber required.

At present, units up to about 50 hp are fully developed. These have some limitations, e.g., that the pumped oil can contain but little sulphur, in order not to create an emulsion with the mercury in the seal.

As the stuffing-boxless pump and motor are put in a single barrel, with the suction and discharge nozzles and the cable connection in the cover of the barrel, a subterranean pit is all that is needed to serve as a pump and motor room for the head of the pump, the control panel being located some distance away. Stations built in this manner, can be readily made bombproof. These units are more suitable for automatic operation, as the number of control items is materially reduced by the elimination of the stuffing box. Furthermore, not having a stuffing box makes the automatic separation of the units from the line, when the unit is not working, unnecessary. It seems that the ultimate design of pipe-line stations will use such units as soon as they are fully developed and proved.

Figs. 9 and 10 show a stand-by plant pumping butane (6). Figs. 11 and 12 illustrate a proposition covering pipe-line pumps for a foreign government (7).

Operating Schedules for Pipe Lines

Under this heading, it may be well to mention the great advance

made in keeping the pipe lines clean, when they are laid, and thus saving the pumps from being "shot" right at the start. After all, high efficiencies are obtained with close clearances, and these can only be maintained with clean liquids. Any precaution in this direction will pay for itself many times in power and maintenance costs.

The other great advance is the cathodic protection of the pipe lines from corrosion, and the maintenance of clean inner surfaces by scrapers, which may be run through without interruption of the flow.

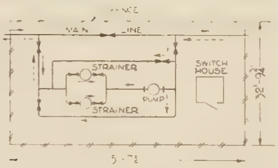

Fig. 11 Stuffing-Boxless Station for Projected Gasoline Pipe Line (7)

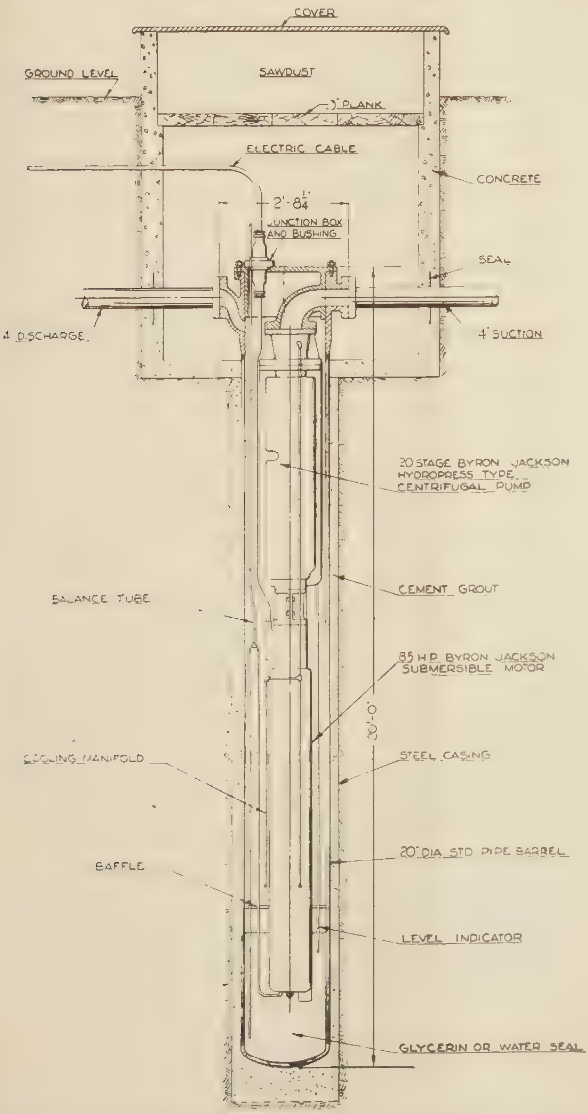

Fig. 12 Cross Section of Main-Line Pump for Proposed Station Shown in Fig. 11

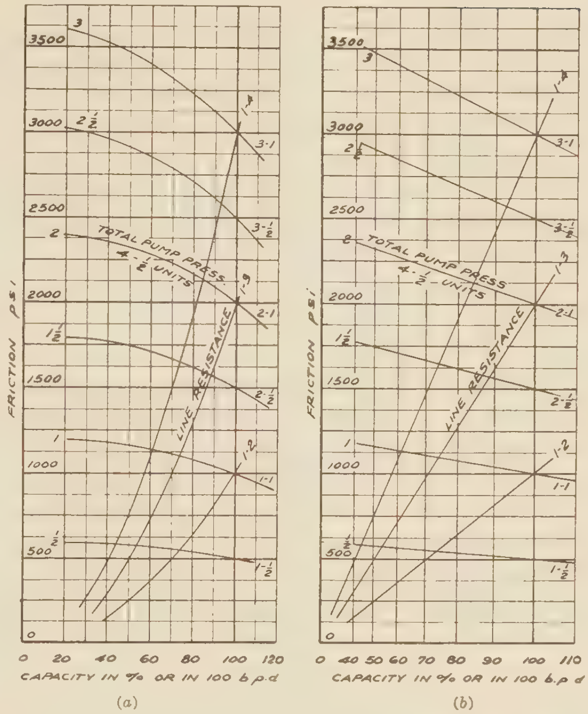

Fig. 13 Pipe-Line Friction Lines and Pump-Performance Curves for Pipe Line With Three Stations at Same Elevation, Each With Two Identical Half Units

Operating schedules of a pipe-line system pumping a single crude, gasoline, or other products are quite complicated problems, particularly if there are many pumping stations, which are also take-off points for given percentages of the oil pumped in definite time intervals. As the line friction is increasing approximately with the 1.75 power of the capacity, the lowest rate of pumping to get the required total for a definite period is the most economical, even if the pumps do not work at their best efficiency. As half pressure means close to three-quarters capacity, and a third pressure more than one-half capacity, the power saving by pumping at low rates is very large. It is a surprise to outsiders to find how small is the total quantity actually pumped, compared with the maximum possible for continuous operation, 24 hr, 365 days a year (8).

It is, of course, understood that the pipe line would earn more by continuous full-load operation and, like the railroads, tries to get all the load which it can handle, but seemingly the full load, at least in the past, was not available.

Many limitations are to be considered in these schedules for partial loading, among them the maximum permissible pressure on the line, the minimum inlet pressure to the pumps, the minimum gradient between stations that goes over the local peaks and the changed loading after each take-off, etc. All these are automatically satisfied at full rate of pumping, for which the line is designed, and also at any lower capacity, if that is obtained by throttling. The problem is to obtain the lower rate of flow with as little throttling as possible. As the dispatcher must have an immediate answer to all conditions, the most economical schedules had to be worked out in advance taking into account all the bottlenecks.

A late development hardly mentioned in the literature is the transformation of some lines designed for a single product to transport many products of different character, as a number of grades of gasoline, kerosene, furnace oil, etc. The scheduling of

such lines, with plugs of different oils of various lengths in the line is even more complicated, as the increased number of take-offs at each station, because of the different products, leads to many more combinations, and because the contamination plugs between the products have to be specially handled.

The charting of a simple constant-diameter line with three stations at the same elevation and an equal distance from one another, each operating with two identical pumps in series (called one unit) at full load, is shown as an example in Fig. 13. For simplicity's sake, the friction lines are shown as second-degree parabolas, Fig. 13*a*. The diagram shows that operating one-half unit at the first station will give 45 per cent capacity, one full unit 61 per cent, one and a half units 72 per cent, two units 83 per cent, and, of course, three full units 100 per cent capacity.

It is proposed to simplify this charting by making the capacity scale a power scale, corresponding to the exponent of the capacity as function of the head, in this case 2, but it could just as well be 1.85 or any other figure.

This is fully justified, particularly for gasoline and heavier products, and even for most of the crude lines, because in practice the Stanton Pannell friction-coefficient line as a function of Reynolds number is shown as a line, flattening out only at high Reynolds number, and elongated as a matter of safety until it meets the viscous-flow line, thus avoiding the uncertain range (9, 10). Flow rates in the viscous range are, as a rule, excluded. To have a single power, that is, substituting a straight line for this coefficient in a logarithmic scale, means that the friction head may be expressed as a power below 2 of the flow rate, thus taking account of the variation of the friction coefficient for the different capacities.

For different oils, different scales may be made, but in most cases this will be unnecessary; it will be sufficient to change the friction-loss figure to agree with the actual test or expected value for a given capacity and use the same capacity scale.

If the ordinate representing the pressure remains linear, the former parabolic or exponential functions will be straight lines, which can be easily drawn. Furthermore, if the pump performance curves are plotted in this scale, they will be found to be remarkably close to a straight line, thus also determined by two points. Fig. 13*a* is repeated in Fig. 13*b* illustrating the simplicity of the method.

Static-head differences are taken care of by drawing a line parallel to the friction lines, at a distance of the elevation difference refigured in psi. Different distances between stations mean a proportional reduction of friction at a given capacity, therefore are also determined by one point. Different pump performances are characterized by two pressure points, e.g., those at one-half and full capacity; they are just as easily added as identical ones. When the number of stations is great and all these factors are varying, the saving of work with this method will be appreciable. Some other applications of this method are illustrated by a few different problems.

Problems of Looping Lines, Equivalent Length, and Take-Offs

(*a*) A problem very often encountered is the looping of the line. As a concrete example of this, a pipe line 30 miles in length, with a friction resistance of 800 psi at 10,000 bbl per day capacity, is to be looped with a line of the same size, so that its capacity is increased to 12,000 bbl per day without changing its resistance The question is what is the length of the loop. The solution is shown in Fig. 14, which has a capacity scale with 1.85 exponent.

Line OA represents the original friction line, H_3 the pressure at 100 per cent capacity. Elongating this line to the 120 per cent capacity (point B) we see that without looping it would have 1110 psi friction (H_1). Looping the line with the same size of pipe means that at any pressure the capacity is doubled. Taking the 50 per cent capacity line, the friction pressure will be CD, which will prevail for a looped line at 100 per cent capacity (point E). Line OE represents the friction characteristics of a looped line for the full length which, elongated to 120 per cent capacity, will give point F and the corresponding pressure H_2. The requirement is that the pressure H_3 be maintained. If the loop length is x per cent of the full length, then the friction at 120 per cent capacity can be expressed as xH_2 for the looped

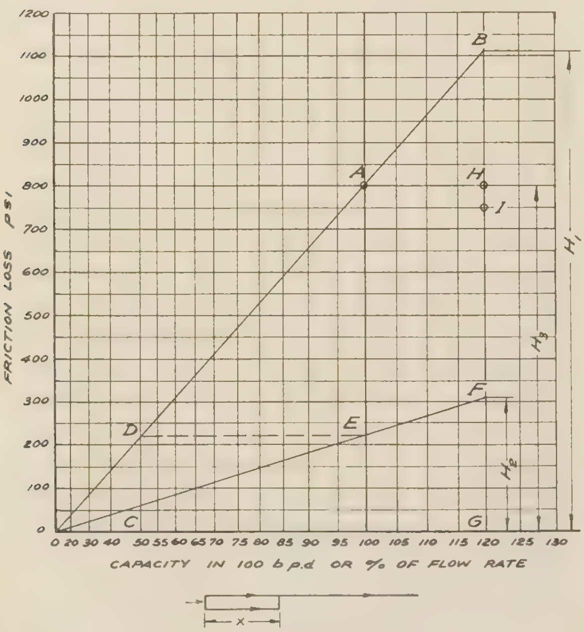

Fig. 14 Determining Length of Loop x for Given Pressure Drop at Given Capacity

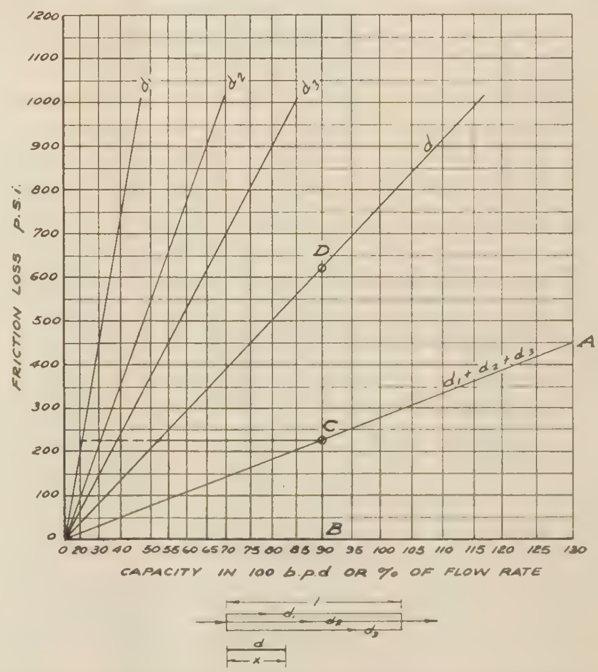

Fig. 15 Determining Equivalent Length x for Given Diameter d of Looped Line of Three Members at a Definite Flow Rate

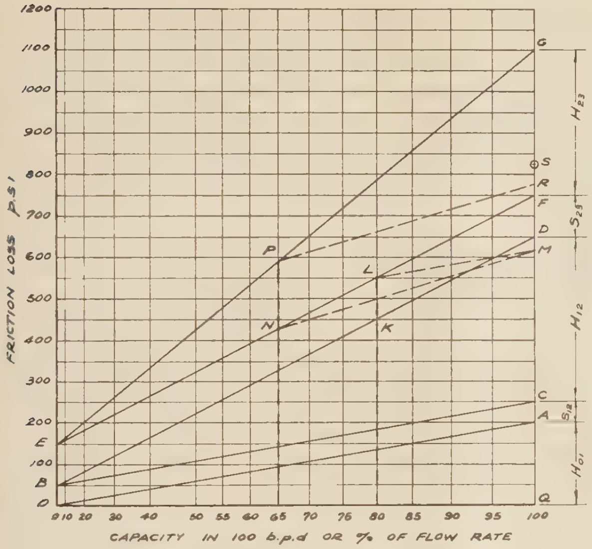

FIG. 16 LINE PRESSURE FOR PIPE LINE HAVING THREE DEPOTS, WITH SPECIFIED SIMULTANEOUS TAKE-OFF CAPACITIES

length and $(1-x)H_1$ for the single line remaining, the sum of these being equal to the total pressure H_3

$$H_3 = xH_2 + (1 - x)H_1$$

and from this

$$x = \frac{H_1 - H_3}{H_1 - H_2} = \frac{310}{800} = 38.7 \text{ per cent or 4.65 miles}$$

If the problem required a reduction of the line pressure to 750 psi, the looped length would be

$$x = \frac{1110 - 750}{1110 - 310} = \frac{360}{800} = 45 \text{ per cent or 5.4 miles}$$

Similarly, if the pipe size were different, it would mean only adding a different capacity at the same pressure for the determination of point E and proceeding the same way. It is the proportionality of the friction with the length which makes the solution so simple.

(*b*) A problem solved the same way is the substitution of a single line for a looped line, and finding the equivalent length which gives the same resistance for a given capacity.

Assuming that there are three lines in parallel of the same length and of d_1, d_2, and d_3 diameters with the friction characteristics as shown in Fig. 15; the equivalent length of a line of d diameter with known friction characteristics is to be determined. Fig. 15 shows the capacities of the lines composing the loop at 450 lb to be 3000, 4500, and 5500 bbl per day, respectively, so that the total capacity is 13,000 bbl per day (line OA). If the equivalent length of d diameter at a flow rate of 9000 bbl per day is wanted, the line BD is drawn, this being the resistance of line D for the full length. The resistance of the looped line is BC; therefore, the length of line d, to have the same resistance, has to be reduced in the proportion of $BC{:}BD$. If the full length is 10 miles, the reduced length will be $L = \frac{225}{625}\,10 = 3.6$ miles for a flow of 9000 bbl per day.

The equivalent length for any other capacity can be similarly determined by a single line in place of the laborious calculations formerly used (8). The flow rates in the different members of the loop may be read off and checked to assure that they do not come into the viscous range.

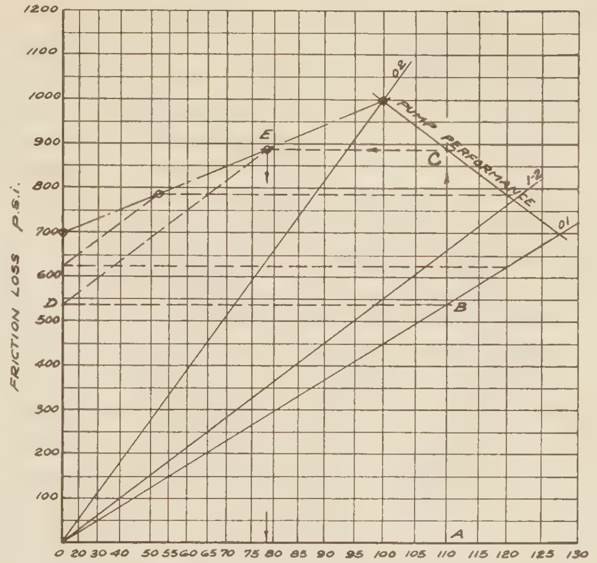

FIG. 17 LINE PRESSURE FOR GIVEN PUMP PERFORMANCE WITH SPECIFIED FLOW RATES AT END OF PIPE LINE, WHICH HAS AN INTERMEDIATE TAKE-OFF

(*c*) A line with intermediate depots and take-offs is the third problem. Suppose the line length to the first depot is 20 miles, from the first depot to the second, 40 miles, and from the second to the last, 35 miles. The corresponding friction resistance at 10,000 bbl per day flow are 200, 400, and 350 psi, respectively, so that the total friction resistance to the end is 950 psi. There is also an elevation difference between the first depot and the second which is equal to 50 psi, and between the second and third, equal to 100 psi.

The question is: If 2000 bbl per day are taken off at the first depot and 1500 bbl per day at the second, what pressure is needed at the pumping station to get 50 psi at the last depot?

The line friction characteristics for the oil pumped are such that the friction varies with the 1.75 power of the flow rate, and the abscissa is laid out accordingly, Fig. 16; H_{01} being the friction for the first section, at 10,000-bbl per day flow rate, line OA being the friction line.

The static-elevation difference between 1 and 2 is S_{12}, while BC is a corresponding line parallel to OA.

The friction from the first to the second depot at 10,000 bbl per day is H_{12}, and BD is the corresponding friction line measured from BC.

Similarly, S_{23}, H_{23}, and lines EF and EG are the corresponding terms between the second and third depots.

The flow to the first depot is 10,000 bbl per day, the resistance being $H_{01} = 200$ psi. Going to the second depot, the static difference is added, giving a total of 250 psi. Taking off 20 per cent, the flow continues at the rate of 8000 bbl per day; the intersection of a vertical at this capacity with BC and BD is the friction of the second section, which is added to BC by drawing a parallel to BC from K. As the next static head is to be added immediately, the parallel is drawn only from point L, leading to a pressure QM.

The flow from this point on is at a rate of 6500 bbl per day, 1500 bbl per day having been taken off. The friction is given by the intersection of a vertical at this rate, with lines EF and EG; that is, NP. It is added to QM by connecting M with N and drawing a parallel to it from P. The line PR is the pressure at the start with zero pressure at the end. However, as a pressure of

50 psi is wanted there, this is added to QR, giving $QS = 825$ psi as the required pumping pressure, the answer to the problem.

(*d*) As a final example: Determine the capacity and pressure at which a pump of a given performance will operate, pumping into a line of known friction characteristics with one take-off. The rate requirements at the end station are given, and the difference between them and the pump capacity is taken off at the intermediate depot, Fig. 17.

This problem is solved by assuming a pumping rate and determining how much of it will arrive at the end station; the few points so determined are then connected to give an immediate answer for any rate.

The friction is, for a flow of 10,000 bbl per day, from the pump to the take-off 450 psi, from there to the end 550 psi, a total of 1000 psi, at which the total capacity is pumped to the final depot, this being an intersection point with the pump characteristics.

The intersection of the first-section friction with the pump characteristics gives another point where the total pump capacity, this time 12,750 bbl per day, is taken off at the first depot.

At the rate of 11,000 bbl per day, the first section will have a friction of OB which is projected horizontally over to D, from whence a line is drawn parallel with the second-section friction line. This will intersect the horizontal line drawn from the pump performance curve and total-friction point C at a point E. Reading it below this tells that, out of 11,000 bbl per day pumped, 7800 will get to the end, therefore 3200 bbl per day has to be taken off in the middle.

A similar determination of another point for 12,000 bbl per day is plotted and the four points connected. The line turns out to be straight enough so that the connection of the two end points with a straight line gives a close approximation.

Discussion

A. J. Stepanoff.[3] The writer has studied certain phases of this subject in considerable detail, one of which, dealing with the determination of a composite-pipe-line characteristic and location of the operating point on the centrifugal-pump head-capacity curve has been the subject of a recently published paper.[4]

[3] Engineer, Cameron Engineering Department, Ingersoll-Rand Company, Phillipsburg, N. J. Mem. A.S.M.E.

[4] "Determining Operating Points of Centrifugal Pumps Working on Pipe Lines," by A. J. Stepanoff, *Oil and Gas Journal*, vol. 40, Dec. 4, 1941, p. 45.

Although the United States leads in pipe-line construction and establishes standards in this field for the rest of the world, the literature on this subject is very scant so that this paper is a welcome contribution to the published information on this subject.

It is interesting to mention that, when Russia decided to build pipe lines, a group of engineers was sent to this country to learn all they could about our pipe-line practice. Upon returning home, one of these engineers, Professor Pritula at the Moscow Engineering School, wrote a two-volume book on the subject of pipe lines,[5] based entirely on American practice. A one-year course was also started by Pritula at the University of Moscow on petroleum transportation.

A new term "size factor" not commonly used is introduced in the paper. Mathematically it is the square root of the "unit capacity," more widely known. There is one feature about "size factor" which does not appeal to the writer, that is, if the number of stages to get the same head is increased, or less head is developed per stage, the "size factor" will increase, while the actual impeller diameter, and hence the pump over-all dimensions per stage, will decrease.

The question of cavitation in pipe-line pumps still presents a problem. There are many stations which do not carry suction pressures high enough to assure freedom from cavitation. Such stations have floating tanks on the line, the level in these tanks determining the suction pressure on the pumps. Such an arrangement has advantages from the operating point of view. The effect of cavitation under such conditions may appear only in a slight drop of the pump head-capacity curve and efficiency. No vane pitting, noise, or sudden breakoff of the head-capacity curve are observed.

The question of relationship between the pump type or specific speed and efficiency is brought up frequently not only among the pump manufacturers but also by the users and operators of centrifugal pumps. The writer has studied this problem from a different point of view from that presented in the paper. The writer has attempted to demonstrate the reasons for efficiency variation with the specific speed. It can be shown that disk-friction and leakage losses increase very rapidly when the specific speeds of pumps are decreased.

The discussion of the stuffing-box problem is incomplete without mentioning mechanical seals. There are many centrifugal pumps in pipe-line service which have given satisfactory operation for several years, pumping crude, gasoline, and propane with suction pressures of 200 to 400 psi, without injection of lubricant or coolant into the stuffing box.

It is possible that there is a definite field for application of small stuffing-boxless pumps described in the paper. Essentially, however, it is not a pipe-line pump. To the writer's knowledge, no vertical pump, such as shown in Figs. 7 to 12 of the paper, was ever employed for pipe-line service as such. The experience with the Rannett pumps, referred to in the paper, shows that, while the pump house is not necessary for the pump protection when in operation, a building around pipe-line pumps is indispensable for servicing pumps, such as dismantling pumps for replacing parts, storage of spare parts and tools. There are many motor-coupled pumps in the refineries installed in the open air without any weather protection. In such cases, repair-shop facilities are available for servicing pumps. The motor protection and stuffing-box care are not the only problems to be considered when deciding upon the automatic pipe-line pumping stations; maintaining the proper suction pressures on individual stations, when the capacity of the pipe line is varied, is only one of them, a satisfactory solution for which is not yet available.

[5] "Oil Transportation," by A. F. and B. A. Pritula, U.S.S.R., State Publication, 1934; in Russian.

AUTHOR'S CLOSURE

The foregoing discussion brings out quite properly, that the United States leads in pipe-line construction; and in this connection the author would like to add that the standard pipe-line pumps are a distinctive American product, simpler in design, better in efficiency and reliability, and easier to assemble because of the split-case volute construction than the competing European pumps.

For his preference of the term "unit capacity" in place of the author's "size factor," Mr. Stepanoff gives as a reason that a pump of "larger dimensions" will have a smaller size factor. It is to correct the natural expectation that the larger pump should be also hydraulically bigger as, for example, a pipe would be, that the author used the "size" term which designates true size in hydraulic terms and gives warning that the larger-diameter unit for a given capacity and speed is hydraulically smaller.

Contrary to Mr. Stepanoff's statement that floating tanks on the incoming lines have advantages from the operating point of view, their elimination and the establishment of a closed line is considered as one of the greatest advances in pipe-line operation. This step, besides eliminating the evaporation loss of these tanks, permitted a much greater flexibility of operation of long lines, as it made high pressure on the incoming line possible, instead of limiting it to the height of the floating tank.

As an example, if the three-station pipe line, shown in Fig. 13*b*, is a closed line, it could operate at a flow rate of 83 per cent of normal without any throttling with four half units, two in the first station and one half each in the second and third stations; the suction pressure would be about 370 psi at the second and about 200 psi at the third station. It could also operate at about 88 per cent of the normal flow rate with five half units (two each in the first and second and one in the third station) by throttling 250 psi at the second station.

With floating-tank operation, in both cases six half units would have to be used, thus increasing the power consumption by 50 per cent for the 83 per cent operation and by 20 per cent for the 88 per cent operation. In the first case, a total of 1000 psi, in the second, 750 psi would have to be destroyed by throttling in the second and third stations. Such operations at partial capacities close to normal are quite common on long lines with many stations, whenever smaller take-offs are required at intermediate points.

On closed lines, the maximum pressure on the outgoing line and the minimum pressure on the incoming line is limited by pressure regulators on these lines, set for a predetermined maximum and minimum, respectively, and actuating the throttle valve on the outgoing line from the station. Provision is made that, whenever the pressure on the incoming line rises to half the maximum line pressure, if two pumps are in operation one will shut down.

Mr. Stepanoff's statement, that for the maintenance of proper suction pressures on individual stations, when the capacity of the pipe line is varied, no satisfactory solution is yet available, may have been true years ago, but for some time a full line of standard valves and auxiliaries have been available from the best manufacturers and are actually installed on a number of pipe lines.

Concerning vertical double-case pumps with a stuffing box as shown in Figs. 7 and 8, Mr. Stepanoff's statement, "no vertical pump was ever employed for pipe-line service as such," was correct up to six months ago. However, there have been several 150-hp units furnished for the Plantation Pipe Line, chosen on the basis of their long satisfactory performance in similar refinery service and their general application in other fields for ten years.

The author is grateful to Mr. Stepanoff for bringing up the mechanical seals which should have been described as one kind of stuffing box, even though they are not mentioned in any pump manufacturer's catalogue. They rely on the contact or throttling by means of one or two small rotating disks running against stationary surfaces; thus unlike the conventional stuffing box, their failure, because of their short leakage path, is very dangerous particularly for lighter hydrocarbons and high suction pressures. For this reason they may be applicable for clean crudes with some lubricating quality even in automatic stations, but for gasoline and propane, especially without auxiliary lubricating feed, they would not be considered in any station without constant attendance.

It is the elimination of this limitation which makes the stuffing-boxless unit especially attractive as a pipe-line pump for an automatic station. The greater subdivision of the station into smaller units, without limitation of suction pressure, permits more efficient operation at partial capacities without throttling, by simply taking one or more units off the line or putting them on as required. The excellent record of the present pipe-line pumps and motors, contrary to Mr. Stepanoff's opinion, certainly would not call for a building to maintain them. The buildings are there, either because the station has to have a constant attendance, or because of the auxiliaries and complicated control of the automatic stations. With the simplified control of the stuffing-boxless units and no auxiliaries, there may be a structure housing the controls, but the pumping units would require none. The possibilities are indicated by the experience of Byron Jackson Company, builders of these units, with a 20-hp propane loading pump, similar to Fig. 12, located 10 miles from the loading station without any building. This unit has been in operation for three years up to the present time, without any servicing or attendance. The development of large units, already under way but interrupted by the war, will constitute a great advance in the realization of a simple and reliable automatic station.

Test Stand for Centrifugal and Propeller Pumps

By G. F. Wislicenus,[1] Harrison, N. J.

This paper describes a new test stand for experimental investigations on centrifugal- or propeller-type pumps, as well as on pump installations. The test stand is particularly suited for a complete determination of the cavitation characteristics of the test pump and for reliable control of the flow conditions at the pump inlet.

The test stand which will be described in this paper is located at the Harrison Works of the Worthington Pump and Machinery Corporation. It was developed for the purpose of experimental investigations and model studies on pumps of the centrifugal and propeller type. Beyond this general purpose, the design of the test stand is intended to satisfy the following specific requirements:

1 To offer means for a reliable determination of the hydraulic operating characteristics of radial-flow, mixed-flow, or axial-flow pumps up to 150 hp, with particular attention to the cavitation characteristics of these machines. The test pumps are subjected to certain limitations regarding size and mechanical construction, since it is not intended that this equipment be used for routine tests on commercial pumps with widely varying mechanical arrangements.

2 To provide sufficient space for modeling, not only the pump, but also the entire pump installation; in particular, the inlet structure.

3 To prevent the throttle valve or any other part of the test circuit from having any disturbing influence on the flow conditions at the inlet of the test pump.

Figs. 1 and 2 show the general arrangement of the test stand.

The Test Circuit

For convenient observation of the cavitation behavior of a pump, it is desirable to vary the inlet and discharge pressures of the test pump simultaneously in such a manner that the difference between these two pressures remains essentially unaltered. In this way, it is possible to study the effect of changes in the inlet head on the pump performance without changing the other operating conditions of the pump. Such simultaneous variations in the inlet and discharge pressures of the test pump can be obtained most simply by the use of a closed test circuit, i.e., a test circuit which at no place is open to atmospheric pressure. The most important pump test stand with closed circuit, so far discussed in the technical literature, is that of the hydraulic machinery laboratory of the California Institute of Technology.[2] The hydraulic-turbine test stand of the Baldwin Southwark Corporation is of the same type.[3] Since Worthington engineers have been in intimate and prolonged contact with the hydraulic machinery laboratory of the California Institute of Technology and were permitted to study the test stand of the Baldwin Southwark Corporation, it is natural that the design of the new test stand was considerably influenced by these two laboratories. On the other hand, the special requirements listed previously lead to an entirely new form of design, borrowing merely a number of general principles from the laboratories just mentioned.

The test circuit of the new test stand, Fig. 1, consists of the test pump, the discharge-pipe system of the test pump, the Venturi meter, the main throttle valve, the stilling tank, and the inlet tank.

The test pump, in all cases, has a vertical shaft. This arrangement was chosen for the following reasons:

1 An ever-increasing number of important pump installations are being built with vertical shafts.

2 Vertical-shaft installations are more likely to require model studies of the inlet structure than pump installations with horizontal shafts.

3 The vertical-shaft arrangement seems to permit a simpler and less expensive mechanical construction of the test pump.

4 It was felt that a vertical-shaft driver offered certain advantages as a dynamometer.

5 It is possible to investigate the hydraulic characteristics of horizontal-shaft pumps by means of model pumps with vertical shafts, excepting extremely large units and installations where an inlet structure with a free water surface has to be included in the model.

Fig. 1 shows an axial-flow test pump, because up to the present the test stand has been used chiefly for investigations on this type of pump. By changing the pump-discharge line, it is possible to test axial-flow pumps of different lengths, as well as mixed-flow or radial-flow (centrifugal) pumps. The test pump is located either on the upper deck of the inlet tank, as shown, or inside of the suction tank with the discharge pipe passing through an opening in the tank wall opposite the stilling tank.

The pump shaft is guided in two bearings with water and grease lubrication. The upper bearing serves as a shaft seal. The small basin on top of the upper bearing collects the leakage if the pump-discharge pressure is above the atmospheric. For discharge pressures below the atmospheric, this basin provides an airtight water seal, using an outside water supply. The test pump does not need to have any thrust bearing. The pump thrust can be transmitted by a special coupling (see discussion of dynamometer) to the dynamometer motor. This arrangement simplifies the mechanical construction of the test pump and eliminates to some extent the uncertain element of stuffing-box friction.

The pump-discharge line above the Venturi-meter vane elbow should be considered rather as part of the particular pump on test than as a part of the permanent test equipment and has to be changed in accordance with the varying requirements of the test pump.

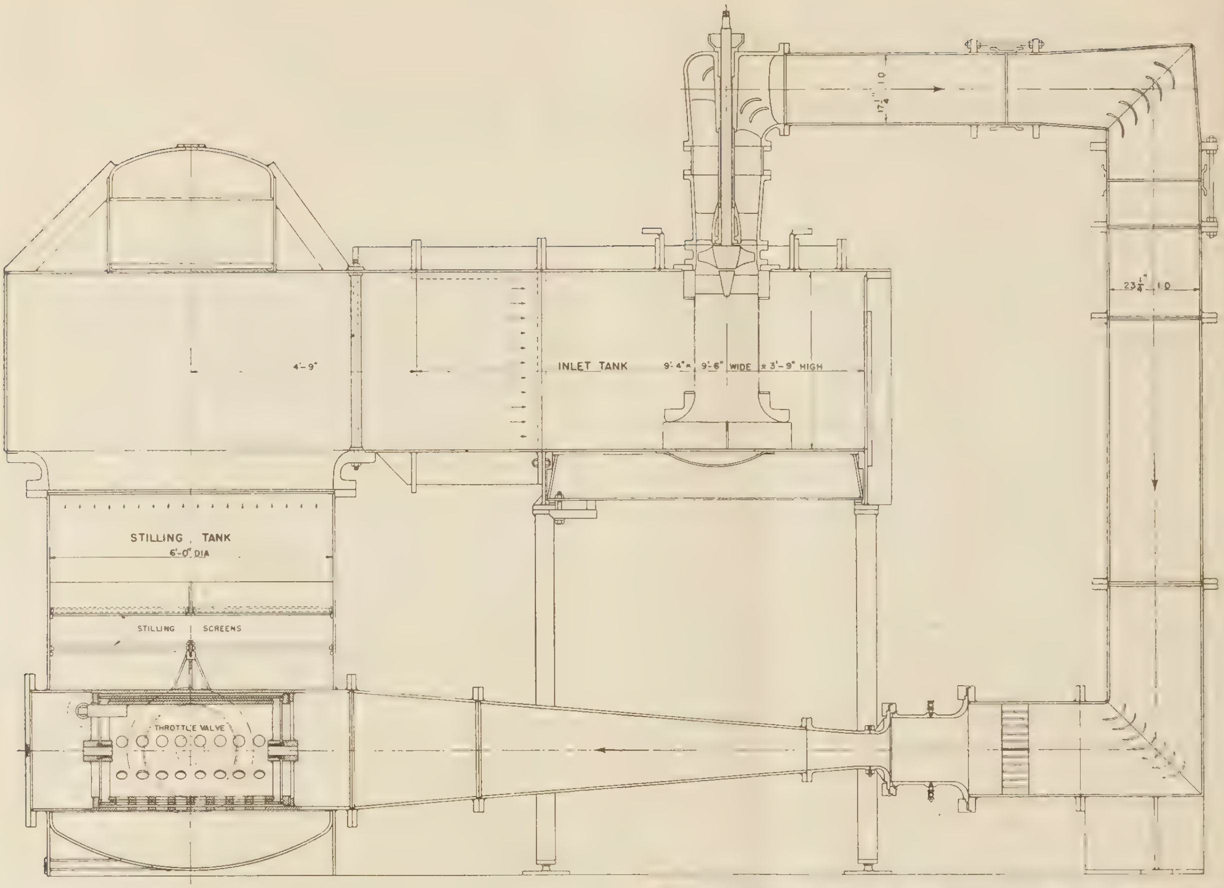

Fig. 1 Test Circuit

The Venturi meter has so far been used without calibration, since the present investigations require comparative results rather than absolute accuracy. The calculated coefficient can hardly differ more than 1 per cent from its true value, but an exact calibration will be made as soon as the general test program will permit this interruption.

It is seen from Fig. 1 that the approach to the meter is carefully guarded by vanes and a honeycomb. In order further to reduce any influence from irregularities in the approaching stream, the conduit has been given a contraction immediately in front of the first measuring station. (This method has been used before in the laboratory of the California Institute of Technology.) The Venturi-meter throat is easily removable so that throats of different diameters can be inserted to cover various ranges in capacity. Four throats from $4^1/_2$ to $10^1/_2$ in. diam are available. (Fig. 2 shows one of these Venturi throats standing on the ground floor.)

The main throttle valve, Figs. 1, 3, and 4, is located in the lower part of the stilling tank at the end of the long discharge cone of the Venturi meter. The throttle valve consists of four concentric cylinders with 64 radial $2^7/_8$-in-diam holes and a number of smaller holes, Figs. 3 and 4. The first and the third cylinder, counting from the inside, can be rotated by about one half the angle between two successive longitudinal rows of $2^7/_8$-in. holes. With the holes of the different cylinders in line, the throttle valve is open. The smaller holes flatten out the throttling effect as the 64 large holes are being pinched off, so that it is easy to adjust for small throttle-valve openings. The movable cylinders are rotated by a tangential link- and-screw arrangement

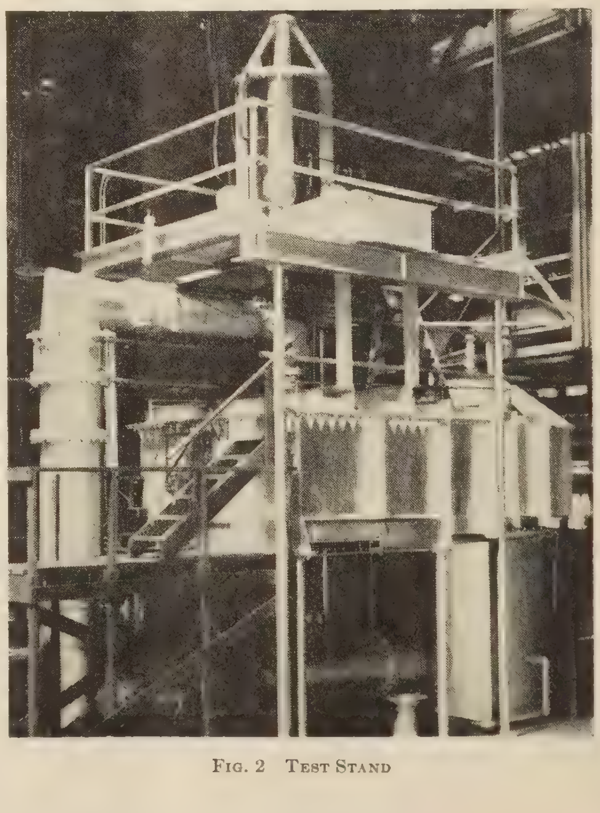

Fig. 2 Test Stand

operated by a two-speed electric drive and controlled by a corresponding switch on the control desk. The housing and opening through which the moving mechanism reaches into the outer throttle-valve cylinder is visible in Fig. 3. The outer throttle-valve cylinder is welded permanently into the stilling tank, Fig. 3, while the other cylinders, Fig. 4, are assembled outside of the tank and are inserted as a unit.

The purpose of this design is, of course, the breaking up of the unavoidable disturbance caused by the throttling action into a number of smaller disturbances which require a correspondingly smaller distance for their dissipation into heat. Furthermore, by using, between the four cylinders, three points of throttling in series, the local intensity and destructive effect of the individual disturbances are correspondingly reduced.

So far this throttle valve has been found to operate according to expectations.

The space around the throttle valve is separated from the upper part of *the stilling tank* by four screens made from $^1/_8$-in-thick steel sheets with $^1/_8$-in-diam closely spaced perforations. Thereby the remaining disturbances are further reduced in size, so that it is safe to assume that they will have practically vanished before reaching the inlet tank.[4] The resistance of the stilling screens tends to distribute the flow evenly over the 6-ft-diam stilling tank, although the average value of this resistance will seldom exceed 1 ft of water. The mean velocity in the upper part of the stilling tank usually stays below 1 ft per sec.

The transition piece between the stilling tank and the inlet tank is approximately semicircular in shape when viewed in a vertical direction. Four stay bolts near the periphery of the stilling tank support the top of the transition piece at the open side of the latter. A dome on the top of the transition piece aids in removing the air from the system if desired. The flow from the stilling tank to the inlet tank, of course, may be guided by suitable vanes which can easily be fastened to the stay bolts previously mentioned. Such vanes, however, should be considered as part of a particular test setup, rather than as a permanent element of the test stand.

The inlet tank is of rectangular shape. Its flat walls are sufficiently stiffened by outside ribs to withstand a high vacuum, as well as an internal pressure of at least 36 ft above atmospheric pressure. No internal supports are used here, so that the inside of the inlet tank is left entirely free for the construction of a model inlet structure. The upper deck of the inlet tank is composed of individual steel panels which are bolted together and are readily removable. The panel which carries the test pump is specially reinforced for mechanical stiffness and may be shifted to various places along the top of the inlet tank. In the lateral direction, the test pump may be displaced by cutting a new opening into the pump support panel. For the investigation of pump-interference problems, it is possible to arrange an auxiliary connection between the desired point in the inlet tank and an opening already provided in the side of the stilling tank outside of the throttle valve and below the stilling screens. A circulating pump has to be placed into this connection. By such an arrangement, it becomes possible to study the effect of a neighboring pump or of a flow past the pump intake on the operation of the test pump.

Arrangement for Cavitation Tests

Control of the inlet pressure is obtained by means of a pressure-control circuit, following essentially the same principle as that used in the laboratory of the California Institute of Technology.

For cavitation tests with a completely filled test circuit, a certain amount of water is withdrawn continuously from the highest point of the dome on top of the stilling tank. The water is being pumped to an open tank of about 60 cu ft content which is located approximately 25 ft above the inlet tank of the main test circuit. From the open tank, the water is returned by gravity through a throttle valve to the low-pressure side of the test circuit. This auxiliary throttle valve is located within sight of the inlet-pressure gage and is used for coarse adjustments of this pressure. Fine regulation is obtained by changing the pump speed in the pressure-control circuit. The field rheostat used for this purpose is located within convenient reach of the observer of the inlet pressure. The pump of the pressure-control circuit is a small centrifugal unit of about 100 gpm capacity and good suction characteristics. It is located on the ground floor about 12 ft below the test pump. This arrangement permits very low inlet pressures for the test pump. Any air which might come out of solution in the test circuit is carried away by the flow through the pressure-control circuit without noticeably disturbing the operation of the pressure-control pump.

The pressure-control circuit just described is not used for

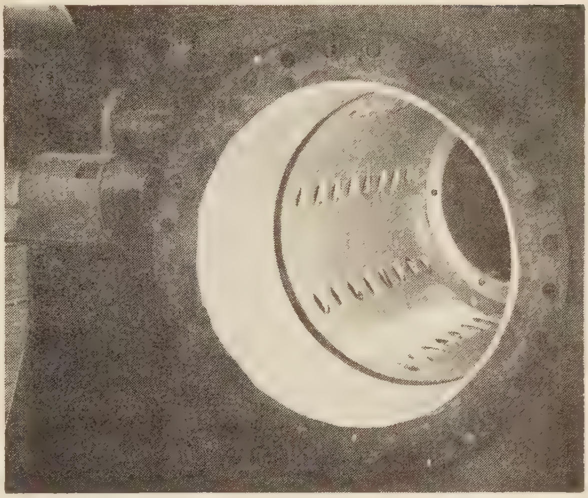

Fig. 3 Outer Throttle-Valve Cylinder in Stilling Tank

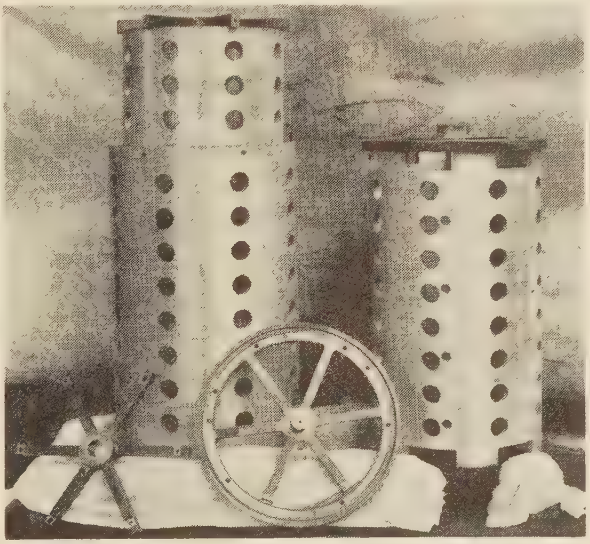

Fig. 4 Removable Parts of Main Throttle Valve

[4] "Beitrag zum Turbulenz Symposium," by L. Prandtl, Proceedings, Fifth International Congress for Applied Mechanics, Cambridge, Mass., 1938, p. 344.

maintaining a high and constant inlet pressure. For this purpose, a very small stream of plant-service water is admitted continuously to the test circuit and is discharged from the highest point of the dome above the stilling tank to a simple overflow about 36 ft above the test pump.

Finally, for extremely low inlet pressures, for tests with a free water surface in the inlet tank, or for deaerating the water in the test circuit, the highest point of the dome can be connected to an ordinary steam ejector. In this way it is possible to bring the pressure in the inlet tank close to the vapor pressure of the water. The inlet pressure of the test pump, therefore, can be varied between this lower limit and a pressure about 36 ft above atmospheric pressure.

No special means were provided for cooling the test circuit. The temperature rise of the water which is due to the absorption of the energy input to the test pump was found not to exceed 10 deg F during normal testing. This change in temperature cannot be expected to have any noticeable influence on the test results, provided proper corrections are made for the corresponding changes in density and vapor pressure. This means that the effect of such variations in temperature on the Reynolds number of the pump flow is being neglected.

The Dynamometer

The test pump is driven by a vertical dynamometer motor capable of developing 150 hp for 2 hr. The motor speed at full voltage (230 v direct current) can be varied between 850 rpm and 2000 rpm. The motor was built by the Crocker Wheeler Electric Manufacturing Company, while the surrounding dynamometer frame and the complete torque-measuring equipment were designed and built by the Worthington Pump and Machinery Corporation.

The dynamometer is supported by a separate platform above the test pump, as shown in Fig. 2. The platform rests on four vertical columns and is braced laterally against the existing building structure. The dynamometer rests on a bridge which spans the frame of the platform. By moving this bridge along the platform and by moving the dynamometer along the bridge, it becomes possible to bring the dynamometer over any desired point of the inlet tank.

The dynamometer is shown in Figs. 5 and 6. The motor is suspended inside the dynamometer frame by means of a suspension rod which carries the total weight of the motor as well as any thrust which is being transmitted from the test pump to the motor thrust bearing. The suspension rod is fluted to reduce its torsional rigidity.

The motor is guided in the dynamometer frame by two bearings shown in Fig. 6. These bearings do not carry any vertical load and only a small horizontal load, resulting from the fact that the measuring torque cannot be applied always as a perfect couple. This horizontal bearing load seldom exceeds 50 lb. With this arrangement it becomes unnecessary to use the customary method of eliminating the friction torque by rotating the outer bearing races continuously in opposite directions. The friction torque was found not to exceed $^1/_{30}$ ft-lb, including the friction of the weight pulleys and all other parts of the torque-measuring apparatus.

The sensitivity of the dynamometer bearings is maintained by means of a special frictionless seal against any dirt carried by the atmosphere. The bearings can be flooded with oil without removing or opening the bearing housing. After draining the bearing, there remains a ring of oil standing in the upper and lower labyrinth of each bearing, forming a hermetic seal against the atmosphere. The pressure inside of the bearing housing is kept in equilibrium with the atmosphere by means of a dustproof breather.

The bearing housings also may be rotated by hand, in order to bring new parts of the bearing races into contact with the balls.

Torque-Measuring Mechanism

Usually the greater part of the dynamometer torque is measured by means of a number of 50-lb weights suspended on steel tapes which are wrapped around the dynamometer motor and pass over four pulleys from a horizontal to a vertical direction. This part of the torque balance is similar to that used at the laboratory of the Baldwin Southwark Corporation. The difference between the moment of the 50-lb weights and the actual dynamometer torque is measured by an oil piston in a rotating cylinder. The use of a hydraulic balance for torque measurements is, of course, not new. The present arrangement differs from earlier applications,[2] and an arrangement proposed by Dr. W. M. White, principally by the fact that it depends clearly on a calibration. This calibration is obtained by placing known weights on the weight pans opposing the oil-hydraulic piston. By recording the corresponding readings of a mercury manometer which measures the oil pressure behind the piston, a calibration may be obtained, not only of the torque-measuring device, but also of all other influencing factors such as pull in the electric cables, any residual torque of the suspension rod, and the like. This calibration has the added advantage of permitting far greater movements of the dynamometer motor than would otherwise be acceptable, avoiding the delicacy of more closely controlled systems or the use of a restoring mechanism.

In the present case, the allowable movements of the dynamometer are restricted only by the limits of elastic response of the

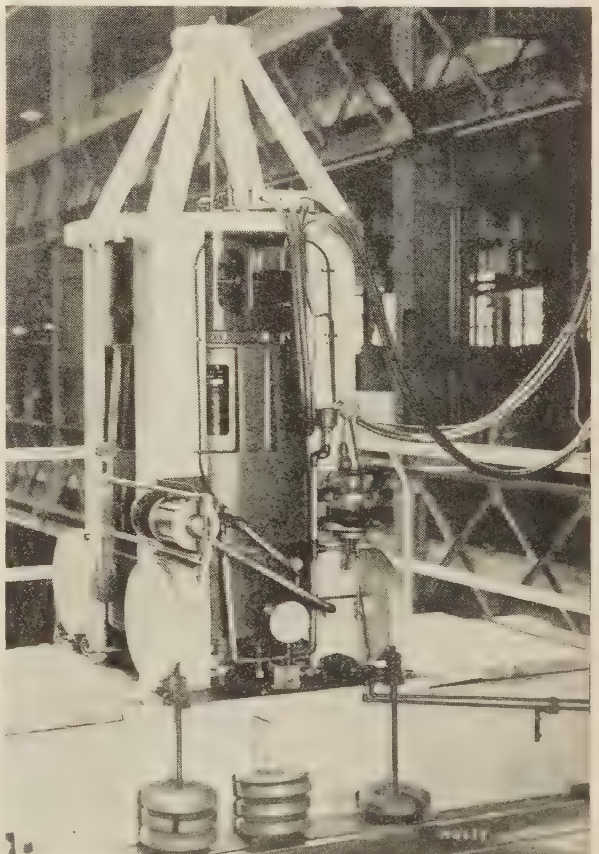

Fig. 5 Dynamometer

electric cables and other influencing factors, and by the mass effect of the motor. Adherence to the former limits can be checked by the calibration while the mass effect was not found to be disturbing in any way, since the peripheral movements of the dynamometer motor seldom exceed $^1/_{32}$ in. during actual operation.

It should be noted that the dial gage, visible in Fig. 5, is not used for measurements but only for crude observations on the dynamometer platform. The measuring manometer is located on the ground floor in a common manometer rack, together with all other manometers of the test stand. The free leg of the torque-measuring manometer is connected to an oil-filled pipe line reaching back to the elevation of the measuring piston at the dynamometer. The free level on top of this return line is visible in the glass bowl, shown in Fig. 5. In this way, any disturbing influences from the long leads of the torque manometer are eliminated.

Dynamometer Speed-Measuring Device

The speed of the dynamometer is measured by means of a Westinghouse precision tachometer generator which is connected to one end of the horizontal shaft above the upper end of the motor shaft. This tachometer generator produces alternating current which controls a dial indicating instrument having a precision of 0.25 per cent. For closer measurements or for calibration of the indicating instrument, it is possible to compare the generator frequency with the frequency of a precision tuning fork by means of a cathode-ray oscillograph. The latter method of speed control was found to be easier for the observer and by far more accurate so that it is used almost exclusively. In this case the speed of the dynamometer motor is held by means of a vernier field rheostat at a speed at which the tachometer frequency has a simple ratio to the frequency of the tuning fork, giving a steady figure on the target of the oscillograph. Such synchronous speeds are available in steps of 100 to 200 rpm, without any mechanical changes in the speed ratios between the dynamometer and the tachometer generator.

Coupling and Instruments

The dynamometer motor and the test pump are connected by means

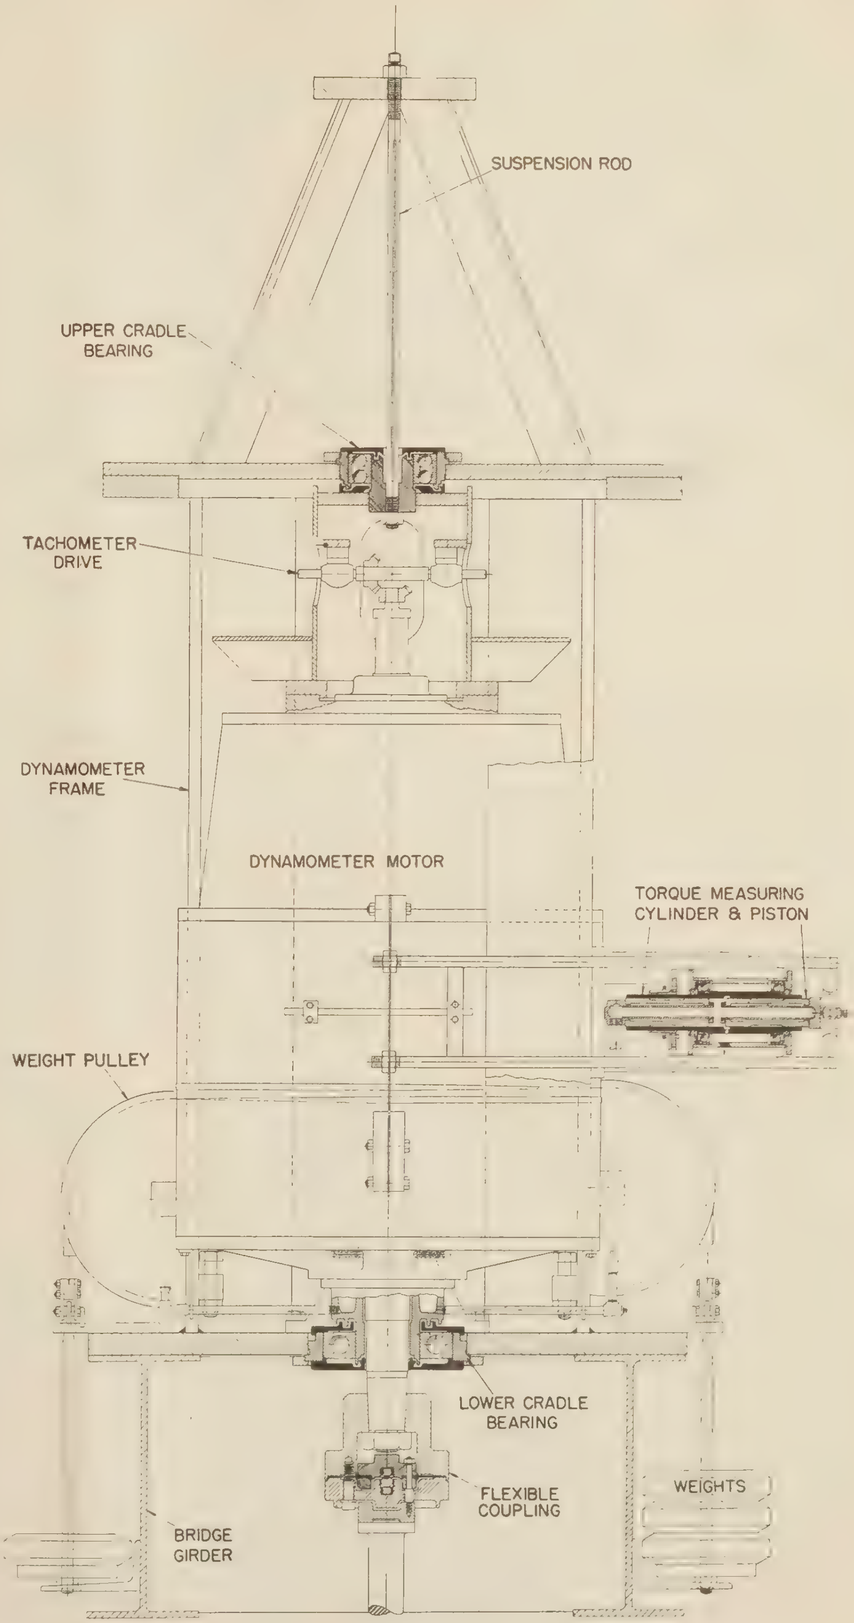

Fig. 6 Sectional Elevation of the Dynamometer

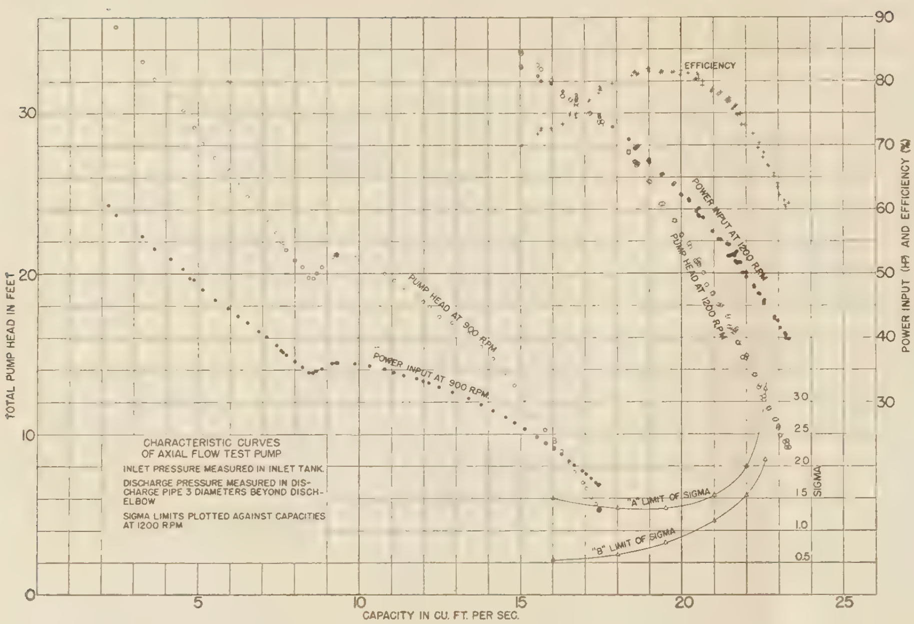

Fig. 7 Typical Propeller-Pump Characteristics

resulting changes in pump head and power input indicate the effect of cavitation on the performance of the pump. The scatter of the cavitation-test points is partly due to the steepness of the head and power versus capacity characteristics of this type of pump. For instance, a change of 0.25 per cent in capacity will cause from 0.5 to more than 1 per cent change in head and power. In spite of this inherent difficulty, it has been possible to derive from these tests surprisingly consistent conclusions regarding the cavitation limits of the test pump. This is demonstrated by the derived cavitation-limit curves in Fig. 7, showing the σ values at the beginning of cavitation A and at the breakdown B, plotted against the capacity. The limits A and B are indicated by the corresponding arrows in Fig. 8.

of a special flexible coupling which is capable of transmitting the pump thrust to the dynamometer. The coupling consists of two parts of identical design connected by a simple spool piece. The length of the spool piece is determined by the distance between the motor and pump shaft of the particular test setup. In each half of the coupling, the torque is transmitted through an elastic diaphragm, while the thrust is carried in compression over a steel ball in the center of the coupling.

As indicated before, all measuring instruments and controls are grouped closely together on the ground floor permitting simultaneous observations and easy adjustments. All pressures or pressure differences are measured by mercury manometers. The throttle valve and the speed controls are within easy reach while observing the corresponding instruments.

Operating Range of the Test Stand

The test stand may be used up to approximately 30 cu ft per second for test pumps of very high specific speeds. For pumps of lower specific speeds, the capacity has to be correspondingly reduced to stay within the speed (850 to 2000 rpm) and power (150 hp) limitations of the dynamometer. For testing low-head pumps, it is significant that the residual resistance of the test circuit with the throttle valve completely open is relatively low, making it possible to subject the test pump at, for instance, 20 cu ft per sec to a head difference as low as 7 ft without requiring the use of a booster pump. Furthermore, by reversing the Venturi meter and adding a suitable booster pump in a large by-pass around the throttle valve, the test pump may also be subject to reversed-flow conditions (turbine operation).

Typical Test Results

The test stand has been in almost uninterrupted operation since the beginning of 1941. As mentioned previously, most of this test work has been devoted to pumps of the propeller type. A typical set of characteristic curves selected at random from these tests is shown in Fig. 7, while some typical cavitation-test results are given in Fig. 8. The latter results are obtained by the well-known procedure of reducing the inlet head step by step, while the capacity is being kept as constant as possible. The

Acknowledgments

The importance of improved facilities for experimental test work is generally recognized. Messrs. M. Spillmann, B. R. McBath, and F. Fritscher were among those advocating the construction of the new test stand on this basis. Prof. L. F. Moody contributed to practically every phase of its development and operation. Mr. O. H. Dorer influenced the design by pointing to the possibility of a misleading effect of a throttle valve in a closed test circuit. Mr. F. C. Gilman assisted effectively in the development of the test stand. The test work has been in the hands of Messrs. T. A. Herman and C. Collar. Thanks are due to the Baldwin Southwark Corporation and to their Mr. K. W. Beattie for the opportunity to study their turbine laboratory.

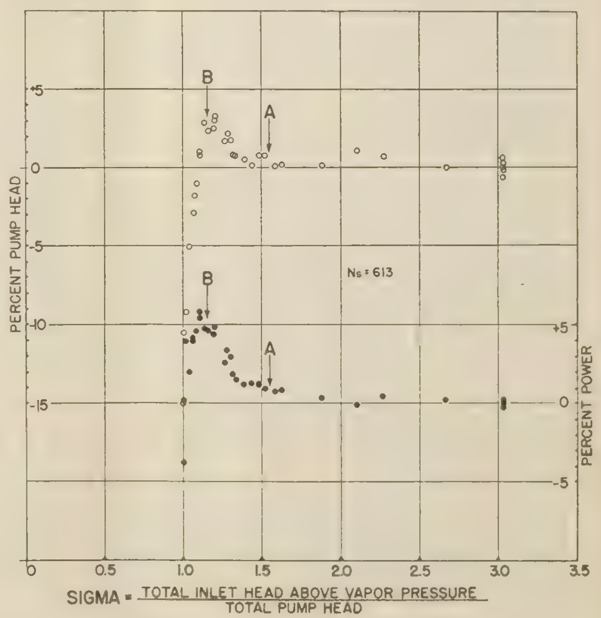

Fig. 8 Typical Cavitation Test Result

The Mercury-Vapor Process

By A. R. Smith[1] and E. S. Thompson,[2] Schenectady, N. Y.

This paper is a brief history of the development of the mercury-vapor process from the first tube tested in 1912 to the latest 20,000-kw unit at the Kearny Station of the Public Service Electric & Gas Company. A typical cycle and a temperature-entropy diagram show how a better efficiency is obtained by raising the boiling temperature of the working substance. Operating results are given for the installations at the Dutch Point Station and at the South Meadow Station of The Hartford Electric Light Company, the outdoor power plant at the Schenectady Works of the General Electric Company, two small units at the Lynn and Pittsfield plants of the General Electric Company, respectively, the original unit at the Kearny Station of the Public Service Electric & Gas Company and the new boiler at Kearny which replaced the original boiler. This latter unit as shown by test is very efficient and reliable. The main reasons for this better reliability are better design, better shaft packings, better welding which results in extremely low air leakage, the use of alloy-steel tubes and the use of chemical treatment of the mercury which wets the interior surfaces of the tubes and insures a maximum heat transfer to the mercury at all times.

The mercury-vapor process is a binary system for producing power from fuel with greater thermal economy than is possible with the steam cycle alone. The mercury cycle can also be considered as a steam producer in which, for a given amount of fuel, nearly as much steam is produced as in a steam cycle and, in addition, the by-product power from the mercury turbine generator is obtained at nearly the mechanical equivalent of the thermal energy. A typical cycle is illustrated in Fig. 1 in the temperature-entropy diagram.

In this process mercury is vaporized in a boiler at compara-

tively low pressure and passes through a mercury turbine which drives a generator. The vapor from the turbine is exhausted to a condenser boiler where its latent heat is transferred to water, which vaporizes at any desired pressure. The steam formed in the condenser boiler is superheated in coils located in the gas passages of the mercury boiler and is then used in steam turbines or for process work. The process is illustrated diagrammatically in Fig. 2. It should be noted that the mercury condenser boiler is in effect an evaporator which permits the use of poorer water than can be tolerated in a superposed steam turbine.

In general, the efficiency of a power cycle is determined by the temperature range through which it operates; the greater the temperature range, the higher the efficiency. The lower temperature limit is rather definitely set by the cooling medium available and, as this is usually river, lake, or sea water, the lower temperature of the condensed steam is in the range of 50 to 100 F. To improve the efficiency it is necessary to increase the initial temperature to the limit allowable by the materials available. It makes considerable difference, however, whether the high temperature is obtained by increasing the pressure or by superheating the vapor. The energy required to superheat vapor to a certain temperature is only a fraction of that necessary to obtain the same temperature by increasing the pressure and maintaining the vapor in a dry and saturated state.

Steam is the best medium available for use as the lower-temperature fluid in a binary cycle. Certain other fluids such as ammonia, methyl chloride, ethyl chloride, sodium dioxide, and ethyl bromide have been investigated but no commercial success has yet been obtained.[3]

[3] "La Turbina A Vapore Ed I Cicli Binari Con Fluidi Diversi Dall'Acqua Fra Le Isoterme Inferiori," by Luigi D'Amelio, *L'Elettrotecnica*, May 10, 1936, vol. 23, p. 250.

All known fluids for use as the top fluid in the binary cycle have been investigated and, with the exception of mercury, have been found lacking in some of the fundamental requirements.

Mercury has many advantages as a thermodynamic fluid for use in power production. Its vapor pressure is low at high temperatures, being 140 psi gage at 975 F and 300 psi gage at 1100 F. Mercury is an element and is stable at temperatures well above the limit imposed by materials now available for boiler tubes, pipes, and turbine nozzles. Its critical temperature is about 2240 F.[4] There is no danger of solidifying in the tubes, as with many other top fluids, for the freezing point of mercury is —37.97 F.

Very little power is required to maintain vacuum in the condenser boiler because air leakage is very low and the absolute pressure is relatively high. With a 25 F terminal difference a mercury pressure of 6.07 psi abs will produce 1200 psi abs steam, and a mercury condenser pressure of 1.20 psi abs will produce 400 psi abs steam.

The specific heat of the liquid is only one thirtieth of that of water at 80 F and one sixty-sixth of that of water at 650 F. This means a steep liquid line on the temperature-entropy diagram so that nearly ideal conditions are inherent in the cycle and no regenerative feed heating is required. Its relatively high density at condensing pressures simplifies the turbine-design problem of providing sufficient length for the last-stage nozzles and buckets. Spouting velocities and available energies for given pressure ratios are much lower than for steam, so mercury turbine speeds are low.

Known world deposits of mercury are large. The yearly production has varied from 2150 metric tons to 5650 metric tons,[5] and there is no reason to suppose this annual production cannot be increased. An increase of 3000 tons per year, which is no more than the ordinary variation, would make available for mercury plants about 1,000,000 kw in combined mercury-steam plants which could be installed each year, and this mercury is not used up as in many industrial processes but would be used year after year. At the time this article is written the market for mercury, as with other metals or commodities which have strategical value, is affected by war conditions. However, studies indicate that in normal times all the mercury necessary will be available for power production without dislocating the market.

History of the Development—Schenectady Tests

The mercury-vapor process was introduced by Dr. W. LeR. Emmet in a paper before the American Institute of Electrical Engineers, Dec. 16, 1913.[6] The first mercury boiler, as shown in Fig. 3, was a single tube containing a solid core with a small clearance between the core and the tube. A central hole in the core provided the down circulation of the liquid. The multiplying lever on the top of the "drum" was connected through a packing to a rod extending through the central core to the bottom of the tube. The average difference in temperature between the outer heated walls and the liquid in contact with the rod was accurately measured with this device. The complete test apparatus is shown on the right in Fig. 3. The funnel on the left was for filling the boiler and the column at the right was the condenser.

Some of the fundamental requirements for mercury boilers were discovered with this apparatus. Further tests with boiling mercury between concentric glass tubes confirmed the fact that very free circulation of the liquid must be provided if large amounts of heat were to be absorbed with small differences in temperature between the liquid and the heated surface. Since the mercury did not wet the heating surface, there was a tend-

[6] "Power From Mercury Vapor," by W. LeR. Emmet, Transactions of the A.I.E.E., vol. 32, Dec. 16, 1913, pp. 2133–2149.

(View showing element at left, and element encased in brick setting at right.)

ency for the vapor to form a film at the tube surface, thus preventing good heat transfer to the liquid. To prevent this condition high circulation ratios had to be maintained so that very little vapor would be formed until the heated liquid reached the upper parts of the tube where the pressure was relieved, thus allowing the stored heat to form vapor. Many years were to pass before a way was found to make mercury wet the tube surface, thereby increasing the heat-transfer rate with lower circulation ratios.

High temperatures made it impossible to maintain tight expanded joints in the tube sheet so it was necessary to resort to a boiler consisting of flattened tubes bent into an arc and welded to two headers which were connected by a return pipe. Several boilers of similar type and various capacities were tested in Schenectady, N. Y., and one unit successfully produced 1000 kw from the mercury turbine generator. The results were encouraging for the economy expected from the process was realized even though many mechanical difficulties had still to be overcome.

period prior to 1922 convinced the executives of the Hartford Company that the binary cycle had sufficient promise to justify the necessary expenditures for proving it on a commercial operating basis.[7]

The first installation at the Dutch Point Station was designed to deliver 1800 kw from the mercury turbine generator and to produce 40,000 lb per hr of steam at 200 psi gage and 100 F superheat. The boiler was a new design employing the fire-tube principle and operated at 35 psi gage mercury pressure. A sectional view of the boiler, Fig. 4, shows the furnace, mercury boiler, liquid heater, steam superheater, and economizer. The boiler looked like a honeycomb with the center cell of each group of seven sealed over to make a return tube for the other six.

Inadequate provision for expansion of adjacent tubes and inaccessibility for cleaning made it necessary to replace this boiler in 1925 with one made up of suspended "porcupine" tubes similar to the tube used in the early experiments. There were four headers each having 160 porcupine tubes. Short coils were also provided above the headers to function as mercury superheater elements. This boiler, partially assembled, is shown in Fig. 5. The operating pressure of the new boiler was increased to 70 psi gage.

The 1800-kw 1800-rpm turbine and generator and the con-

[7] "Experiences With the Mercury Boiler and Turbine," by Samuel Ferguson, *Journal of The Franklin Institute*, vol. 220, no. 6, December, 1935, pp. 687–717.

denser boiler were installed on a deck above the boiler. This arrangement allowed the condensed liquid to flow back by gravity through the sump and liquid heater to the boiler drum. The turbine was originally a single-stage unit but, at the time the boiler was replaced, the turbine was rebuilt as a three-stage machine with the rotor overhung from the generator. The condenser boiler tubes were dead-ended with a center strip inside to aid circulation from the large steam drum at the top.

The first unit produced a total of 2,423,500 kwhr and 54,427,000 lb of steam while the second unit produced 2,056,500 kwhr and

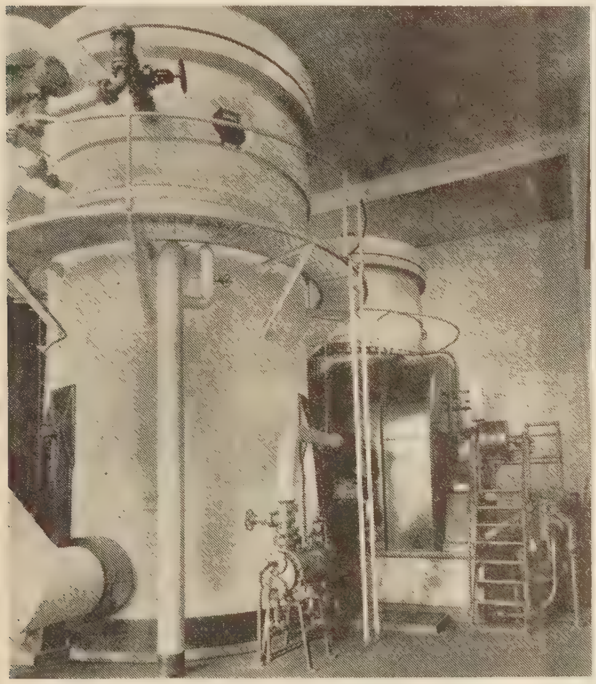

FIG. 7 10,000-KW MERCURY TURBINE GENERATOR UNIT
(View of generator end, showing generator and condenser boilers. South Meadow Station, The Hartford Electric Light Company, Hartford, Conn.)

33,817,000 lb of steam. The improvement in efficiency of the second unit can be noted from the greatly increased electrical output per pound of steam produced.

During 1927 plans were being perfected for the next step which was to install a unit of much larger size.

TABLE 1 PERFORMANCE RECORD OF 10,000-KW MERCURY PLANT AT SOUTH MEADOW STATION OF THE HARTFORD ELECTRIC LIGHT COMPANY

Year	Kwhr mercury only at approximately 4000 Btu	Kwhr total mercury and steam (net)	Btu per kwhr	Hours run

Data 1934 to present from station records.

HARTFORD ELECTRIC LIGHT COMPANY—SOUTH MEADOW STATION

The mercury plant now operating at the South Meadow Station was installed in 1928. An isometric section, Fig. 6,[8] of the plant shows the path of the fuel, gas, mercury, and steam throughout the system. The mercury boiler, which operates at 85 psi gage and 908 F, has seven drums 37 in. OD $\times$ 30 in. ID, 21 ft, 6 in. long. Suspended from each drum are 440 porcupine tubes 5 ft, 6 in. long $\times$ $3^1/_8$ in. OD. The circulation path in these tubes is shown in the sectional view in the upper right-hand corner of Fig. 6.

The 720-rpm turbine has five impulse stages on the rotor which is overhung from the generator. Enclosing the inlet end in this manner eliminates the high-pressure packing.

The condenser boilers supply steam to the superheater from which it is delivered at 375 psi gage and 700 F, to the station mains. The turbine floor assembly, Fig. 7, shows the two condenser boilers and the 10,000 kw generator.

The mercury turbine generator output, the total output from mercury and steam, the net plant heat rate, and the hours run are shown in Table 1. Up to, and including 1934, a steam-turbine water rate of 10 lb per kwhr was used. From 1935 to September 25, 1940, the steam was used in a better turbine, so a turbine water rate of 9.5 lb per kwhr was used.

SCHENECTADY WORKS STATION OF GENERAL ELECTRIC COMPANY

Two plants were built in 1932, one for the Schenectady Works of the General Electric Company and the other for the Kearny Station of the Public Service Electric and Gas Company of New Jersey. The capacity of these plants was double that of the Hartford plant and the mercury-boiler pressure and temperature were increased to 140 psi gage and 975 F.

The boiler shown in Figs. 8 and 9 has seven drums and the same type porcupine tubes as the Hartford boiler but much better utilization of the radiant heat was obtained by lining the upper furnace walls with mercury vaporizing surface and the lower part of the furnace walls with steaming tubes. The mercury wall tubes were made by embedding three tubes in copper in a frame to obtain more uniform heat transfer around the periphery of each tube. The feed for these wall-tube sections is obtained from outside downcomers at each end of each drum. The wall tubes and underside of the porcupine tubes are shown in Fig. 10. The waterwalls in the lower part of the furnace function as a standard 400-lb-pressure steam boiler with the steam drums located on each side of the furnace as may be seen in Figs. 8 and 9.

The Schenectady plant differs from all previous plants in that the turbine generator and condenser boilers are not placed above the boiler. Condensed mercury liquid is returned to the boiler by means of a centrifugal pump. This pump requires only 8 hp per 1000 kw of mercury-turbine capacity.

The mercury turbine shown in Fig. 11 is rated 20,000 kw, 5-stage double-flow, 900 rpm. Vapor enters the center annular chamber and flows in both directions to the exhaust openings and to the two condenser boilers. Projection of the shaft through the turbine casing is in the vacuum space so two packings to prevent leakage of air into the condensers are used but no high-pressure packing is required.

The total steam output from the condenser boilers and waterwalls is superheated and then is added to the output of a steam boiler and flows at 450 psi gage and 750 F to a 6000-kw 3600-rpm back pressure steam turbine. The steam from the exhaust of this turbine at 225 psi gage and 647 F flows to the Schenectady Works where it is used in various industrial processes.

The Schenectady plant is an outdoor station. It has passed through several severe winters without any operating difficulties.

TABLE 2 MERCURY PLANT—SCHENECTADY WORKS OF GENERAL ELECTRIC COMPANY

Year	Kwhr mercury turbine generator	Pounds of steam produced	Hours run
1933	2,537,000	53,317,000	425
1934	52,136,000	1,088,411,000	4,921
1935	31,304,000	687,040,000	3,203
1936	28,248,100	693,597,000	3,671
1937	17,066,800	567,209,000	3,375
1938	36,752,100	1,136,689,000	7,225
1939	47,345,200	1,169,399,000	6,384
(1940 to 9–1–40)	36,464,900	870,830,000	4,555
Total	251,854,100	6,266,492,000	33,759

The mercury turbine generator, condenser boilers, steam turbine generator, feedwater heaters, and evaporators are exposed to the elements but very infrequent attention to these units by the operators is required. The control panels, firing aisles, pumps, pulverizers, and other equipment are under cover.

Power or heating plants for industry generally grow over a long period during which time styles and sizes of apparatus change so materially as to make the original building plan quite unsuitable for contemplated new equipment. Furthermore, buildings are especially designed to suit the original equipment and it seems unwise to construct a special building good for a life of seventy-five years to house apparatus which may have to be replaced in twenty-five years.[9]

A section through the plant, Fig. 12, gives a clear picture of the heat-flow path from coal car to stack. An airplane view of the completed plant is shown in Fig. 13.

This plant runs at reduced loads over week ends so that high capacity factors are not obtainable. The output since the start in 1933 is shown in Table 2.

The only changes made in the seven-year period have been the replacement of the liquid heater by a mercury convection surface above the drums and a change to the condenser boiler tubes in which adjacent dead-ended tubes were connected to improve circulation.

station was first operated in March, 1933. The boiler, turbine generator, and condenser boilers were duplicates of those at Schenectady but the mercury-boiler feed is returned by the gravity system as at Hartford. Floor-space limitation was a major factor in this decision.

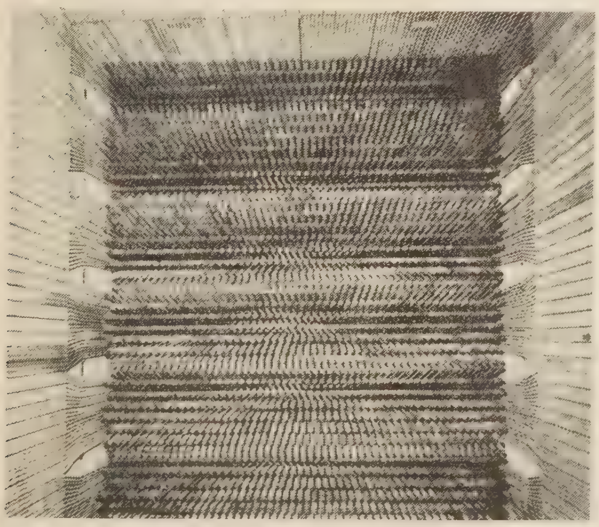

FIG. 10 MERCURY BOILER IN OUTDOOR MERCURY-STEAM-ELECTRIC POWER STATION, SCHENECTADY WORKS, GENERAL ELECTRIC CO.
(Interior view upward showing tubes and walls of No. 1 mercury unit, 20,000 kw.)

The first boiler was operated until September, 1938, when it was removed to make way for a new one of advanced design, which will be described later. The plant production from 1933 to 1938 is shown in Table 3.

FORCED-CIRCULATION BOILER

An interesting development in the process was a 1000-kw forced-circulation boiler which was tested in Schenectady. The firebox was formed of helically wound tubes forming a cylindrical combustion chamber. For a short distance above the bottom of the firebox, the tubes were open-spaced to allow the gas to pass out and up through a concentric mercury-liquid heater and steam superheater. After leaving the steam superheater the gas passed through a two-pass air preheater to the stack.

Mercury liquid was pumped into a distributing chamber at the bottom of the boiler and then through the radiation tubes to a ring header at the top which discharged to the separator. The separator contained nozzles in which the vapor was formed

by flashing due to release of pressure. To prevent any vaporization in the boiler surfaces a circulation ratio of 35 to 1 was maintained. A circulating pump, fed directly from the liquid outlet of the separator, pumped 35 lb of liquid through the boiler for each pound of vapor formed. Liquid return from the condenser boiler was forced by a feed pump through the liquid heater to the separator. The two pumps had mercury centered bearings which functioned quite satisfactorily. Test data and experience obtained from this installation led to the design of the unit for the River Works.

Unit Power Plant at the River Works of the General Electric Company at Lynn, Mass.

The power plant installed in 1937 at the River Works of the General Electric Company in Lynn, Massachusetts, was composed of elements which could be completely assembled in the factory, thus requiring a minimum of expense for field erection.

The forced-circulation mercury boiler, Fig. 14, is similar in design to the 1000-kw boiler but of increased rating. It delivers sufficient mercury vapor at 165 lb gage and 1000 F, dry and saturated to produce 1000 kw from the mercury turbine generator and 12,650 lb per hr of steam at 180 lb gage and 150 F superheat. The radiation tubes, convection tubes, liquid heater, and steam-superheater assembly is lowered into the casing as a unit as shown in Fig. 15. The casing is formed of two thin concentric sheets which form a narrow air space through which air is forced on its way to the air preheater, the top of which can be seen at the upper left in the photograph. This air-cooled jacket takes the place of the usual lagging on the exterior of boiler casings.

The mercury turbine generator and condenser boiler are so arranged that the generator and turbine can be moved back out of the condenser boiler so as to expose the turbine for inspection or repair as shown in Fig. 16. This was the first 3600-rpm mercury turbine. It is overhung from the generator and operates above the critical speed.

The condenser boiler was built with two drums and outside downcomers to assure positive and adequate circulation of the boiling water.

The steam-driven circulating pump recirculates the mercury from the separator through the boiler at a flow of 4,750,000 lb per hr at a head of 45 ft of mercury when operating at 1200 rpm. The steam from the superheater at 380 lb gage and 645 F is reduced to 180 lb gage and 150 F superheat in passing through the high-speed single-stage turbine which drives the pump through a reduction gear. The mercury centered pump bearing is supplied with mercury from the feed-pump discharge.

The unit could be started and stopped very rapidly with no danger of unequal heating of tubes. It operated successfully for 6000 hr during which time it produced 4,480,000 kwhr from the mercury turbine generator and the equivalent of 4,000,000 kwhr from the steam produced in the condenser boiler. It carried full load without difficulty and, when sufficient experience was gained with this type of boiler, the plant was shut down in August, 1939.

An advantage of the forced-circulation type of boiler appears to be the possibility of conforming the firebox and tube circuits to confined spaces such as are encountered on ships and locomotives.

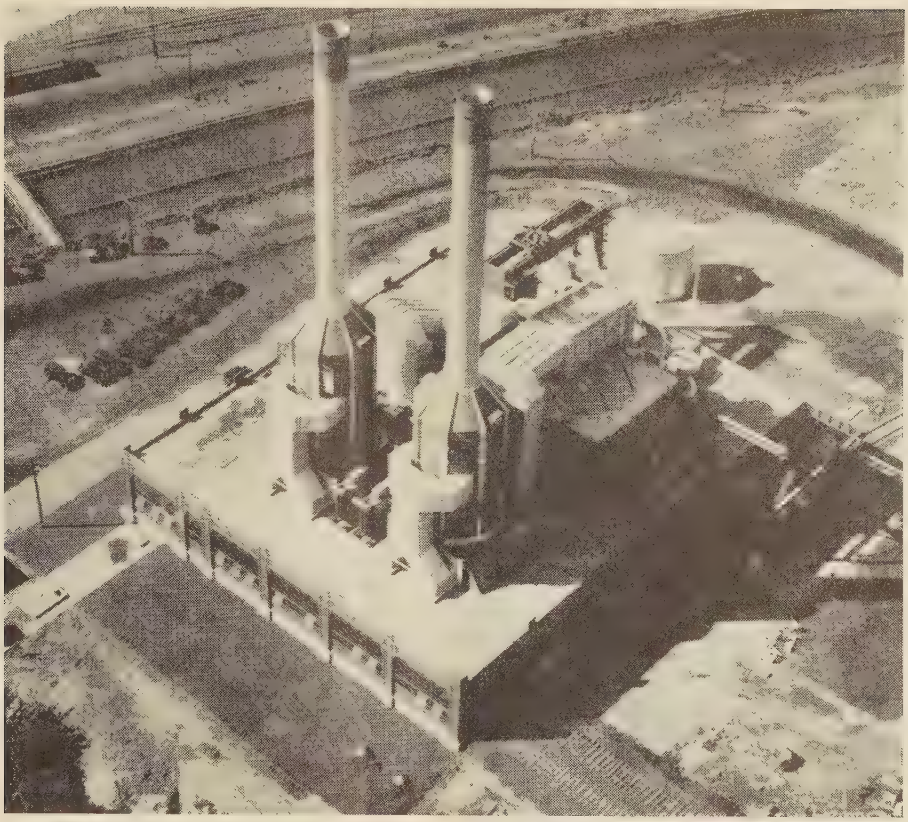

FIG. 13 OUTDOOR MERCURY-STEAM-ELECTRIC POWER STATION, SCHENECTADY WORKS, GENERAL ELECTRIC COMPANY

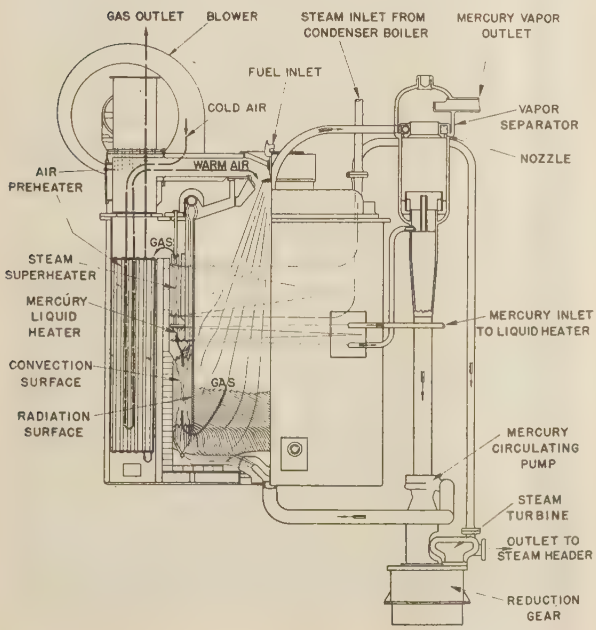

FIG. 14 OIL-FIRED FORCED-CIRCULATION MERCURY BOILER, FOR UNIT POWER PLANT, 1900 KW, RIVER WORKS, GENERAL ELECTRIC COMPANY, WEST LYNN, MASS.

TEST BOILER AT PITTSFIELD WORKS OF THE GENERAL ELECTRIC COMPANY

A small boiler was installed at the Pittsfield, Mass., works of the General Electric Company in 1937 to study the action of a unit composed of relatively high vertical wall tubes with natural, or thermal, circulation. This was also the unit in which most of the advances in treatment of the mercury were made. The tubes were arranged to form a cylindrical firebox and brought together into a short horizontal drum as shown in Fig. 17. The burner for oil firing was at the bottom and the gas was directed out by two baffles at the top to a liquid heater, steam superheater, and air preheater.

The remainder of the equipment, including the generator, mercury turbine, valves, and condenser boiler, was used originally in the Dutch Point installation twenty years before, but it performed admirably during the two-year testing period at Pittsfield.

The unit produced 4,931,000 kwhr from the mercury turbine generator and 82,000,000 lb of steam at 185 psi gage and 650 F during the test operation.

NEW MERCURY BOILER AT KEARNY

The new mercury boiler at the Kearny Station of the Public Service Electric and Gas Company of New Jersey began operation on May 5, 1940. It produces 20,000 kw from the mercury turbine generator and 300,000 lb per hr of steam at 365 psi gage and 750 F.

The new boiler, shown in Figs. 18 and 19, occupies the same space as the old boiler. The furnace is of octagonal shape in plan, for the purpose of conserving mercury and better to equalize the heat absorbed by all the furnace tubes. The burners are located on each of the eight sides. A uniformly distributed flame can be carried by proper selection of burners throughout the load range. The burners are so constructed that either coal or oil may be used.

The furnace walls are completely covered with mercury tubes, which are practically contiguous, having a minimum inside diameter of $^{13}/_{16}$ in. at the bottom and 1 in. at the top of the vertical run. At the beginning of the arch at the top of the vertical run the tubes are supported by hangers, Fig. 20, so they hang vertically and, in turn, partially support the bottom which is formed as a unit with a structural-steel frame. Large coil springs on the underside aid in supporting the bottom. In order that no single tube may be overstressed by this hanging load, they are attached through small springs to the structural bottom which allows for a reasonably individual motion consistent with possible temperature differences between tubes. The expansion of the tubes downward at full load is $2^{13}/_{16}$ in.

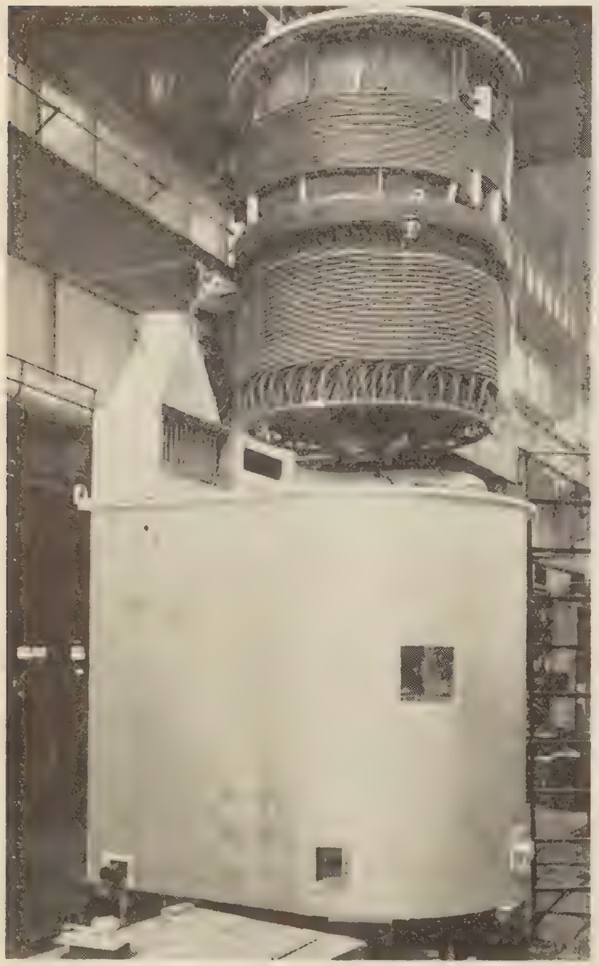

Fig. 15 Mercury Boiler, 1900 Kw, for General Electric Mercury-Vapor-Steam Unit Power Plant

View of firebox, convection tubes, liquid heater, and steam superheater before lowering into casing; outlet of air preheater at upper left.)

Insufficient experience was available at the time the original Kearny boiler was built in regard to the pumping, or circulating ability, of high vertical furnace wall tubes. The Hartford boiler was the first large boiler and it had no mercury wall tubes. The next large boilers at Kearny and Schenectady had mercury wall tubes over the upper half of the firebox and waterwalls forming the lower half. The new Kearny boiler completes the evolution and the tubular lined firebox is now quite similar to those of modern waterwalled steam boilers as may be seen from the interior view of one wall, Fig. 21.

The experience to justify the new design was obtained from

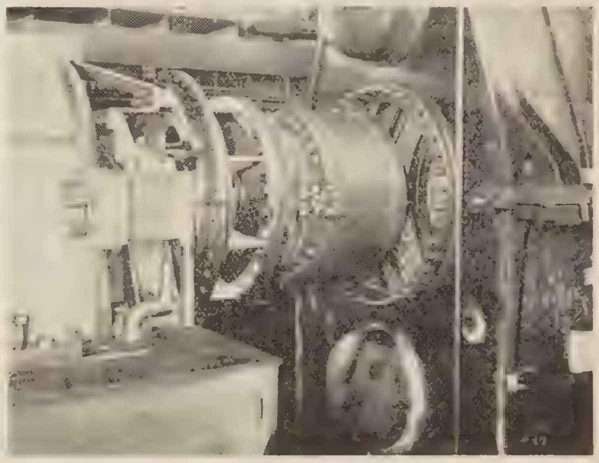

Fig. 16 Mercury Turbine Being Pushed Into Condenser Boiler of Mercury-Vapor-Steam-Electric Power Plant, 1900 Kw, River Works, General Electric Company at West Lynn, Mass.

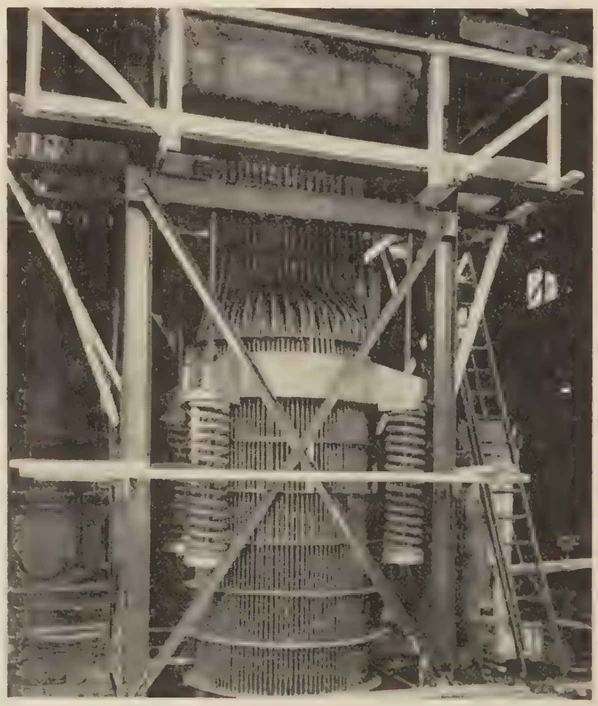

Fig. 17 Tube Assembly for Mercury Boiler, Pittsfield Works, General Electric Company

the Pittsfield boiler tests, and from tests in Schenectady of typical full-size tube circuits. Every new design detail of this boiler was adopted only after exhaustive tests on full-scale models with water-air mixtures, mercury-air mixtures, and under actual fired conditions, with mercury vapor being formed. This care has resulted in the excellent performance of the equipment from the first day of operation to the present.

The porcupine tubes used for many years in mercury boilers were ingenious in design and functioned quite well, but the small passages were a potential source of plugging by foreign material and they were hard to clean and expensive to manufacture, so they were not used in the new boiler. By substituting wall tubes for the former porcupine-tube surface it became possible to remove the complication of seven drums which involved equalizing difficulties and other disadvantageous features. The new boiler has a single drum of 54 in. ID with $4^1/_2$-in-thick walls, 30 ft long, weighing 90,000 lb. A section through the drum, Fig. 22, shows the arrangement of baffles which are functioning so well that there is no measurable moisture carry-over. In fact, the pressure drop from the drum to the turbine produces about 30 F superheat in the vapor. The air-water test on a full-

size model of the drum baffles showed a maximum moisture carry-over on a mercury basis of seven parts per million, or only 0.007 per cent by weight, and the solids about one two-hundredth of this value.

To form the slag screen, shown in Fig. 23 (which is a view upward from below), 288 of the furnace wall tubes are continued across the reduced section or neck of the furnace, being attached at one end to a movable panel, Fig. 24, and at the other end to the drum. The $1^{11}/_{16}$-in. OD $\times$ $1^{1}/_{8}$-in. ID tubes are arranged in 36 sections, 8 tubes high on $8^{3}/_{4}$-in. horizontal centers. The catenary shape helps to keep the stresses low and the movable panel, which is moved by the expansion of four tubular columns which are heated by circulating boiler mercury, maintains a low stress for all temperature conditions, including those encountered during starting and shutting down the boiler.

The convection surface consists of the six bundles of tubes above the drum. They are separated for soot blowers and for accessibility. The tubes are individually supported by vertical tube supports cooled by water circulating thermally from the condenser boiler drums on the floor above.

The mercury convection tubes are $2^{3}/_{8}$ in. OD $\times$ $1^{7}/_{8}$ in. ID in the lower bank and $2^{3}/_{4}$ in. OD $\times$ $2^{1}/_{4}$ in. ID in the two upper banks. They are fed from 180 of the furnace wall tubes at the top of the upper bundles and at the top of the lower bundles. The middle bundles are in series with the upper bundles. During

operation the thermal circulating action lifts the mixture of liquid and vapor to the top of the tube banks and from this point it flows back to the drum by means of a combination of pressure drop and gravity head. When the boiler is cold all the mercury, normally in the convection tube bank when operating, drains back into the drum because of the constant hydraulic grade from the top to the bottom.

The steam superheater, located above the fog bank, is of standard design and is the one originally installed in 1933.

The air preheater is the single-pass tubular type which was installed in 1933.

The Kearny boiler contains 392,000 lb of mercury. The heat developed suffices for the generation of 20,000 kw in the mercury turbine and 30,000 kw from the steam generated in the condenser boiler. Since auxiliary equipment requires 1200 kw, the total mercury in the boiler amounts to 8.0 lb per net kw.

The convection surface is empty when cold but, in service, is filled with a mixture of liquid and vapor, mostly vapor. It is believed that an extension of this principle of mixture-filled tubes to the hotter parts of the furnace would materially reduce the amount of mercury needed in future designs so that its cost and obtainability would be less important factors.

The design of this boiler in so far as the functioning of the mercury is concerned was by General Electric Company. The mechanical design, combustion facilities, and building and erection were done by The Babcock & Wilcox Company.

Between May 6, 1941, and Feb. 1, 1941, the new plant has produced 103,540,000 kwhr from the mercury turbine generator and 1,505,232,000 lb of steam. There are approximately five thousand field and factory welds in the boiler and no leaks were found in the hydrostatic test or during operation.

Operation has been excellent and practically all the time at full load. (See load chart, Fig. 25.) Firing has been with oil for the most part. Because of the unusual boiler design and the temperatures at which the tubes work, it was thought advisable to try out coal firing to find the nature and location of slag deposits before installing soot blowers.

phragms after five years' service can be seen in Figs. 26 and 27. One of the shaft packings, which prevent leakage of air into the turbine, is shown in section in Fig. 28. It is a liquid-seal packing in which the seal is maintained by mercury liquid being whirled by the rotating cup which is part of the shaft sleeve. Mercury overflowing from the cup, as well as mercury from the inner casing, drains by gravity to a cooler, in which the cooling is done by a water-filled coil, and is then drawn back into the rotating cup by the vacuum on the condenser side of the seal. A drain to the condenser ahead of the outside carbon packing ring prevents any escape of mercury. Neutral gas is supplied to the middle carbon ring box and the excess, together with any air which leaks past the outside carbon ring, is sucked off to the stack from the outside packing box. The small amount of make-up liquid required is obtained from that which is condensed in the air-removal coolers on the condenser boilers.

It is desirable to remove the air from the entire system and to have a vacuum of about 0.4 in. Hg abs before firing the boiler. The turbine shaft when idle, or operating below normal speed, is sealed by pumping a sufficient quantity of mercury liquid through the packing so that the shaft is submerged. The pump has a capacity of 1,800,000 lb per hr at 60 ft head, which is far in excess of normal requirements unless the labyrinth teeth on the packing are seriously damaged. This pump is mounted in a small tank containing a cooler so that the liquid for starting is in a closed circuit. The mercury from the tank can be returned to the boiler after normal speed on the turbine is reached.

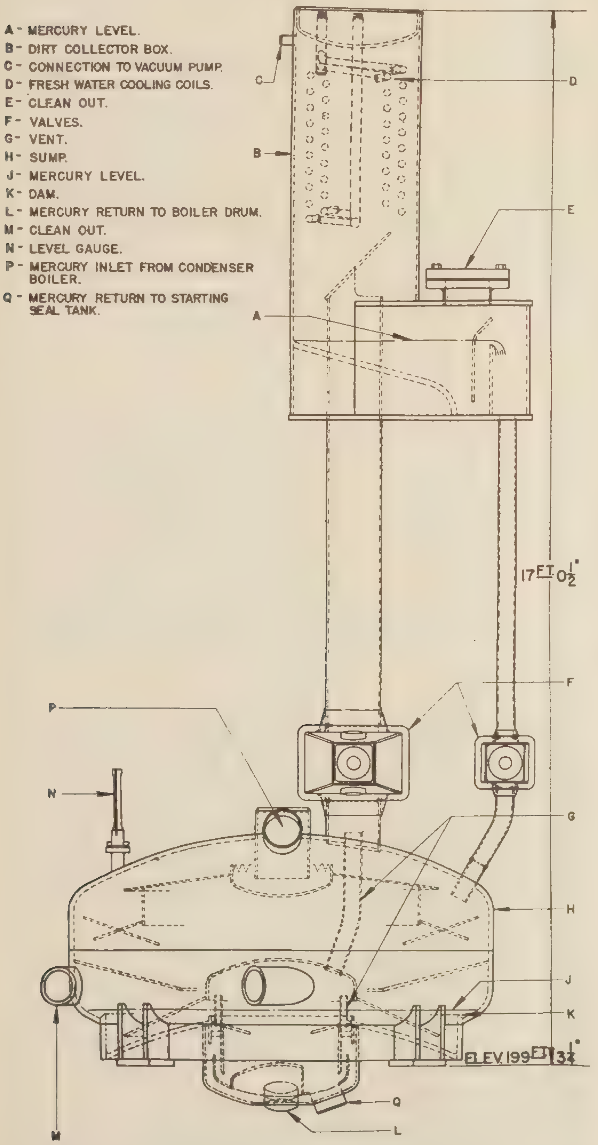

Fig. 29 Mercury Impact Cleaner. For the Public Service Electric and Gas Co., Kearny, N. J.

Mercury Impact Cleaner

The mercury impact cleaner for removing dirt and solids from the mercury consists of a sump and dirt-collector tank with interconnecting pipes and valves as shown in Fig. 29. Condensed mercury from the two condenser boilers flows by gravity to the sump where it is cleaned and flows back to the boiler drum by gravity.

A vacuum of about $^1/_2$ in. of mercury higher than that in the condenser boiler is maintained in the dirt-collector box by means of the vacuum pump. Mercury liquid cascading down over the shelves in the sump tends to break up into fine particles and the dirt-bearing liquid is flashed, or reboiled, because of the reduced pressure, and carried up to the dirt-collector box. Here the vapor is condensed by the water-cooling coils and then returns over the baffles and through the small pipe to the sump. The fine dirt remains on the surface of the pool in the dirt-collector box and at infrequent intervals during operation the two connecting valves can be closed and the flange cover removed for cleaning.

Any heavy foreign material, such as welding beads, will be washed and held behind the dam around the inside of the sump. At a regular plant-inspection period this dirt can be removed through the openings provided. The sealing arrangement at the bottom maintains the vacuum in the sump and prevents vortexing of the outflowing liquid.

Air Removal and Vacuum System

An air-removal cooler is provided for each condenser boiler. The cooling coil passes all the feedwater entering the condenser boiler steam drum. Air and other noncondensable gases are drawn from the condenser shell into the air-removal cooler and then through a secondary cooler to the vacuum pump. Mercury condensed in the air-removal coolers is used as make-up for the shaft seal packings and any excess is drained directly back to the condenser. Mercury condensed in the secondary cooler is drained to the sump.

Steam-jet air ejectors are used for rapidly reducing the pressure in the system before starting. During operation a Kinney vacuum pump is used. The air leakage has been maintained below 0.4 cu ft per hr.

Boiler Filling and Draining System

A tank in the basement will store the 392,000 pounds of mercury in the system if it becomes necessary to drain the boiler. In the event of a leak two emergency drain valves can be opened which allow the mercury to rapidly drain through a cooler to the tank. A small pump in this tank will return the mercury to the boiler drum.

Mercury Tube Temperature Recorder

In order to have complete knowledge of the action of this boiler during the initial operation, a thermocouple was attached to the back of each of the 764 tubes surrounding the firebox. A temperature recorder is attached to the couples from 78 typical tubes and a record is automatically made of each of these tem-

peratures, as well as the mercury saturation temperature, every thirty minutes. The recorder is mounted on the boiler instrument panel and has been accepted by the operators as a real aid in operation. A sample section from the recorder chart is seen in Fig. 30. The other thermocouples are attached to portable recorders and temperatures were measured during the starting period.

Mercury Detector

The first reliable mercury detector depended upon the action of mercury vapor on selenium-sulphide coated paper. Samples from the flues were continuously blown on a slowly rotating chart and the chart was scanned by a photoelectric cell which would actuate an alarm if the paper darkened due to the presence of mercury vapor in the gas. Selenium sulphide is extremely reactive toward mercury vapor, black compounds of mercury sulphide and mercury selenide being formed. This instrument can detect one part per million of mercury vapor in the flue gas.

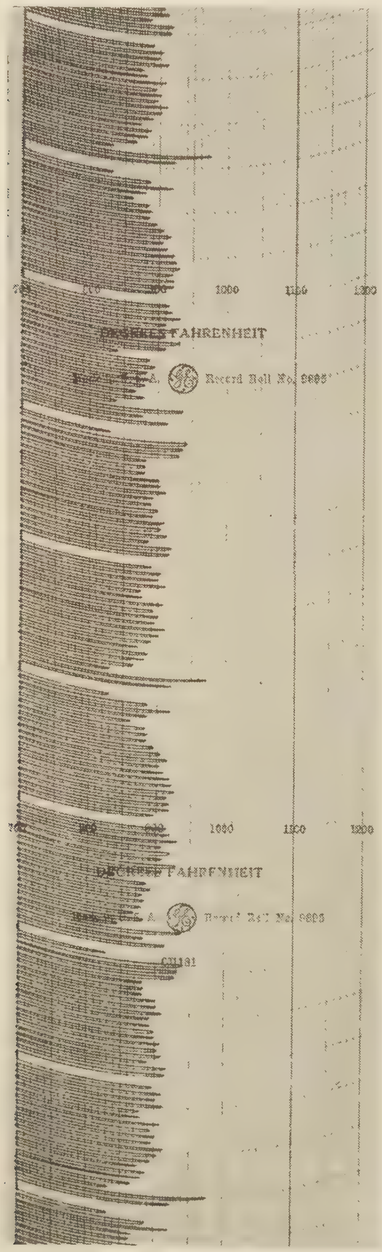

Fig. 30 Repeating Temperature Record of 80 Thermocouples on General Electric Mercury Boiler. The Public Service Electric and Gas Co., Kearny, N. J.

The latest mercury detector is of the optical type and its operation depends upon the opacity of mercury vapor to ultraviolet light of a certain wave length. A flue-gas sample is continuously passed through a chamber at one end of which is an ultraviolet lamp and at the other end a photoelectric tube. Through proper amplification the photoelectric tube records the vapor concentration on a meter located on the boiler instrument panel. This detector will accurately detect a concentration of one part per hundred million. The normal test consists of throwing one cubic centimeter of mercury into the fire which gives full scale reading on the concentration meter.

Tube Material

Up to the time of the Lynn boiler which had chrome-molybdenum-steel tubes, all previous mercury boilers were made of

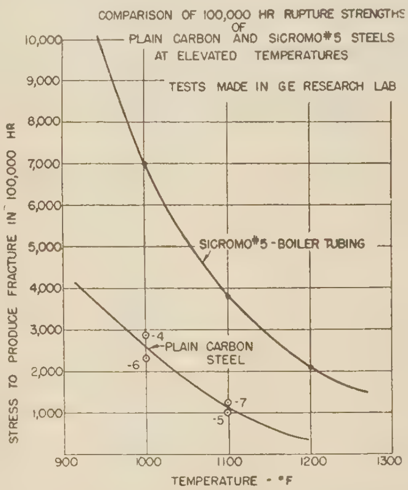

Fig. 31 Comparison of 100,000-Hr Rupture Strengths of Plain Carbon and Sicromo 5 Steels at Elevated Temperatures

(The steel originally known as Sicromo 5 is now known as Sicromo 5S.)

ordinary low-carbon steel, and in most cases were calorized by the dip method and heat-treated. This was done before there was any knowledge of the rupture strength of such material at high temperature for extended periods of time. In 1937 test machines were started to study the long-time rupture strength under temperature of carbon steel and many kinds of alloy steels. The General Electric Company now has seven such furnaces in operation at different temperatures, each holding twelve samples.

The results of these rupture tests, together with other considerations mentioned later, led to the selection of an alloy called Sicromo 5S (formerly known as Sicromo 5) for the Kearny boiler tubes. This alloy contains 0.12 per cent carbon, 0.50 per cent molybdenum, 5.0 per cent chromium, and 1.5 per cent silicon. Fig. 31 shows that 3000 psi is the 100,000-hour rupture strength of carbon steel at 975 F, whereas the Sicromo 5S is equally good at 1140 F.

The particular composition selected for these tubes contains sufficient chromium and silicon to resist oxidation at the operating temperature and with the usual character of coal or oil ash. In the cooler passes of the boiler Croloy 3, used for the lower bundles

of the fog bank, and Croloy 2, used for the upper bundles of the fog bank, will give equal protection.

Solubility of Iron in Mercury

The solubility of iron in mercury at high temperature has been a fundamental obstacle in the development of the mercury cycle. This action reduced the thickness of the metal, and the disintegrated iron and iron oxide were deposited in some places on the heating surfaces in the lower-temperature regions, frequently restricting or stopping the flow of mercury or vapor.

How far this solubility is retarded by the use of Sicromo 5S steel can be seen from Table 4, which shows the rate of solubility per year expressed in mils. The carbon steel is the material used in Hartford, Schenectady, Pittsfield, and the old Kearny boilers. The 5 per cent chrome steel was used in Lynn. The new Kearny boiler and slag-screen tubes are made of Sicromo 5S.

TABLE 4 SOLUBILITY OF STEEL IN MERCURY IN MILS PER YEAR

Temperature, deg F	Carbon steel	5 per cent chrome	Sicromo No. 5S
900	4	2	0.2
1000	9	4	0.5
1100	22	10	1.1
1200	53	25	2.5

While these tests, which were carried on over a period of five years, showed a possibility of extending the period between cleanings 20 times, or the possibility of using higher temperatures with the same period between cleanings, a parallel investigation was made to find some element which could be added to the mercury to inhibit solubility of the steel. Zirconium and titanium were found to be the most promising, the latter being preferred because of its ease of application. The present indications are that a low percentage of titanium maintained in the mercury completely stops solubility of the steel. The amount of solubility is readily detectable by measuring the deposit on tubes and by analyzing the solids in the sump and pipe lines. The amount of titanium required is a function of the temperature with a spread of 0.0001 per cent for 850 F up to 0.001 per cent, or ten parts per million, for 1000 F saturation mercury temperature.

Wetting and Dewetting

Steel surfaces, even though slightly oxidized, can be wetted by mercury alone with time and patience. But such surfaces will not remain wetted if more oxygen is introduced. In other words, mercury is a poor deoxidizing agent. As the result of a comprehensive search for suitable deoxidizing and wetting agents, the combination of magnesium and titanium has been found to hold the boiler tubes in a properly wetted condition unless the air infiltration is excessive. In combination with the titanium concentration previously mentioned it is necessary to maintain 0.002 per cent metal magnesium in solution in the boiler. It appears that magnesium is essential to maintain the titanium active, and that titanium assists in wetting the steel.

Oxides

The formation of oxides formerly caused considerable trouble in the mercury cycle. These difficulties appeared as dewetting, causing poor heat transfer, and mercury-oxide and iron-oxide deposits in tubes, sumps, and pipes. The possible sources of oxygen are air infiltration through the turbine and condenser casings operating below atmospheric pressure, the turbine shaft packings, air in the boiler when starting up, and water leaks in the condenser boilers or coolers.

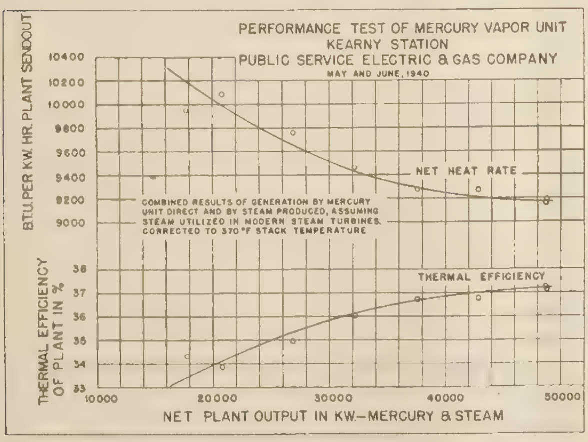

FIG. 32 PERFORMANCE TEST OF GENERAL ELECTRIC MERCURY-VAPOR UNIT, KEARNY STATION, THE PUBLIC SERVICE ELECTRIC AND GAS COMPANY OF NEW JERSEY. MAY AND JUNE, 1940

Excessive oxygen means loss of the titanium and magnesium and the production of solids. To prevent air leakage the new-type mercury shaft packing was developed, and valve stems operating under vacuum were covered with metal caps. These precautions have reduced the air leakage at Kearny from 300 cu ft per hr to less than 0.4 cu ft. An operating rule for all the mercury plants is to investigate any leakage greater than 1 cu ft per hr.

With this slight amount of air which still infiltrates into the system it is relatively easy to absorb all the oxygen with the magnesium, forming magnesium oxide which is easily cleaned out.

When shutting down a plant, nitrogen is bled into the system until the temperature is so low that the rate of oxidation is negligible. When starting up a plant, it is pumped down to a reasonable vacuum before the fires are lighted.

KEARNY TEST RESULTS

During the months of May and June, 1940, tests of the mercury plant at Kearny were conducted by the General Electric

Company with the assistance of The Babcock & Wilcox Company and the Public Service Electric and Gas Company of New Jersey. Eight-hour tests at $37^1/_2$, 50, $62^1/_2$, 75, $87^1/_2$, and 100 per cent load were made, allowing at least 48 hr at each load before making the test. A test at 30 per cent load was run for two hours.

The generator terminal output was obtained from the station totalizing wattmeter which is periodically checked by the Public Service Company. The steam flow from each condenser boiler and the steam superheater was measured by calibrated steam flowmeters. The total flow from the steam superheater closely checked the sum of the flows from the condenser boilers. The fuel-oil flow was measured by an accurately calibrated oil flowmeter. All pressure gages, thermocouples, and thermometers were calibrated before the test.

The steam from the superheater was delivered to the station mains. As no particular steam turbine was driven by the steam produced in the mercury plant it was necessary to make a calculation of the total plant auxiliary power, which was deducted in order to arrive at a net plant heat rate. The equivalent power from the steam is based on the assumption that the steam made in the mercury plant was being used in modern steam turbines from which steam was extracted to heat the feedwater to the temperatures prevailing during the tests.

At reduced loads corrections to the steam-turbine water rates were made for reduced temperature and pressure but no correction was made for increased water rate due to reduced flow. In other words, it was assumed that the steam produced was mixed with the station steam and credit was taken only for the power which would be generated by the steam produced in the mercury plant. With only one steam turbine receiving all its steam from the mercury plant, which would be the case with a mercury-vapor-steam condensing plant, the plant heat rate would be somewhat higher at light loads than those shown, because of the increased steam-turbine water rate at reduced load.

The test results are shown in Table 5 and the net plant heat rate is shown in Fig. 32. The full-load heat rate of 9175 Btu per kwhr, or 37.19 per cent thermal efficiency, means that a kilowatthour is being produced for 0.502 lb of 18,275 Btu per lb bunker C fuel oil.

Applications

All the mercury equipments built so far have been "topping" units. This is the field for the widest application of the process, as any steam plant, no matter what its operating temperature and pressure, can be given a new lease on economic life if mercury equipment is added.

With mercury superposed over 600 lb gage and 730 F steam, 7250 kw may be generated per 100,000 lb per hr of steam produced in the condenser boiler, whereas a superposed steam turbine at 1200 psi gage and 925 F can generate 1960 kw per 100,000 lb per hr steam flow. Even when such a steam turbine is superposed over low-pressure turbines operating at 350 psi gage and 635 F, the power generated by the high pressure is only 3330 kw per 100,000 lb per hr steam flow. Looking into the future, mercury might be superposed on modern 1200 psi gage and 925 F steam and in this case 5650 kw would still be generated per 100,000 lb per hr of 1200 psi gage steam. This illustrates the large amount of by-product power which can be produced by superposing the mercury cycle over a fixed amount of steam flow.

As time goes on there will, no doubt, be applications for superposition over higher existing steam pressures and superposing still greater capacities over moderate steam pressures.

Industries requiring steam for process work at any pressure and temperature will find the mercury plant furnishes an economical means of supplying the steam, with greater amounts of by-product power available than can be furnished by any other power cycle.

The mercury process, because of its better fuel economy, should be well suited for ship propulsion. The savings in fuel would result in an increase in pay load for merchant ships, or an increase in cruising radius of naval vessels.

A mercury-vapor steam-turbine electric locomotive could be built with the steam turbine exhausting at atmospheric pressure, thus decreasing the size of the air-cooled condenser. Even with high exhaust pressure, considerable savings in fuel would be realized.

The mercury cycle offers an extremely simple and profitable means for producing power and is especially adaptable to any case where cheap power is desired.

Discussion

Perry Cassidy.[10] The boiler manufacturer has generally kept pace with the prime-mover manufacturer with respect to the pressures and temperatures required. Probably he, as well as the turbine manufacturer, has been somewhat ahead in his readiness to build beyond the economic operating limits demanded by the user. Steam boilers have been built for pressures approaching the critical, and superheaters for average steam temperatures over 950 F, and with maximum steam temperatures above 1000 F in individual elements due to imperfect distribution of steam and gas flow. Carbon steel constitutes the principal material for steam-boiler pressure parts, with a tendency toward higher tensility but with no need for alloys, except for higher-temperature superheaters. Since we are not limited by available materials, we are ready to produce steam boilers which meet the further requirements of the turbine design and operating engineers.

When asked by the General Electric engineers to co-operate with them in the design and to build the second mercury boiler for Kearny, we were able to draw upon our experience with steam boilers and superheaters, but we were not limited by ideas and practice entirely applicable to steam. It was necessary to change the basis of design from maximum temperatures of 600 to 650 F inside the generating tubes, the usual maximum limit for steam, to a range of 975 to 1070 F for mercury. Only the hot end of the highest-temperature superheaters had approached such temperatures. Even with the best commercial alloys available for generating tubes, the minimum as well as maximum temperatures in the second Kearny mercury boiler are well within the range where creep limits the design stress. The maximum calculated tube temperature in this boiler is such that even the best available commercial alloy steel will require operating experience to determine its limitations and usefulness.

Both the earlier mercury units and the high-pressure steam units have brought about a realization of the factors involved in thermal gradients through thick pressure members, such as drums, and tube connections. Thermal sleeves and other means of keeping temperature gradients within suitable stress limits have been developed for all purposes required. Fig. 22 of the paper shows such a thermal sleeve at the mercury-feed connection. This same factor is also involved in the rate of bringing up a unit with thick drums and other pressure parts where stresses due to temperature gradient must be respected.

One of the most important factors in connection with the construction of the Kearny rebuilt unit is the tube welding, both shop and field. The assembly and construction of such a unit, without adequate knowledge of welding and heat-treating of

[10] Executive Assistant, The Babcock & Wilcox Company, New York, N. Y. Mem. A.S.M.E.

many welds in alloy steels throughout this unit, would be impossible. Many long circuitous tubes without headers or junction boxes are being used in steam boilers as well, which demonstrates that any development in a given field involves certain problems which, when solved, apply to other similar problems. The development of the steam unit helps mercury, and vice versa.

The early designs and construction of mercury boilers were quite complicated and involved expensive fabricating operations. The attempt to utilize plain-carbon-steel pressure parts and the difficulties involved in keeping the tubes wetted by the mercury without the stoppage of some of the circuits by deposits of solids in the tubes resulted in continued complication. Until the time of the design and installation of the present new Kearny unit, this condition became worse rather than better. In the Kearny boiler the best available alloys were used and, in addition, every detail of design was carefully studied in order to produce as safe and conservative an operating unit as possible, with the consideration of cost as secondary.

In developing newer boiler designs, the General Electric Company has considered lower-head units with less spread between the drum pressure and that at which boiling begins, which is probably where the highest tube temperature occurs. This permits higher drum pressures with higher thermal efficiency of the cycle, or the use of less expensive alloy tubes, or a higher factor of safety on tube temperatures for the same alloy.

Wider tube spacing in the furnace and higher heat-release rates per square foot of furnace surface and furnace volume tend to make boiler costs still lower, particularly by reducing the mercury content of the boiler.

It is likely that the ultimate economic limits of temperature will be established by the rate of oxidation of the outside of the tube subjected to the hot gases of combustion. This may also be the limit in temperature of steam-superheater elements, affecting the choice of alloys and their costs and establishing the ultimate economics of the unit.

Progress toward simplicity applies to the condenser boiler also. The use of alloys in this case is not a factor. The application of the principles of steam-boiler design to the design of condenser boilers does not present any special difficulties. The boiler casing must be designed to stand the full vacuum on the condenser and of course all-welded construction is necessary.

The solution of the wetting problem in the mercury tubes by the General Electric engineers, in the development of chemical treatment with minute quantities of titanium and magnesium is, in our opinion, an outstanding example of the application of the highest type of engineering. We wish to pay tribute to the work of those men whose labors have contributed to this accomplishment.

We are of the opinion that engineers responsible for the installation of power equipment should be aware and fully informed as to the possibilities of mercury power generation.

The development of the mercury-power cycle may proceed from this time with increasing rapidity and, even though power engineers may not find mercury justifiable at present, they should not necessarily assume that this will be true in later years as the art progresses.

B. P. Coulson, Jr.[11] Throughout the development of the Emmet mercury-vapor process, the mercury boiler design has been the outstanding problem. In the early experiments with mercury boilers, the overheating of tube surfaces was not understood, and it was not until later years that the importance of wetting by mercury was fully appreciated. Methods to insure adequate wetting of heating surfaces were not developed until recent years by the General Electric Company.

In some of the early experiments, it was observed that the boiler surfaces did not become overheated in the liquid regions of the tubes but, where vapor started to form, the heat transfer became uncertain. From these observations, it was considered important for the hottest gases first to pass over that portion of all the tubes containing liquid and thus apply a less intense heat where vapor is formed. Also, to insure against overheating, a vigorous circulation was considered necessary. On this principle the honeycomb type of boiler, shown in Fig. 4 of the paper, was designed. The gases in this boiler entered all of the tubes at the bottom, in the region of the liquid mercury. The radiant heat from the furnace is absorbed also by the liquid circulating in the lower ends of all the tubes.

This boiler had an additional feature for providing dry vapor by allowing the vapor to cross over the upper portion of the tubes between baffles before leaving the boiler. This boiler was, however, abandoned because of insufficient provision for unequal expansion of the tubes, which caused leaks to develop through the welds at the bottoms of the tubes. To provide for free expansion of tubes, a dependent porcupine-tube boiler was adopted, as shown in Fig. 5 of the paper. Some years before this boiler was installed at Hartford, a porcupine-tube mercury boiler was made having tubes attached to a single upper header, the gas flow being across the tubes. At that time, the principle of applying the hottest gases at the bottom of all the tubes in the region of the liquid was not known, thus the tubes became overheated on the sides where vapor was formed. The gas flow over the boiler tubes, shown in Fig. 5, was parallel with the tubes in an upward direction, and the four headers were spaced to allow the gases to pass between them.

A further development of this boiler was the adoption of round headers, thus eliminating objectionable stay bolts. Three features of this boiler which at that time were of great importance were as follows:

1 When repairs were made to the boiler the mercury could be left in the tubes, and thus the interior surfaces were not exposed to oxidizing air which might impair the heat transfer.

2 The boiler tubes could be easily calorized by the dip method.

3 In case mercury leaks developed in any one of the tubes, the maximum loss of mercury could not be excessive.

In the early days of this development several minor mercury leaks developed in the boiler tubes.

When designing the new replacement boiler for Kearny, the all-important problem of coal-slag accumulation on heating surfaces was given the utmost consideration.

When slag screens were first proposed for mercury boilers, some doubt was felt for their safety, as they are exposed to both radiant and convection heat. To make sure of this a slag-screen tube was suspended across the furnace of the mercury boiler in the Schenectady Works of the General Electric Company, and its operation was observed for several weeks. These slag screens not only screen out some of the slag from the gases but also shield the slag particles which go through the screens from the radiant heat of the furnace. Thus, the slag particles assume the temperature of the gases and enter the convection surface in a dry condition.

In addition to slag screens to insure against slag accumulation on convection surfaces, the furnace-wall surfaces were designed with liberal proportions, thus the heat absorption from the furnace is high and so further reduces the temperature of slag particles both entering the convection surface and in the furnace proper.

This liberally proportioned furnace also insures good combus-

[11] Consulting Engineer, General Electric Company, Schenectady, N. Y.

tion, which in turn insures more complete oxidation of the iron in the slag, thus elevating the fusing temperature of the ash.

The mercury boiler at Kearny has now been operating at overloads for many months burning coal, and the slag conditions are most satisfactory.

It is now believed that the success of the Emmet mercury-vapor process is assured, the only requirements being to put into production an inexpensive boiler requiring only a small quantity of mercury.

W. LeR. Emmet.[12] The writer is very glad that this paper has been written. It gives a brief but nearly complete outline of the long history of this process, shows the very high degrees of fuel economy which it affords, and demonstrates that such results are not merely matters of theory but have been reduced to actual practice in recent months in the plant at Kearny, N. J.

The new knowledge, which, in spite of many setbacks, has developed step by step through experience with this process, has caused abandonment of methods which were at first considered practicable. In such things, every change of plan is likely to mean long delay.

If the mercury process does not come to the full commercial success which the writer knows that it deserves, it will be the first engineering failure that he was ever connected with. Naturally, there is a strong personal interest, since success with it would be more important than anything that the writer was ever able to accomplish, even his steam-turbine work.

The mercury installation, which has been operating at Hartford for many years, has been uniformly successful in all respects, except in the matter of the mercury boiler which, while still commercially available at a somewhat reduced load, has long since shown limitations which convinced the writer that a very much better and cheaper type of boiler must be devised, if this process were ever to come to its proper development. It has been mainly to the boiler problem that the writer has devoted such means as he could command in the last 7 or 8 years of his retirement.

Papers[13] have been presented before this Society and the Society of Naval Architects and Marine Engineers in which a new type of mercury boiler is described, which has been developed as a result of the studies and experiments of the writer.

Two definite aims were in mind in designing this new type of boiler: (1) To make a boiler of which every part of the interior is readily accessible for cleaning; and (2) to develop a mercury boiler in which the cost for construction and for mercury required is sufficiently low to give this process advantages over others with which it must compete. Experience has taught the lesson that first cost is vital, if it is desired to make a progressive move in the power industry. In these days of governmental expenditures of billions, the writer's ideas may seem small, but they may appeal to some of the practical men who attend meetings of this Society.

In his work in the power industry, whether electrical or mechanical, the writer has long used a rough rule as a basis of comparison and that is that, if we can save 1 per cent of the fuel, we can afford to spend a dollar a kilowatt to do so. This means that, if we could build a plant which did not require fuel at all, we could, in many cases, not add more than $100 per kilowatt to that cost without getting into difficulties in the matter of fixed charges.

Whether the exact rate here stated is or is not correct, the rule is valuable and applies to added parts which are expected to give improvements, as well as to complete plants.

The type of mercury boiler, which the writer has designed, is the only one so far proposed which in his opinion meets the two requirements that have been stated. Incidentally, it has shown another very valuable advantage, namely, that the chemical treatment of mercury mentioned in the paper under discussion has acted effectively in the one boiler of this type which has been commercially operated. Reference is made to the boiler at Pittsfield, shown in Fig. 17 of the paper. In other boilers known to the writer, conditions have appeared with this treatment which are considered dangerous.

It is hoped that what the writer has presented to the published record during his recent years of retirement may lead others to use the principles which he has demonstrated.

H. N. Hackett.[14] The rebuilt Kearny mercury boiler is a success. The plant operates at full output continuously except for minor outages for cleaning and repairs. The availability of the rebuilt mercury plant to date has rarely, if ever, been equaled by steam units of like size. We believe this record can be duplicated over and over again in new installations.

The heat rate of the Kearny mercury unit is approximately 9200 Btu per net kwhr, which is better than originally expected. Heat rates of less than 9000 Btu are now attainable, and who can predict what the final figures will be when the steel producers make it possible radically to increase the temperature and pressure at the mercury turbine. A mercury unit, operating at 500 psi and 1500 F, superposed over the best steam cycle, should approach 7500 Btu per kwhr.

Kearny is successful. The development engineers have progressed sufficiently far to produce predicted results, and the operators are securing high availability from the equipment.

If the second book of "The Story of Mercury" is to be written, the principal text must come from the vast laboratories of the power industry, as the future of mercury unquestionably lies in that field. Expansion and commercial development can only come through increased use.

The leaders of this industry must again show the same courage and determination demonstrated while writing "The Story of Steam."

The search for higher and higher efficiencies, along with the relative simplicity of mercury operation, will most certainly provide the incentive for carrying this great development to its conclusion; thereby opening a new era of power generation that is destined to be as gigantic as the one we now enjoy.

H. E. Melton.[15] The development of turbines, boilers, and related equipment for the utilization of mercury vapor under pressure has been one of the engineering achievements of the last few years. The progress made since the early experiments at Schenectady has been very clearly described by the authors.

The engineers of the General Electric Company are justified in being proud of the latest installation. This is an outstanding accomplishment of engineering design, construction, and performance. Great credit is due them, not only for having pioneered this highly efficient thermal process, but also for having at the same time put it on the successful commercial basis demonstrated at Schenectady, Hartford, and Kearny.

There are enormous possibilities for the application of mercury

[12] Deceased since the discussion was presented on March 19, 1941. Inventor of the Mercury-Vapor Process of power generation; formerly Consulting Engineer, General Electric Company, Schenectady, N. Y. Mem. A.S.M.E., and A.S.M.E. Medalist, 1929.

[15] Sun Oil Company, Marcus Hook, Pa.

vapor as a heating medium in many industrial processes. There are at present several mercury boilers operating in widely divergent fields. Perhaps the best examples of these are in the Marcus Hook Refinery of the Sun Oil Company. Sun Oil was the first to take advantage of mercury vapor for extremely close control of a large-scale manufacturing process.

The authors have described the 1925 porcupine-tube boiler at Dutch Point, the first commercial unit. This was known to the builders, The Babcock & Wilcox Company, as HgB1.

The next unit, HgB2, was put into service in April, 1926, at Sun Oil Company. This boiler was not so hard to sell, perhaps, as was the first one at Hartford, since the Sun Oil Engineering and Development Department had, at that time, just perfected a process for the continuous vaporization of oil using mercury vapor as a heating medium. This process will be described only briefly here, as it has been widely discussed. Essentially, it is the same as a double boiler on a stove, with a layer of oil in the upper part and mercury vapor underneath. If one can conceive of a series of double boilers connected together and inclined slightly downward with oil flowing by gravity continuously from one to the next, with a certain proportion of the oil stream being vaporized off in each step, he will have a good idea of how the plant functions and how products of different viscosities are obtained by means of a heating medium held at a constant temperature within 1 or 2 deg F.

The oil heaters are overhead, and condensed mercury returns by gravity through rundown lines to the boiler. The entire system is welded, and the mercury side operates under pressure. The oil vapors are distilled over to towers where side cuts are made through condensers and coolers to products tanks.

Mercury does not come in contact with the oil.

The advantages of such a system, compared to the old separately fired batch still, are obvious. One of these is the fact that the mercury plants have an "on-stream" factor of 95 per cent. Closely controlled production of lubricants and specialty oils, ranging from the lightest to the heaviest, is carried on for months at a time without forming coke, due to "burning" of the oil. The heating surfaces over which the oil flows are only a few degrees hotter than the oil being heated and no hot spots exist. As a result, the transfer rates remain high, the charge to the plant in barrels per hour can be held uniform and the specifications of any particular product can be duplicated at any time.

Since 1926, six additional boilers have been put in operation at Sun Oil. Thus, out of a total of seventeen mercury boilers built to date, Sun Oil has taken seven.

The latest boiler dates from January, 1938, and is of the twisted-tube or catenary type. The unit comprises a main boiler bank, convection bank, and air heater, and is rated at 30,000,000 Btu per hr absorbed. Boiler tubes are of carbon-molybdenum steel and are calorized. The fuel is dry gas, a by-product from stills in the refinery.

This unit, containing 55,000 lb of mercury, has comparatively small-bore tubes and natural circulation. It carries the load of one of the lubricating-oil plants which was formerly carried by two dead-end-tube-type boilers, each containing 45,000 lb of mercury. These two older boilers are now stand-bys for the newer boiler. This last unit has operated continuously for 3 years with the exception of four scheduled shutdowns per year for cleaning the oil side of the plant and one forced outage caused by the equivalent of a case of low water, due to a holdup in the gravity-return system.

The characteristics of this unit are as follows:

Design pressure, psi	100
Mercury content, lb	55,000
Gas temperature entering tubes, F	2400
Gas temperature to convection bank, F	1250
Gas to air heater, F	750
Gas to stack, F	500
Air to burners, F	500
Fuel fired, cu ft of gas per hr	22,000
Heat units absorbed per hour, Btu	27,000,000
Mercury vapor per hour, lb	210,000

Until 1938, Sun Oil's experiences closely paralleled those of General Electric in the matter of solubility of iron in hot mercury and the consequent restriction of vapor passages in the tubes with redeposited metal. To take care of this difficulty, it was the practice to pickle each boiler once every 2 years, an operation requiring about 3 days per boiler. In 1938, chemical treatment was started under the direction of General Electric chemical engineers, using magnesium and titanium. This has overcome the dissolution of metal, the surfaces being free of oxides and completely wetted by mercury. The experiences with chemical treatment have likewise closely paralleled theirs, except that, with the closed system, no air-leakage or moisture problems exist while operating, and the limits are therefore much easier to maintain.

The removal of accumulated oxides and "dirt" from the Kearny system is accomplished by means of a flash sump. At Sun Oil, this material is trapped out in a submerged horizontal section of the return line. The area at this location is such that the liquid velocity is decreased to the point at which the material floats out. For the quantities of mercury flowing, 6-month cleaning periods suffice to keep any oxides from carrying back into the boiler.

Of the total of seven mercury boilers installed at Marcus Hook, three have become obsolete. None of the seven can be compared in size or capacity with the General Electric, Hartford, or Kearny installations, but back of them is a record of 15 years of sucessful operation in the manufacture of lubricating oils. This is conclusive proof that the adaptation of mercury vapors to process work is fundamentally sound and highly advantageous.

R. C. Muir.[16] The writer has followed this development closely for the last 10 years, being first impressed with its possibility for great simplicity in design, aside from its great promise as an efficient cycle. In many respects, it is simpler in principle than the closed cycle of the sealed household refrigerator.

The difficulty experienced in its development has been the lack of suitable high-temperature materials and the unknown behavior of high-temperature mercury in steel enclosures.

The metallurgists have now given us suitable materials, with the promise of still better materials, and the chemists have supplied simple treatments for the mercury so that it will behave properly in steel containers. The designers and engineers can now proceed with continuing improvement in the simplicity of design. The writer is confident that the mercury-vapor process for power production will assume an important place in the future.

T. H. Soren.[17] The mercury boiler at the Dutch Point Station was placed in operation on September 7, 1923. This was the first installation in which welding was used for mechanical strength, particularly on piping.

The present mercury boiler at the South Meadow Station is in regular operation, carrying about 6000 kw 24 hr a day. The availability of the mercury equipment is about 90 per cent for the year.

The mercury boiler at South Meadow is operating in every essential exactly as it was laid out by its inventor W. LeR. Emmet. There have been no fundamental changes in operation

[16] Vice-President in Charge of Engineering, General Electric Company, Schenectady, N. Y. Fellow A.S.M.E.

[17] Vice-President, The Hartford Electric Light Company, Hartford, Conn.

and no material changes in the original equipment. We are not using any chemical beyond illuminating gas on the vacuum side of the unit.

The reason for the reduced capacity at which the unit operates is that, with higher capacity, it is necessary to boil out the accumulation of iron and mercury oxides in the boiler tubes with acid every 2 or 3 months. At lower capacity, the unit can operate from 12 to 15 months without cleaning.

The entire unit was built of low-carbon steel, and the bottoms of the boiler tubes are beginning to show some hair cracks on the inside, indicating that there is a definite life to the carbon steel at high temperatures.

It is not practical to retube this boiler for the reason that the ligaments in the boiler drum between tubes are about $^5/_8$ in. and would not stand a complete retubing of 3080 tubes. It is the intention at some later date to replace this boiler with one of a later design. The mercury turbine is in good condition. Some of the last-stage buckets show signs of erosion. This probably would mean rebucketing one stage and possibly two.

It has been necessary to increase our capacity twice in the last few years. The first increase was 40,000 kw, and the present one, 45,000 kw. At the time of the first increase, the General Electric Company was not in a position to offer a mercury unit of sufficient size to take care of our additional load.

The present increase of 45,000 kw will go into operation in 1942 and is required for the tremendous increase in war load at the United Aircraft Company, Colt's Patent Fire Arms Manufacturing Company, and in the other local machine shops.

This 10,000-kw unit was started in 1928, and it was limited in operation for three of the first 6 years of its operation. The other 3 years produced 334,000,000 kwhr. It was on the line 75 per cent of the time. Total operation has produced 1,346,598,000 kwhr, and for the last 8 years it has been on the line 90 per cent of the time. The per cent of the time out has been due to repairs on the furnace and steam auxiliaries, as well as mercury.

G. B. Warren.[18] In connection with the consideration of the mercury boiler and mercury turbine which has been so ably presented, it might be worth while to emphasize the possibilities of one particular application, that is, the application, in the near future, of the mercury cycle as a superposed cycle over present highly efficient steam plants. It may be that for some time the mercury-vapor-steam plant will cost slightly more than a corresponding steam plant. Experience in the power-plant field, today, indicates that a somewhat more costly but more efficient cycle can be justified as a superposed cycle than can be justified as a straight-condensing cycle. The economics back of this situation seems to be sound. To a great extent this is due to the greater capacity which the more efficient cycle will permit in the superposed plant when superposed over a given existing plant capacity.

The present mercury plants have largely been superposed over 250- to 400-psi steam plants. A careful study of the situation indicates that the over-all economy may be slightly improved if the mercury cycle is installed over a high-pressure high-temperature, or high-pressure resuperheated steam plant; and, further, when so applied, the cost and size of the mercury-vapor turbine is considerably reduced. In addition, the total kilowatts which can be developed from a given mercury boiler is also increased.

All of these considerations point to the possibility that one of the big applications for the mercury-vapor cycle may be as superposed capacity over the 600-lb and 1200-lb stations of which 2,000,000 kw were installed during the period from 1925 to 1932. Such superposition will probably be on the base-load sections of these plants, in which a considerable portion of the boiler depreciation has undoubtedly already been taken.

Note: A joint discussion by P. H. Hartung of this paper and the paper, "Mercury for the Generation of Light, Heat, and Power," by H. N. Hackett, appears on page 653 of this issue of the Transactions.

Authors' Closure

The cost of mercury depends upon supply and demand and the amount mined depends upon the price. The result is that the price has fluctuated from \$50 to \$250 a flask of 76 lb. If the mining and refining operations were put on an economical basis for a good regular output per year, it is believed that the cost of mercury can be brought down to from 35 to 50 cents a pound.

The mercury content can be reduced in a moderate-sized boiler to 2 lb per kw which would include the kilowatts generated by the steam, as well as the mercury. A plant costing \$100 per kw, and mercury 50 cents per lb, the mercury cost would represent 1 per cent.

The condenser boiler is not an expensive piece of equipment. The temperature difference between the mercury vapor and the water is low and fixed, and a tube cannot burn out from overheating.

The mercury cycle has a large volume flow, and, where the volume flow is large, the turbine is generally inexpensive for small-capacity units. On the other hand, a large volume flow makes the large-capacity turbines more expensive.

Mercury losses can be figured like depreciation. If the Hartford, Schenectady, and Kearny units pooled their losses for all the years the plants have been operated, the loss would represent about 1 per cent depreciation.

With 140 psi in the drum, the pressure at the boiling point in the Kearny boiler is 260 lb, so that every pound of mercury vaporized at the 260-lb pressure will be expanded in the boiler down to 140 lb upon reaching the drum, thus making an efficient heat pump. Such mercury liquid as is vaporized at some pressure between 140 lb and 260 lb will have that much less heat head as a pump. The transport of heat is done by the vapor and the circulation of an excess amount of liquid is ineffective work. Therefore, if the drum is lowered, the amount of liquid circulated becomes less, and the velocity of the mercury becomes greater.

It is recalled that the Dow Chemical Company admitted some years ago that diphenyl oxide dissociated above 750 F, and that it had no advantage over a steam cycle which is capable of using higher temperatures. This fluid seems to be most successful as a heat-transfer medium at moderate temperatures.

Mercury for the Generation of Light, Heat, and Power

By H. N. HACKETT,[1] SCHENECTADY, N. Y.

This paper outlines the principles upon which the mercury boiler was first developed and tested in a small unit in 1912. Many difficulties were experienced in units built in succeeding years, the full importance of which was not apparent until the two 20,000-kw units at Schenectady and Kearny were placed in operation in 1932 and 1933, respectively. The major problem from then on was the elimination of mercury attack on the steel tubes, which after short periods of operation became plugged with an iron crystalline deposit. As a result of extensive research, a mercury-sodium-titanium amalgam was discovered which solved the problem of dissolution of the steel. This development combined with the exclusion of oxygen from the boiler, piping, and valves greatly improved the situation. The final solution came in the redesign of the Schenectady plant in 1937 and the construction of an entirely new mercury-vapor unit at Marcus Hook in 1939, in which magnesium and titanium were used in the boiler mercury. Details are also given of the more recently rebuilt plant at Kearny, incorporating all known improvements. This unit, producing 21,000 kw per hr from the mercury turbine and 30,000 kw per hr from by-product steam, operates on 0.5 lb of fuel oil per kwhr. During more than 15 months of operation, this boiler has carried an average hourly load of 205 per cent of the national average for steam-generating units for 1940.

MERCURY, the only metallic element that is liquid at atmospheric temperatures, has been known and used by man for centuries. It occurs in nature chiefly in the form of red sulphide HgS, called "cinnabar," which as a rule is accompanied by more or less of the reguline metal and is found in formations of all ages. It has been found in both sedimentary and eruptive rocks of the most varied character.

The normal world production of mercury is about 120,000 flasks per year, but at the present time it is estimated to be in the order of 160,000 flasks per year. Of this amount, approximately 50,000 flasks are being produced by the United States, Canadian, and Mexican mines and the remainder by Spain and Italy. The United States yields about 34,000 flasks from approximately 100 mines.

Uses of Mercury

Industry, medicine, and the arts consume approximately 85 per cent of the world's production in the form of mercury compounds. The following statement from a recent article[2] gives some of its many uses:

"Vermilion, used for paint and cosmetics (an ancient use) is the sulphide. Mercurochrome is one-quarter mercury; calomel, a seed disinfectant as well as a medicine, is 85 per cent mercury; and corrosive sublimate is 74 per cent mercury. Compounds of the metal are used as catalysts in making acetic acid, caustic soda, and chlorine. Ships may be protected with a mercury antibarnacle paint. The dentist may use vermilion to color his plates to match the gums, and mercury amalgam (formerly much used in smelting gold and silver) in making fillings. Mercury goes into electric arcs and lamps for signs. Even the felt-hat industry depends on mercury. The process of making fur into felt uses mercuric nitrate.

"As an out-and-out war material, mercury is used as a detonating agent, in the form of mercury fulminate, invented in 1799. Before that time muskets were fired with the famous flint and steel. To make fulminates, mercury is treated with nitric acid and alcohol."

Power Generation With Mercury

For the generation of power, a binary cycle employs the latent heat of boiling mercury to convert the heat of the fuel to electrical energy with greater thermal efficiency than with the steam cycle alone. The power from the mercury-turbine-driven generator is produced at nearly theoretical mechanical equivalent of the thermal energy; the heat wasted being recovered by producing steam, in a condenser boiler, and using it in an ordinary steam turbine. The economy of such a process is plain when it is considered that the power is generated in two turbines with only the same boiler waste and condenser loss that is accepted with a steam turbine alone, Fig. 1.

The use of mercury for generating power and making lubricating oils has had very little effect on world consumption, as in over a quarter of a century only about 21,000 flasks have been used for these purposes.

Mercury, as a medium for the generation of light, heat, and power, was first experimentally tested by General Electric in 1912, on a small mercury boiler. Observations of the boiling fluid were made by looking down the open end of the pipe in which the mercury was being heated.

In 1912, mercury was considered to be a coherent mobile liquid that would actively amalgamate with such metals as gold, silver, copper, or tin, but would not wet glass, iron and steel, or objects placed in it. When heated, the metal expands uniformly and vaporizes at 458 F at 29 in. vacuum, and at 975 F at 140 psi gage pressure. The vapor is colorless. The heat of the liquid is low, being only 0.033 Btu per lb per deg temperature rise. Likewise, the heat of vaporization is much less than for steam, being about 125 Btu per lb. Because of the greater available energy throughout any temperature range, the binary mercury cycle produces power with less heat loss than can be done with steam alone, with resulting thermal efficiencies above 37 per cent. Future applications of the cycle may exceed 50 per cent thermal efficiency.

Early experiments with the mercury-vapor-steam cycle on a 100-hp boiler and later on a 1500-kw unit, operating at 10 psi

[1] Construction Engineering Department, General Electric Company. Mem. A.S.M.E.

[2] "The Many Uses of Mercury," *Mechanical Engineering*, vol. 61, 1939, pp. 920–921.

Contributed by the Power Division and presented at the Annual Meeting, New York, N. Y., December 1–5, 1941, of The American Society of Mechanical Engineers.

gage and 730 F vapor temperature, indicated that mercury was practically inactive to iron or steel.

In fact, the affinity of iron for mercury was so slight that considerable difficulty was experienced in securing suitable heat transfer from the steel-tube walls to the boiling mercury. Relatively long periods of operation at low rates of heat application were necessary to "break in" a boiler properly, before expected outputs could be secured.

As time went on and larger boilers were built burning greater

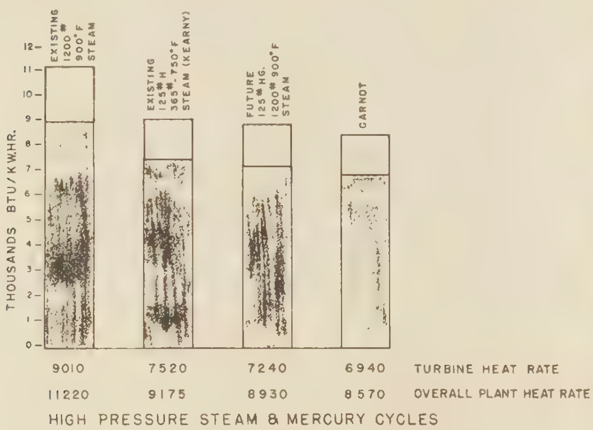

Fig. 1 High-Pressure Steam and Mercury Cycles

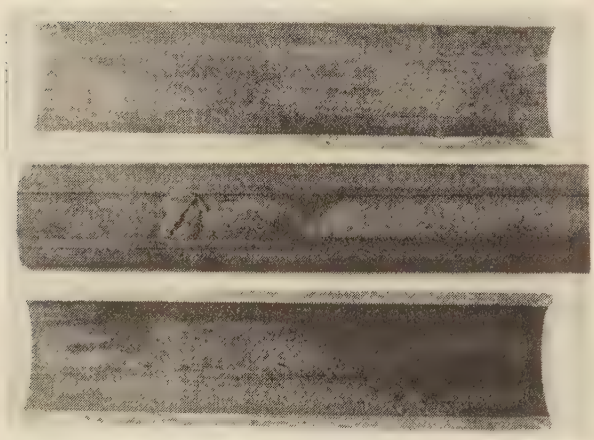

Fig. 2 Boiler Tube Removed From Hartford 10,000-Kw Unit, Showing Deposits of Previously Dissolved Tube Metal Resulting in Restriction of Mercury Circulation

quantities of fuel, it was discovered that the heat-absorbing ability of a tube filled with mercury was not only uncertain but unpredictable to such a degree that pronounced overheating and actual damage to the boiler tubes occurred. Furthermore, mercury did cause disintegration of the steel to such a degree, by dissolving slowly great quantities of iron from the inside walls of the tubes and redepositing it in the cooler regions, that the tubes became plugged at their upper ends. Overheating occurred, due to restriction of mercury circulation, Fig. 2.

Mercury Attack on Tube Steel

The full importance of these difficulties was not appreciated until after the two 20,000-kw units—one installed in the Schenectady Works of the General Electric Company, and the other in the Kearny Generating Station of the Public Service Electric & Gas Company of Newark, N. J.—were placed in service in 1932 and 1933, respectively. However, the first positive results of mercury attack on the tube steel were evident after nine months of operation of the 10,000-kw mercury unit in the South Meadow Station of The Hartford Electric Light Company in 1930. Because of incorrect diagnosis, nothing of a fundamental nature was done to correct the trouble.

The deposits of iron in the Hartford tubes were thought to be from mechanical erosion of certain cast-iron filler pieces in the drums and were removed by means of acid pickle. Even though this operation required the use of some 10,000 gal of 20 per cent

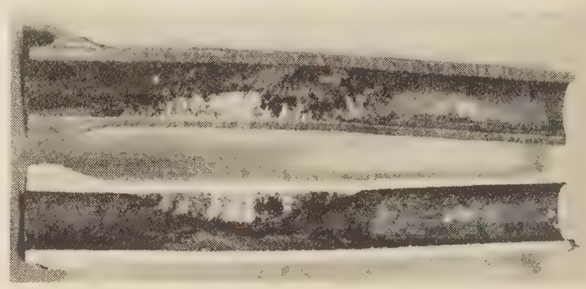

Fig. 3 Section of Mercury Wall Tube Showing Mercury-Iron-Oxide Deposit

concentration hydrochloric acid to clean the 25,000 sq ft of inside drum and tube surfaces, the results seemed sufficiently satisfactory to proceed with the building of the Schenectady and Kearny units.

Shortly after the Kearny unit had been placed in operation, examination of the external surfaces of the tubes indicated that overheating had occurred, as certain of the mercury-filled furnace-wall tubes were distorted and bent, and several hundred of the porcupine boiler tubes had increased in diameter at their lower ends. Internal examination of the porcupine tubes disclosed the same iron-crystalline deposit at the upper end, as was previously found at Hartford, and the upper ends of the $^{7}/_{8}$-in-diam furnace tubes were likewise plugged with similar material, Figs. 3, 4, and 5.

This could not be attributed to mechanical erosion, as was first thought at Hartford, since the lower portions of the furnace tubes showed actual loss of metal of a measurable amount. The deposits were principally iron oxide, mechanically combined with mercury particles. The inside surface of the tubes was believed to be nonwetted, because of formation of oxide films on the surface.

It soon became evident that these two problems had to be solved if full-load operation was to be attained, as the boiler at Hartford had to be cleaned again some ten months after the first experience. It was necessary to pickle the units to continue operation. This practice existed for many months at Schenectady and Kearny, until suitable correctives were found. It is still followed at Hartford. Some loss of iron occurred with each pickling operation, which necessitated the addition of equal volumes of mercury so that correct operating levels could be maintained.

The rapid dissolving of the iron from the lower tube surfaces with the subsequent redepositing of the metals, as either iron or iron oxide at the top, and the unexpected overheating of the tubes were both problems for which no immediate answers were available.

It was believed that, if the dissolving of the iron could be stopped, the operation of a mercury boiler would be satisfactory, as relatively long intervals between pickling operations would not be objectionable. To accomplish this desirable result, three general lines of attack were followed.

Steel specifications were altered and various alloys were developed in an effort to find a material that would reduce or, if possible, entirely eliminate the loss of metal by dissolving. Some success was attained, as certain alloys showed definite improvement.

An all-liquid boiler using alloy tubes, in which the mercury-liquid temperature continuously increased throughout the heating circuit, was built and thoroughly tested in the belief that the dissolved metal would not be released in the tube circuit, but in a large receiver or flash chamber where flashing of the heated liquid occurred. These hopes were only partially realized, as some dissolving of the tube material, as well as appreciable deposits of oxidized metal, did occur after a few months of operation.

Overheating of the mercury-filled tubes was not cured entirely by either of these two procedures, although considerable improvement did occur with the all-liquid boiler.

Research on Effect of Mercury on Steel

Ultimate and complete success was realized, however, as the result of an extremely active research program in which the metallurgical and chemical properties of mercury, combined with other metals, were thoroughly studied by the scientists and chemists of the General Electric Laboratory.

Hundreds of small "harp" boilers, in which were placed small test pieces of polished and weighed steel on which the experiments were to be made, were operated many hours at temperatures of 1200 to 1300 F to accelerate the results. The mercury in each of the test boilers contained small quantities of one or more of the known elements and metals, such as tin, lead, sodium, magnesium, silver, titanium, or zirconium. Sometimes combinations of these several metals were used together and in varying amounts to study the effects.

After more than 300 tests, in which mercury, titanium, and sodium were used, one harp boiler produced startling results. The test piece of steel showed no dissolving; it was perfectly silvered or "wetted," and when cleaned of all adhering mercury, weighed exactly the same as when it was placed in the boiler many hours before. Repeated successes with identical harp boilers indicated that a satisfactory method had been discovered

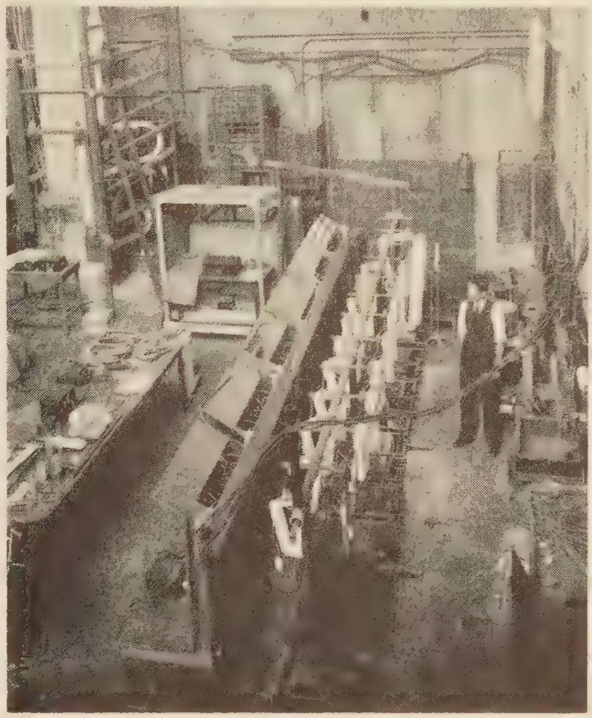

Fig. 6 Harp Boilers Used for Testing Effect of Mercury Amalgams on Steel

which would not only control but apparently stop the dissolving of the iron in the boiler mercury. The steel maintained its original weight and size with no loss of metal. The mercury-filled tube became a suitable and reliable absorber of heat at unbelievably high rates. Plugging and overheating of test boilers had been eliminated. Apparently only minute quantities of these elements were sufficient, only a few parts per million by weight of mercury, Fig. 6.

What chemical or metallurgical effects had been performed by the simple combination of these well-known metals, operating in heated mercury-boiler tubes, was not known. Microscopic examination of the treated mercury-coated surfaces and careful chemical analysis of the treated mercury brought to light the phenomena which are believed to be responsible for the successful results.

Mercury-Sodium-Titanium Amalgam Solves Problem

The steel was found to be perfectly wetted with the dilute mercury-sodium-titanium amalgam to such a degree that intimate

and positive contact occurred between the steel and the mercury. The spheroidal properties of the mercury were entirely gone, and the liquid spread over the tube surface to form a tenacious layer almost impossible to wipe away.

Sodium was believed to be the wetting agent, causing a breakdown and removal of oxides on the surface of the steel and in the mercury, thereby allowing actual intimate contact of the mercury and the steel. The sodium was also thought to reverse the meniscus of the mercury, thereby causing it to spread uniformly over the tube surface to produce the effect of wetting.

Titanium was found as a thin microscopic layer deposited on the surface of the steel, as well as a eutectic compound with iron in the mercury. It was not known whether the surface deposits of the iron-titanium alloy functioned to inhibit the dissolving of the iron, but that this occurred was certain.

Could this information be applied to the large power boilers in use in Hartford, Schenectady, and Kearny? To apply the meager knowledge gained from the laboratory test boilers, weighing only a few pounds, to the great power units, weighing more than 6,000,000 lb each, offered many problems.

Treatment of Boiler Mercury at Kearny

For certain reasons, Kearny was chosen for the first application of what is now known as "treatment of boiler mercury." During the night of March 4, 1934, sufficient metallic sodium in the form of a 25 per cent sodium-mercury amalgam was added to the boiler mercury to bring the sodium concentration to 100 ppm by weight of mercury. No titanium was added as yet. The immediate results were astounding, as the boiler at the time the sodium-mercury amalgam was added could only carry 20 per cent of full rating without overheating the boiler tubes. Immediately after the injection of the amalgam, the fire was increased to produce one-half capacity. The following day, the load was increased to full rated output of the boiler and was subsequently operated continuously for three months. During this period, efforts to add titanium to the mercury were ineffectual. Various appliers were used, but to no avail, as the titanium refused to dissolve in the boiler mercury. However, the boiler appeared to operate satisfactorily with no overheating of the furnace tubes.

These results were very gratifying, but actual success was only partial, as stoppage occurred in certain furnace tubes of the mercury boiler. This time, however, the effect was different as the plugging was not at the top of the tube but at the bottom, caused by a ball of hard material which, when analyzed by the chemists, was found to be a mechanical mixture of mercury and sodium ferrite.

The elimination of sodium ferrite, $Na_2OFe_2O_3$, the end point of a chemical reaction between sodium, iron oxide, and oxygen, was believed to be a difficult problem. Further tests were conducted which proved conclusively that oxygen was the principal offender and would have to be eliminated.

Just how this was to be done was not known. The problem involved a great power unit weighing millions of pounds, having thousands of square feet of steel surfaces exposed to air and mercury, containing hundreds of pounds of oxygen-bearing iron rust and scale. This vast unit must be made free and kept free of oxygen.

Improvements Made in System

The turbine shaft rotating at high speed in shells in which high vacuum is maintained must be perfectly sealed. Many feet of welded and bolted joints must be made absolutely tight, as well as

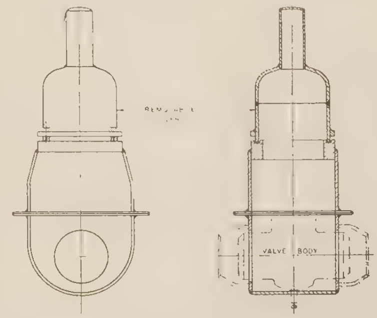

Fig. 8 Airtight Enclosed Vacuum Valve
(End elevation, left; vertical section, right.)

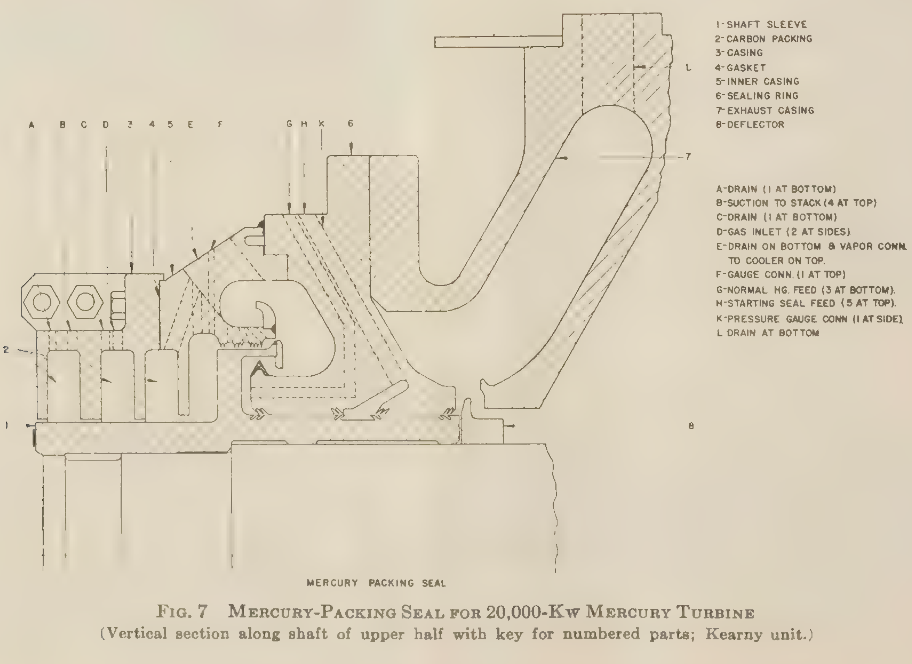

Fig. 7 Mercury-Packing Seal for 20,000-Kw Mercury Turbine
(Vertical section along shaft of upper half with key for numbered parts; Kearny unit.)

the stems of leaking valves. None of these things were required in steam plants of like size.

New and effective shaft seals were built, Fig. 7, using the centrifugal force of a revolving cup of liquid mercury to form the seal; designs were altered; the best technique of welding was employed for making welded joints tight; flanges and valve stems were sealed by special means, Fig. 8. Air infiltration was reduced from 500 cu ft per hr to less than 1 cu ft per hr.

Further laboratory and field tests discovered that magnesium and titanium had all the desirable wetting features of sodium and titanium and none of the undesirable ones, so magnesium replaced sodium in the boiler mercury. It was found that magnesium did not form the hard dangerous balls when reaction between the metallic magnesium and iron oxide or free oxygen took place in the boiler mercury. The final products of the reaction were, instead, a very fine, dry, harmless powder consisting of free iron and magnesium oxide, easily removed from the boiler mercury.

All the known improvements were made on the Schenectady unit in 1937, with immediate and unqualified success. No difficulties or unexpected results from the mercury or its ingredients developed, and the equipment operated at satisfactory output 93 per cent of the time for the next 18 months, when further alterations were made to the plant to increase its capacity.

This success was duplicated in a 1000-kw test boiler of simple design in Pittsfield in 1938.

An entirely new boiler, embodying all the developments so painstakingly discovered, was built and placed in operation in the Marcus Hook Refinery by The Babcock & Wilcox Company for the Sun Oil Company in early 1939, for the purpose of producing

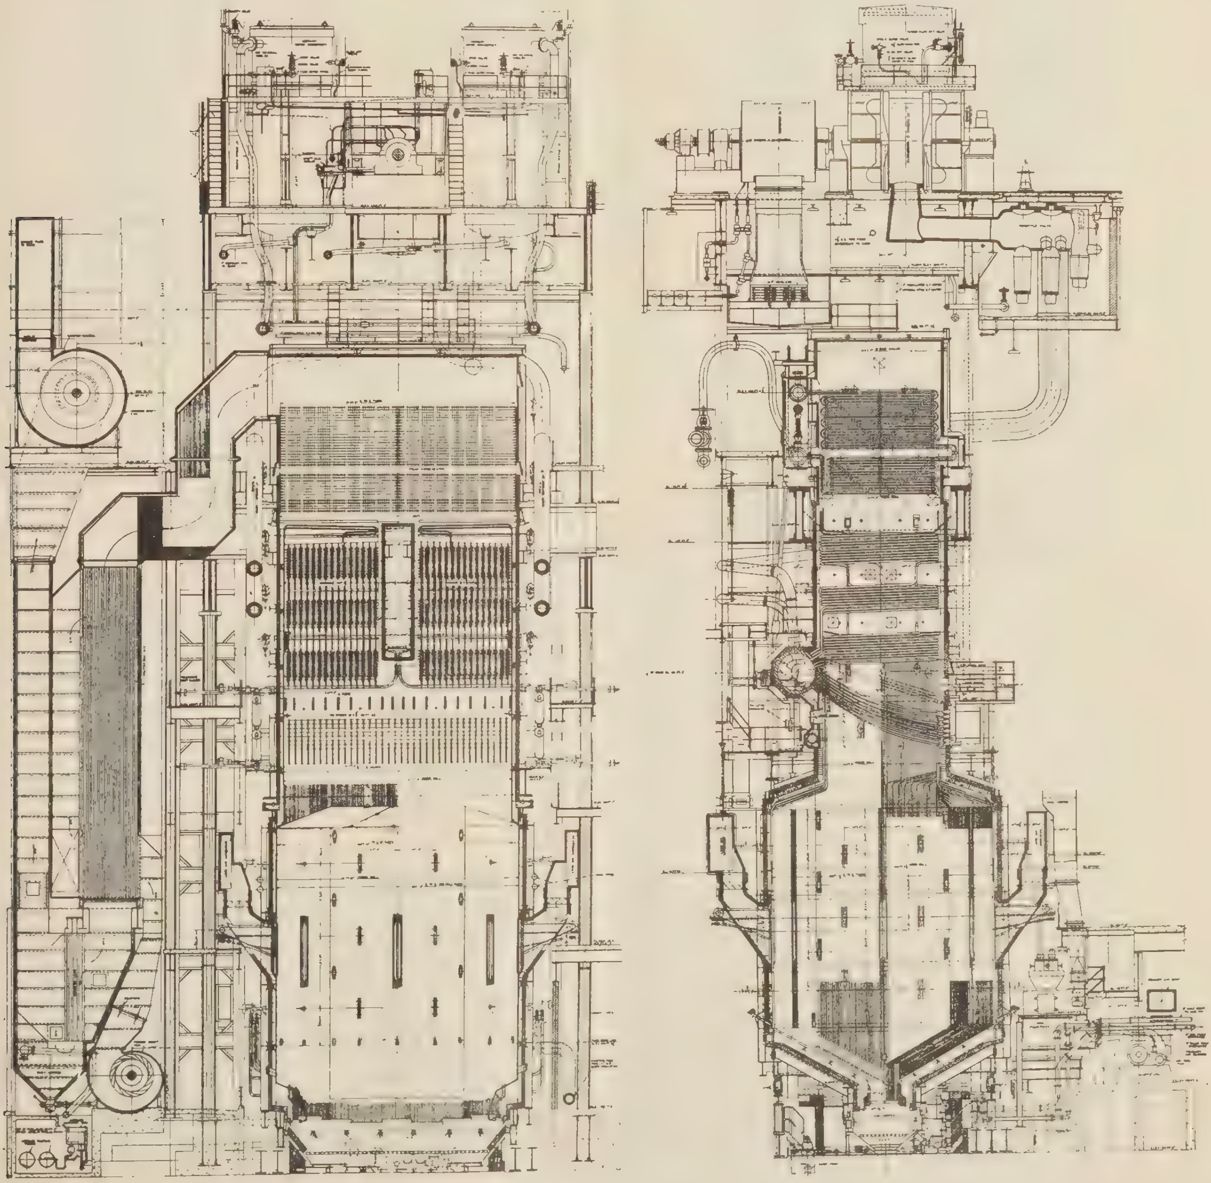

FIG. 9 VERTICAL SECTIONS THROUGH MERCURY BOILER AND TURBINE-GENERATING SET; KEARNY STATION OF PUBLIC SERVICE ELECTRIC & GAS COMPANY OF NEW JERSEY

lubricating oils. Its complete success as a new venture, designed and planned to incorporate all the known facts, made it appear that sufficient knowledge was at last available to expect predicted results.

Operating results from Schenectady, Marcus Hook, and Pittsfield indicated unquestionably that our chemical and metallurgical data were sufficiently correct to warrant the building of a replacement boiler for Kearny, capable of carrying rated output continuously. It would be necessary to apply accurately all the available knowledge of mercury, chemistry, metallurgy, and engineering to do the job successfully.

Fig. 10 Model of Mercury Boiler for Kearny Station
(Right-side section of tubes shown; scale 1 in. = 1 ft. Constructed by The Babcock & Wilcox Company.)

Rebuilt Mercury Boiler for Kearny Plant

The Kearny unit was rebuilt with complete success, Figs. 9 and 10, and its record of operation has rarely, if ever, been equaled by steam units of similar size. The new mercury boiler followed conventional steam-boiler designs and employed all the facts so carefully learned at Schenectady, Marcus Hook, and Pittsfield. Simple through-flow mercury circuits were employed, using fog-type convection surface to the limit of existing experience with the result that, of the 24,407 sq ft of mercury heating surface, 17,400 sq ft, or 71 per cent, was of the fog type, which is empty of liquid mercury at starting. The only liquid-filled tubes are those below the center line of the mercury drum, Fig. 9.

The octagonal furnace is approximately 26 × 28$^1/_2$ ft × 50 ft high inside the furnace, having a sloping bottom and a top covered by wide-spaced slag-screen tubes. The over-all height of the boiler is approximately 67 ft to the top of the fog tubes and 100 ft to the top of the steam superheater, Figs. 9 and 10.

All the furnace tubes are relatively small, varying from $^7/_8$ in. ID × 1$^7/_{16}$ in. OD to 1$^1/_8$ in. OD × 1$^{11}/_{16}$ in. ID in the slag screen, in order to reduce the mercury content of the boiler. Because these tubes must operate at metal temperatures of from 1050 to 1180 F and pressures of from 140 psi gage at the drum to 395 psi gage at the lower header, Croloy 5 MSi, a ductile chrome-alloy steel, was chosen as the best material from which to make the furnace and slag-screen tubes. Because of the lower metal temperature encountered in the 1$^7/_8$-in-ID fog convection tubes, Croloy 3 was used in the lower bank and Croloy 2 in the upper two banks of the 2$^1/_4$-in-ID tubes.

The 4-in-thick 54-in-ID carbon-molybdenum drum is 35 ft 6 in. long and operates at 150 psi gage, 985 F mercury temperature, as do the downcomers and vapor piping which also were made of the same material.

Of the 310,000 lb of mercury in the boiler, which is all below a 4-in. drum liquid level at starting, 41,000 lb ultimately is flowing through the fog tubes as a finely divided mixture of liquid and mercury vapor when the boiler is at full output or less. The fog surface only requires approximately $^1/_{20}$ of the mercury per square foot as the liquid region, indicating its great economic value. A boiler using all liquid-filled surface might be prohibitive in mercury cost.

Even though a boiler of like dimensions and operating temperatures had never before been built, using such quantities of alloy metals, assembled throughout by perfect welding, the unit went into service in May, 1940, and has operated almost continuously since at 20,000 to 21,000 kw either coal- or oil-fired, generating power at 9200 Btu per kwhr, the lowest Btu rate per kwhr in history, with only two short outages due to equipment failures, Fig. 11. The normal rated output of the unit is 21,000 kw per hr from the mercury-turbine generator and approximately 30,000 kw per hr from the by-product 365-psi-gage steam produced.

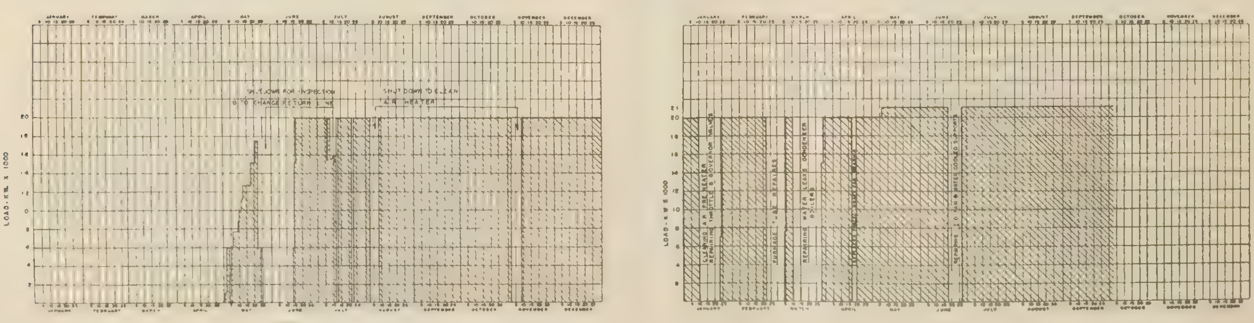

Fig. 11 Load Chart, Mercury Turbine, Kearny Generating Station of the Public Service Electric & Gas Company of New Jersey

Operating the New Unit

The operation of the new unit is extremely simple, requiring no more attention from the "operators" than similar steam equipment. Because of its high availability, the mercury-vapor plant has proved to be the most reliable generating equipment in the system. During more than 15 months of operation it has carried an average hourly load of 205 per cent of the national average for steam-generating units for 1940.

The scientists, chemists, and engineers can now produce predicted results. The successes at Schenectady, Marcus Hook, and Kearny can be duplicated over and over again, with ever-improving efficiencies. Mercury at Kearny now produces 1 net kwhr for 0.5 lb of fuel oil. If a new plant were built of similar capacity, the fuel burned to generate the same amount of power would be still less. If, in the future, mercury were used at 500 lb pressure and 1500 F temperature, the power could be produced at a fuel consumption of only 0.41 lb of oil per kwhr.

Because of a very valuable and somewhat unexpected development, resulting from the use of chemicals in the mercury, it is possible to design and build low-mercury-content boilers for any desired capacity at reasonable cost.

A Development Which Reduces Cost of Mercury Boiler

A tube surface properly wetted with treated mercury is coated with a tenacious film which because of high surface tension can be superheated considerably above its normal saturation temperature before becoming destroyed due to heat application, as long as the film is continuously supplied with other treated mercury as fast as loss is sustained by evaporation from the surface of the heated film. Such thermal action makes possible the use of large-diameter tubes, fed by relatively low-density mixtures, or a fog of mercury vapor and mercury droplets of the order of 5 parts of liquid to 1 part of vapor or less, by weight, with complete safety at high rates of heat input. As long as reasonable mixture velocities are maintained, the tubes may be operated in any position, flat, sloping upward or downward, or vertically in either direction, with no apparent limitation of size, shape, or length of the heated circuits.

About 71 per cent of the heating surface of the new Kearny boiler is of this type. It is believed possible to use upward of 90 per cent in future boilers with complete safety.

By taking full advantage of these new principles of boiler design, utilizing maximum rates of heat absorption throughout the boiler, made possible by the definitely controllable heat-absorbing properties of properly treated mercury in the boiler circuits, the mercury-vapor cycle offers an exceptionally economic and reliable method of generating light, heat, and power when and where it is needed.

Discussion

P. H. Hartung.[3] The writer's discussion of this paper and that by A. R. Smith and E. S. Thompson[4] deals entirely with the new mercury boiler at the Kearny generating station of the Public Service Electric & Gas Company.

The performance of the mercury unit to date has been most satisfactory. This is clearly shown in Fig. 11 of the paper. To complete the load chart, it should be extended at 21,000 kw to October 27, 1941. From May 5, 1940, the initial starting date, to October 27, 1941, the unit was in service 83.6 per cent of the time. During that time the average hourly load was 19,700 kw and the capacity factor 82.3 per cent.

The run from March 27 to October 27 is particularly noteworthy, for during that time the unit was in service 4786 hr of the total 5139 hr or 93.1 per cent, and carried an average load of 20,770 kw. In this span of 7 months, continuous operation was interrupted only twice, once because of bearing trouble on the forced-draft fan; and again to repair the induced-draft fan and make burner changes in the furnace. The last run was 121 days long with an average hourly load of 21,040 kw.

Since October 27, the unit has been out of service to make changes in the superheater to increase the steam temperature, to install rotary classifiers in the pulverizers, to continue with the removal of the bottom spacer plate in the condenser boilers, to install an automatic tube-temperature recorder, and to investigate the cause of an increase in the temperature of one tube. These changes were all designed to improve the performance of the unit as a whole and had been planned well in advance.

Up to March 7, 1941, the unit was oil-fired, with the exception of a few days in July, 1940, when the coal-firing pulverizing equipment was tried out. At that time it became clearly evident that it was impractical to attempt to fire coal until mechanical cleaning equipment was installed. The boiler is so constructed that it is impossible to clean it with hand lances; and it was thought that continuous firing with coal at full load would soon result in a shutdown for external cleaning.

Since the completion of the soot-blower installation in March, 1941, the boiler has been coal-fired exclusively with the exception of starting-up periods and the times when a pulverizer was out of service for cleaning or repairs. When coal firing was first started, it was thought that the boiler would slag up quickly and a very elaborate soot-blowing schedule was initially set up. However, for the first time, the boiler failed to come up to expectations and before long many of the blowers had been tagged out as unnecessary while others were operated only as conditions required. It was found, in fact, that until some slag has built up on the walls, coal firing is somewhat unstable even at full load. It is felt that changes made during the last outage will go far toward eliminating this instability and greatly improve coal-firing performance. It is interesting to note that since going over to coal firing, we have experienced no trouble whatsoever with plugging in the air preheater. During the first outage after coal firing was started, the preheater was washed but that was not considered necessary. Since then no effort has been made to clean the preheater.

The mercury unit while in operation must be checked regularly for magnesium and titanium concentrations in the mercury, the component elements of the gas evacuated from the condenser boilers, as well as the regular analysis of the water in the condenser boilers. The gas analysis, together with the rate of discharge, gives a constant check on the tightness of the negative-pressure side of the mercury system and, at the same time, gives a valuable lead in the location of possible sources of leakage. For instance, within certain limits, an increase in gas discharge, accompanied by an increase in oxygen content, indicates a leak external to the mercury system, i.e., in the air-removal system; whereas an increase in gas discharge without the oxygen showing up probably indicates leakage into the condenser boiler. The former does not present any hazard to operation. The latter, however, is quite serious as it can have a direct bearing on the concentrations of chemicals in the mercury and consequent wetting of the tubes. It is interesting to note that during the last run the average air leakage was 0.20 cfh.

The most important factor in operation is the control of the concentrations of magnesium and titanium in the boiler. Without proper concentrations, the tubes are in grave danger of overheating. During the starting-up period, analyses are made every

[3] Superintendent, Kearny Generating Station, Electric Generation Department, Public Service Electric & Gas Company, Kearny, N. J.

[4] This is a joint discussion of the present paper and the paper, "The Mercury-Vapor Process," by A. R. Smith and E. S. Thompson, appearing on page 625 of this issue of the Transactions.

4 hours, until the concentrations tend to level out, when the frequency is decreased. After a stable condition has been attained, analyses are made twice a day, i.e., one in the morning, and the other the last thing in the afternoon. The fact that the unit has been operating in a most satisfactory manner for some time does not warrant any relaxation of vigilance in this work. Three occasions have been experienced when, for no apparent reason, the magnesium concentration was sharply reduced to a value which would have made continued operation at full load hazardous to the equipment. The reason for these changes in concentration is not definitely known, but it is quite possible that they may be due to changes in furnace conditions which produced sudden changes in circulation rates, with an attendant stirring up of some oxides which had settled out. Fortunately, these decreases were detected early and were carefully followed by increasing the frequency of analysis. The addition of large dosages of magnesium in each case corrected the trouble. It may seem that a considerable amount of chemical work is involved, but the tests are relatively short and simple, and the normal routine can be easily handled by one man.

It has been very forcefully brought out that the operation of the boiler without knowledge of the temperature of the individual tubes in the furnace wall is most hazardous. When the unit first started up, readings of the thermocouples attached to the back of each of the tubes were made at $^1/_2$-hr intervals and served as an indication of the speed with which wetting took place. When stable conditions had been established, these readings were discontinued and we relied solely upon the automatic temperature recorder, which reads the temperature of one tube in every ten and gives an excellent indication of general conditions in the furnace wall. The failure of a wall tube through overheating demonstrated the need for regular readings of the temperature of all the tubes, and these have been taken manually, while automatic equipment was being developed. This equipment has now been installed but, because of the short period it has been in service, the writer is unable to say anything about its performance except that to date it has been successful.

The elapsed time from lighting a cold boiler to full load is approximately 16 hr. This time is divided roughly as follows:

To bring the boiler-drum pressure up to 75 psi, $6^1/_4$ hr.
To bring the machine up to speed and synchronize, $1^3/_4$ hr.
To raise the load to 6000 kw, 1 hr.
At the rate of 2000 kw per hr., to attain full load, 7 hr.

The reason for the rapid initial loading is to bring the convection surfaces, or "fog banks" as they are called, into action as soon as possible. Sufficient pumping does not take place under 6000 kw to keep these surfaces cool.

Although the station personnel has operated the mercury unit since its installation, it has only recently had the responsibility of the entire maintenance of the unit as well. Based on our experience to date, and that includes a wide range of items, several of which we hope will not require attention in the future, we do not believe that the mercury-unit maintenance is more difficult than that of a steam unit, or that it presents problems which a well-trained crew is not thoroughly capable of handling.

In the 18 months of operation of the new unit, it has been subjected to three severe operating disturbances, more than its predecessor experienced in its lifetime. The first of these occurred in July, 1940, when, during a severe lightning storm, the throttle tripped on overspeed while the unit was carrying full load. This electrical disturbance also took out the mercury-unit auxiliaries. Notwithstanding, the machine was back in service in 49 min. The second instance came 12 days later when a switchboard operator tripped out the field of the mercury generator instead of the steam-driven machine which was coming out of service. The mercury generator had been carrying full load, and the consequent by-passing of the high-pressure mercury vapor into one condenser boiler caused overheating which required about 3 hours to rectify. This shutdown served to indicate some weak points in our operating setup which were immediately corrected. The writer is confident that, were the same thing to happen now, the unit would be synchronized in a very short time. The last instance occurred in February, 1941, when a piece of steel lodged across the entrance of a wall tube and so restricted the flow of mercury to the tube that it burned thin and finally ruptured. To reduce the loss of mercury through the failed tube, the boiler was drained as far as possible through the emergency coolers into the main storage tank. The boiler which had been carrying full load was shut down and drained in 30 minutes.

No operating man wants emergency shutdowns but, in this case, they had a most beneficial effect. They proved that the boiler could "take it" and, together with its excellent performance and operating record, have created in the operating personnel a feeling of great confidence in the mercury unit.

H. J. Kerr.[5] Mr. Hackett's paper tells in a few simple words of the successful completion of a job which has required some thirty years of hard work by his organization, in which he has played a prominent part.

With the fact established that the mercury cycle was materially more efficient than the simple steam cycle, it remained to develop the apparatus that would make the utilization of this method possible.

One of the obstacles was the cost of mercury. Because of this factor, efforts were directed from the beginning to decreasing the internal volume of the boiler. Some of the early boilers, which were built by the company with which I am connected, were fitted with annular spaces for the mercury to pass through, $^1/_{16}$ in. wide. As the paper describes, an entirely new approach has been made to this problem, and the Kearny boiler is fitted with tubes having a minimum ID of $^3/_4$ in. In accomplishing this, the General Electric Company engineers have violated one of the most sacred traditions of boilermakers, in other words; they are deliberately designing a boiler to be operated with low water (i.e., low mercury), and with this condition they are operating the boilers successfully and without a mechanical pump.

Another obstacle was the solution of the steel of the boiler. The rate of solution at lower temperatures was not so rapid, but as the temperature increased so did the rate. Not only did this become serious from the standpoint of the loss of steel, but the resulting iron sludge led to overheated tubes and general interference with circulation. This situation can be appreciated when the size of the annular spaces of the older boilers is considered.

A third major obstacle was failure of the mercury to wet the tube surface, except when it happened to be in the humor to do it. A mercury tube would be tested one day and show a temperature differential of 25 deg, then a few days later, a similar test would show a differential of 200 deg. The overcoming of these two obstacles by treating the mercury with minute quantities of magnesium and titanium is an accomplishment that has made the mercury power cycle practical.

While in the past steel quality was a problem for the high temperatures required, satisfactory alloy steels are today available which have been proved. The Kearny unit is evidence of this fact.

After the years of effort and engineering research which have been expended on this method of making power, the company and the engineers who have made this possible are to be congratulated on their accomplishment.

[5] Executive Assistant, The Babcock and Wilcox Company, New York, N. Y. Mem. A.S.M.E.

While the paper in most part deals with mercury vapor as a means of making power, the advancements described are equally applicable to the use of mercury for process work, in which field it has already proved its value as a means of obtaining constant high-temperature conditions at low pressure.

H. E. Melton.[6] The author has outlined very clearly the necessity for developing a special chemical treatment for mercury boilers. That some treatment would be required to enable these units to operate successfully at high ratings became evident only after the mercury boiler was well established in the power and process industries. The effort expended by the General Electric Company in search of the answer has been of tremendous importance not only to company engineers, but to operators of the large power-generating units and to those utilizing mercury vapor as a heating medium in numerous processes.

Originally, we had the idea that the mercury boiler was the ultimate answer to the wish for a boiler that would be forever free from cleaning, scale troubles, and the necessity for chemical treatment. This idea had a rude awakening after about one year of operation at Hartford, and possibly two years after the first large process boiler was put into service at the Marcus Hook Refinery of the Sun Oil Company.

Experience at Marcus Hook with the Emmet porcupine-tube-type boiler closely paralleled that at Hartford. After approximately a year of service at relatively high temperatures, the heating surfaces in contact with hot liquid mercury would become free of oxides to the extent that at least partial wetting of the steel occurred. When this stage was reached, it was felt that the ideal was being approached.

Following this, however, there came, at more or less frequent intervals, certain tube failures which could not be attributed to any particular cause, unless it were poor circulation. In those days it was customary to blame circulation when steam boilers were in trouble, so at least in this respect we were being consistent with steam-boiler practice.

After several such failures, it became evident from inspection that the direct cause was restriction of vapor passages due to accumulation of an amalgam of oxides, pure iron, and mercury. It was found that metal from the lower portion of the tubes was being dissolved by the hot liquid. This metal, together with suspended oxides, was being redeposited near the upper end of the tubes. This accumulation would finally restrict circulation; the resultant overheating of the lower end of the tube would cause cracking, and a leak would develop.

The original attempt to clean a boiler mechanically, after removing liquid mercury, was such a task that subsequent cleanings were carried out by boiling the mercury off through a condenser to storage tanks and then pickling the unit with a hydrochloric-acid solution.

Until the inauguration of chemical treatment in 1938, each boiler was thus cleaned by pickling at intervals of $1^1/_2$ to 2 years.

Chemical treatment of the latest-design twisted-tube-type boiler, installed by The Babcock & Wilcox Company, which went into service in January, 1938, consists of introducing magnesium and titanium, as required to maintain an excess of a few parts per million in the boiler liquid. The capacity of the boiler and the amounts of chemicals used are small, as compared to Kearny or Schenectady. The heating surfaces under liquid are "silvered" and entirely wet by the mercury. The treatment apparently completely inhibits the dissolution of boiler metal by hot mercury.

The product of this treatment is a gray amalgam of mercury and magnesium-titanium oxides. As formerly was the case with the amalgam of mercury and iron, this would accumulate in the boiler, except for the fact that it is evidently being continually carried along as a dust with the vapors throughout the system, and is then washed back through the return lines with the mercury condensate. One portion of the return system is submerged below the mercury level in the boiler so that the line runs full of mercury. In this section, the velocity is quite low so that the entrained oxides separate out of the stream as a sludge and are trapped for periodic removal. This part of the mercury system is practically the only one that is ever opened at present. Cleanouts and traps which formerly were cleaned during each shutdown are now free of any accumulation.

The mercury side of the lubricating-oil plant at Marcus Hook is of all-welded construction, except for a few flanged cleanouts; there are very few valves and the system operates under pressure. There are no shaft seals to contend with as in a turbine installation and the problem of oxygen leakage, therefore, does not exist. Whenever the plant is shut down, the mercury side is allowed to cool, and it is then filled with nitrogen before any part is opened. In this way oxidation of chemicals, mercury, and equipment is kept to a minimum.

[6] Sun Oil Company, Marcus Hook, Pa.

A. J. Nerad.[7] The development of the mercury-vapor process for power generation, as the author in his interesting paper has shown, is full of many puzzling problems. The difficulty in discovering that mercury dissolves steel lay in the very slow rate of surface attack, about 2.5 mils per year at the mercury temperature of 500 C in the Hartford mercury-boiler tubes. This rate increases 5 times for every 100 C. The use of pickling agents for cleansing the mercury-boiler tubes before operation tended to mask the effect of the dissolving by the mercury. However, early in 1932, by microscopic examination of the surface of a piece of a core from a Hartford mercury-boiler-tube unit, dissolving of the steel by mercury was discovered.

Laboratory tests followed quickly. In a few months, an inhibitor had been found, the rates of dissolution of ordinary steel for temperatures up to 800 C had been established, and the somewhat limited increase in resistance to dissolution of some alloy steels observed. From that time on, the application of wetting agents and inhibitors to large mercury boilers was studied, until the very satisfactory magnesium-and-titanium addition to the mercury was developed. The success of this chemistry on mercury boilers is largely due to the efficient efforts of the engineers who obtained in commercial units conditions comparable to those obtained in the near-test-tube-size laboratory boilers holding approximately $^1/_{100,000}$ of the mercury of a large unit.

Author's Closure

The control of air and water leakage into the vacuum spaces of the mercury turbines and condenser boilers is essential for proper control of the magnesium and titanium used for mercury treatments. In the two large plants in Schenectady and Kearny, the consumption of magnesium metal is at a rate of about 1 lb every 200 hr, with the titanium usage varying from 2 lb per day at Kearny to 2 lb per week in Schenectady.

Both metals are applied to the boiler mercury through a simple "locking" device by the mercury condensate from the condenser boiler. The magnesium metal dissolves readily in the mercury condensate, which is at a temperature of approximately 450 F. The titanium metal dissolves in the magnesium-treated mercury in the boiler.

The ultimate efficiency of the binary mercury cycle cannot be predicted, as it depends largely upon metallurgical developments to produce steels capable of operating at temperatures in the order of 1500 F and pressures of 500 psi or more. However, with

[7] Research Laboratory, General Electric Company, Schenectady, N. Y. Mem. A.S.M.E.

existing materials and operating experience, large power units can be built having approximately 41 per cent thermal efficiency.

Wear and erosion of the turbine parts are negligible, giving long life and good reliability, as is borne out by operation in all the mercury plants. The 10,000-kw Hartford turbine has operated some 80,000 hr since it was last opened for inspection, and the Schenectady turbine has not been taken down for inspection since the summer of 1935, with some 47,000 hr of operation in that period. No bucket replacements have been made since its installation in 1932. The Kearny turbine was opened in 1938 for alterations to increase its capacity, but no replacement parts were required.

The Flow of a Flashing Mixture of Water and Steam Through Pipes

By M. W. Benjamin[1] and J. G. Miller,[2] Detroit, Mich.

This paper presents a method of designing piping to carry a flashing mixture of water and steam. An example of such piping is the cascade drain lines between feedwater heaters. The flow formula is based on a thermodynamic analysis of the problem, and the necessary coefficients of friction have been determined from tests. Calculations indicate the possibility of a critical-pressure condition at the end of a pipe carrying a flashing mixture. Each of the drain lines included in the study exhibited this phenomenon. The paper also includes a discussion of erosion of elbows in pipe lines carrying a flashing mixture, and suggests designs for minimizing or preventing failures from this cause. A criterion for predicting the comparative life of different sizes of pipes for a given line carrying a flashing mixture is set up on the basis of the total force on the elbows due to the momentum of the flowing fluid. An example of the application of the proposed flow formula to an actual design case is given in the Appendix.

During recent years power-plant engineers have become more and more interested in the flow of a flashing mixture of water and steam through pipes in connection with the design of cascade drain lines between extraction feedwater heaters. Several such lines, designed by the rule-of-thumb methods that have been used heretofore either have caused trouble with erosion in the elbows or have been unnecessarily large and expensive.

The case of fluid flow, involving a flashing mixture of water and steam, can readily be analyzed on the basis of thermodynamic equilibrium. However, to derive a usable formula for design purposes, it was necessary to obtain test data from which coefficients of friction could be determined. Since it was thought such tests might well include the friction effect of elbows, valves, and tees, it was decided to conduct an experimental investigation using existing cascade drain lines, particularly those in which trouble with erosion was being experienced.

While the data presented in this paper are not complete, sufficient information is given to be of assistance in the design of pipe lines to carry a flashing mixture of water and steam. An analysis is made of the flow in several cascade drain lines in order to learn why some have failed because of erosion while others have not. Several other factors of particular interest in designing pipe lines to carry water and steam are also discussed.

More complete results could have been obtained by means of special equipment, but the extra cost was not considered warranted by the amount of data which could be obtained by such equipment over that which could be obtained from tests of the existing drain lines.

In this paper the term "flashing mixture of water and steam" is used in preference to "boiling water" as used by earlier writers since it is considered to be more definite and possibly more accurate. It is used to denote a mixture of saturated water and steam in which additional steam is continually being formed at the expense of the sensible heat in the water, made available as a result of the continuing reduction in pressure as the mixture flows down the pipe.

Flow of a Flashing Mixture of Water and Steam Through Pipes

When saturated water flows from a receiver at one pressure through a throttling valve (or an orifice) and pipe to a receiver at a lower pressure, the following changes take place:

(*a*) As the pressure decreases the saturation temperature also decreases, and the enthalpy of that part of the fluid that remains liquid water is reduced in proportion to the drop in temperature.

(*b*) The heat liberated by the reduction in enthalpy of the water is all absorbed as latent heat in evaporating part of the water.

(*c*) The specific volume of the mixture of water and steam increases rapidly as steam is produced.

(*d*) The energy which becomes available with the decrease in pressure is expended in accelerating the mixture of water and steam and thus increasing its kinetic energy.

For example, if saturated water flows from receiver A, Fig. 1, through the throttling valve and the pipe into the lower-pressure

Fig. 1 Schematic Diagram Illustrating Flow of Flashing Mixture of Steam and Water Through a Pipe Connecting High- and Low-Pressure Receivers

receiver B, some of the water will flash into steam immediately following the valve at point 1, and an increasing amount of water will flash into steam as the mixture flows toward receiver B. The amount of steam flashed at point 1 in the pipe depends upon the initial temperature in A and the pressure P_1. Pressures P_1 and P_2 (at points 1 and 2) are functions of the initial saturation temperature in A, the weight of mixture flowing through the pipe, the size and length of the pipe, and in some cases the pressure in B.

Equations of Flow. According to the continuity equation

$$V = \frac{wv}{A} \qquad [1]$$

where V is the velocity in ft per sec; v the specific volume in cu ft per lb; w the weight flowing in lb per sec; and A the cross-sectional area of the pipe in sq ft.

Since w/A is constant for flow through a pipe, the velocity and, therefore, the kinetic energy at any point along the pipe during expansion depend upon the specific volume of the mix-

[1] Engineer, Engineering Division, The Detroit Edison Company. Mem. A.S.M.E.

[2] Engineer, Engineering Division, The Detroit Edison Company. Jun. A.S.M.E.

Contributed by the Power Division and presented at the Annual Meeting, New York, N. Y., December 1–5, 1941, of The American Society of Mechanical Engineers.

ture. The rate of increase of the velocity and kinetic energy during the expansion is a function of the rate at which the specific volume increases. Fig. 2 shows an example of the increase in specific volume of a flashing mixture of water and steam for an isentropic expansion from an initial pressure of 15 psi abs. This curve shows that, if saturated water flowing through a pipe expands from 15 psi abs to 3 psi abs, the velocity at the end of the pipe, due to the increase in specific volume of the flashing mixture, would be 475 times the velocity of the water at the entrance.

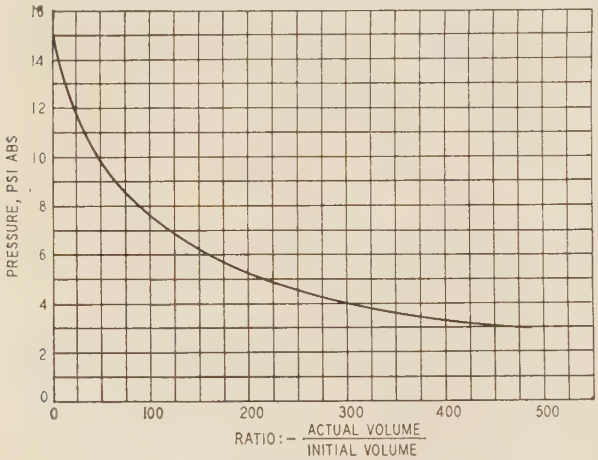

Fig. 2 Increase in Volume of Flashing Mixture of Water and Steam During Isentropic Expansion From Saturated Water at 15 Psi Abs

A mixture of saturated water and steam in which additional steam is continually being flashed is not strictly an elastic fluid, although it is believed to behave in much the same way and will, therefore, be treated accordingly. The general energy equation for the flow of fluids can be expressed in the form

$$vdP + \frac{VdV}{g} + \frac{KV^2}{2gD}\,dx = 0 \qquad [2]$$

in which v is the specific volume in cu ft per lb; P the pressure in lb per sq ft; V the velocity in ft per sec; D the diameter of the pipe in feet; K the friction factor; and x the distance in ft through which the mixture flows. This equation may be derived either from the energy relation as given by Goodenough[3] or by using Bernoulli's theorem.

From Equation [1] $(w/A)v$ can be substituted for V in Equation [2] to give

$$vdP + \left(\frac{w}{A}\right)^2 \frac{vdv}{g} + \frac{K}{D}\left(\frac{w}{A}\right)^2 \frac{v^2}{2g}\,dx = 0$$

or

$$\frac{1}{v}\,dP + \left(\frac{w}{A}\right)^2 \frac{1}{g}\frac{dv}{v} + \frac{K}{D}\left(\frac{w}{A}\right)^2 \frac{1}{2g}\,dx = 0$$

substituting ρ for $1/v$ and integrating

$$\int_{P_1}^{P_2} \rho dP - \left(\frac{w}{A}\right)^2 \frac{1}{g}\int_{\rho_1}^{\rho_2}\frac{d\rho}{\rho} + \left(\frac{w}{A}\right)^2 \frac{1}{2g}\frac{K}{D}\int_0^L dx = 0$$

or

$$\int_{P_1}^{P_2} \rho dP + \left(\frac{w}{A}\right)^2 \frac{1}{2g}\log_e\left(\frac{\rho_1}{\rho_2}\right)^2 + \left(\frac{w}{A}\right)^2 \frac{1}{2g}\frac{KL}{D} = 0 \qquad [3]$$

The density (or specific volume) used in Equation [3] is determined by assuming isentropic expansion in the pipe. In the actual expansion, the fluid friction and pipe friction impose a throttling action which causes the expansion to depart to some extent from the isentropic. However, in the usual case, the density of the mixture will be very nearly the same whether an isentropic expansion or a constant-enthalpy expansion is assumed.

No attempt has been made in developing Equation [3] to in-

clude the effect of a static head due to a vertical section of pipe. In most of the heater drain lines encountered by power-plant engineers, a major part of the pipe is horizontal; therefore the effect of the static head is of secondary importance compared to the thermodynamic head.

Before Equation [3] can be used, values for the friction factor K must be determined experimentally. All of the other quantities in the equation will be given for each design case under consideration.

Experimental Investigation of Flow of a Flashing Mixture of Saturated Water and Steam Through Pipes

The experimental work was carried out on some of the heater drain lines on 30,000-kw and 60,000-kw steam turbines at the Connors Creek Power Plant. Schematic sketches of the drain lines tested are shown in Figs. 3, 4, and 5.

During each test, temperature measurements were taken at various points along the drain-line piping, as shown in the sketches and, since the flashing mixture in the pipe was a mixture of saturated water and steam, the pressures at the various points were obtained from steam tables.[4] The quantity of drains flow-

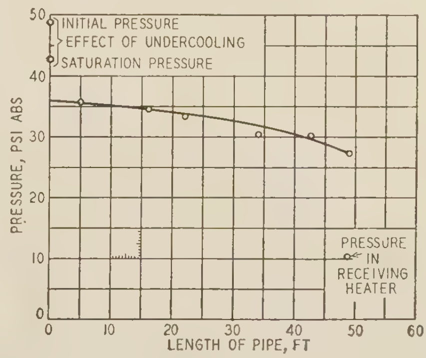

Fig. 7 Measured Pressures Along Drain Line Shown in Fig. 4, as Found in Run No. 1 Given in Table 2

ing through the line was determined by heat-balance calculation.

All temperatures were determined with iron-constantan thermocouples and a temperature indicator of the potentiometer type. It is believed that the measured temperatures are in error by no more than ±1 F. The design of the thermocouple well is shown in Fig. 6.

Test Results

Included in the results of the tests are the pressures at various points along the drain lines, the weight flowing through the pipe, and the values for the friction coefficient K from Equation [3]. In determining the values for K, the length of pipe used in Equation [3] was the equivalent length determined by use of data from various sources.[5]

Table 1 gives the results of a test of the drain line illustrated in Fig. 3. This test was conducted primarily to verify the existence of a critical-pressure condition in the end of the pipe or at the entrance to the low-pressure receiver. The weight of mixture flowing through the pipe was estimated from previous test data, and the values determined for K have been given here mainly for the record.

Table 2 gives the results of a test of the drain line illustrated in Fig. 4. This test was conducted to determine the friction factor K. Fig. 7 shows the pressures at the various points along the pipe for run No. 1 plotted against the equivalent length.

Table 3 shows the results of a test of the drain line illustrated in Fig. 5. This drain line, which operates with about the same initial and final pressures and quantity of mixture flowing as the one illustrated in Fig. 4, but which is somewhat different in piping arrangement, was investigated because of trouble with the float-operated drainer trap.

Analysis of Results

As far as the authors know only two other writers[6,7] have discussed the subject of the flow of a flashing mixture of water and steam through pipes and only one of them offered any test results.[7] His investigation consisted of a single test, and it was felt that additional test data were needed to establish a basis for design. As previously stated, the results of the tests given by the authors in this paper are not complete; however, they do include data that apparently are not available elsewhere, and it is for this reason that this paper has been written. These data offer assistance in designing piping to carry a flashing mixture of water and steam, and it is hoped that other investigators will publish such information as they may have on the subject to provide a still better basis for design work.

Critical Pressure at End of Pipe. It has been known for some time that when an elastic fluid flows through a pipe a critical pressure will occur at the end of the pipe when the ratio of the velocity to the specific volume is a maximum. This critical pressure with an elastic fluid, such as steam, occurs when its velocity equals the velocity of sound in the fluid.

It is interesting to note that a critical-pressure condition can also occur when a flashing mixture of water and steam flows through a pipe, as shown by the test results in Tables 1, 2, and 3. Since the velocity of sound in a mixture of steam and water is not known, it is impossible to state whether or not the velocity attained by the mixture when the critical-pressure condition occurs is that of sound. It may be stated, however, that the critical pressure in the end of the pipe is reached when the increase in energy made available by an increment drop in pressure balances the resulting increase in kinetic energy and the increase in friction. From Equation [3], this relation can be expressed

$$\left(\frac{w}{A}\right)^2 \frac{1}{2g}\log_e\left(\frac{\rho_1}{\rho_2}\right)^2 + \left(\frac{w}{A}\right)^2 \frac{1}{2g}\frac{KL}{D} = 144\int_{p_1}^{p_2} -\rho\, dp$$

or

$$\left(\frac{w}{A}\right)^2 \frac{1}{2g} \times \frac{1}{144} = \frac{\displaystyle\int_{p_1}^{p_2} -\rho\, dp}{\log_e\left(\dfrac{\rho_1}{\rho_2}\right)^2 + \dfrac{KL}{D}} \qquad [4]$$

in which ($p \times 144$) has been substituted for P in Equation [3].

Fig. 8 is a graph of solutions of Equation [4] for various downstream-end pressures, assuming a fixed initial pressure of 35 psi abs. As shown by the curve, the maximum value of $\left(\frac{w}{A}\right)^2 \frac{1}{2g} \times \frac{1}{144}$ and therefore the maximum capacity of the pipe is reached when the downstream-end pressure is about 22 psi abs. From

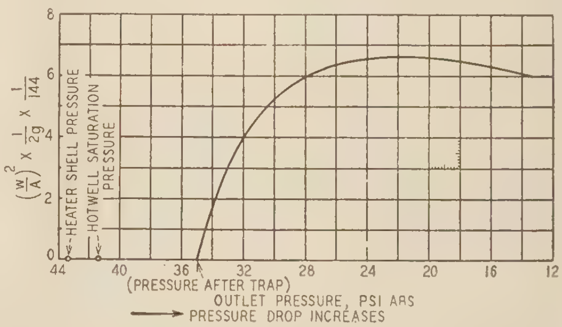

Fig. 8 Illustration of Graphical Method Used in Connection With Equation [4] to Determine Pressure After Trap and End, or Critical Pressure, in a Pipe Carrying Flashing Mixture of Steam and Water

(The pipe size in this case is 4 in., and the equivalent length following the trap is 90.3 ft. The value of K is considered as 0.0120 and w equal to 22.2 lb per sec.)

Table 3 and Fig. 5, it is seen that the 22-psi-abs downstream-end pressure is the critical pressure found on test at the end of the line, and the 35-psi-abs upstream pressure is that found on test near the outlet of the trap, while the flow of 22.2 lb per sec through a 4-in. pipe corresponds to the maximum value of 6.65 shown in Fig. 8, for $\left(\frac{w}{A}\right)^2 \frac{1}{2g} \times \frac{1}{144}$. In this calculation, which is given in detail in the Appendix, the equivalent length was 90.3 ft and the value for K was taken as 0.0120. From this example, it is seen that, when the saturation temperature, quantity of the water, and length and diameter of the pipe are known, it is possible by use of Equation [4] to determine the critical pressure at the end of the pipe, and the initial pressure following the throttling valve or orifice. Also Equation [4] can be used to determine the best pipe size when the saturation temperature, quantity of saturated water, and the length of the line are known.

Friction Factor, K. The friction factor for the flow of a mixture of water and steam through a pipe in which a critical-pressure condition exists at the end of the pipe was found to vary from 0.0116 to 0.0131, see Tables 2 and 3. In his test Bottomley[7] found the friction factor to be 0.0120 which compares favorably with the values found by the authors.

[a] Test results; all others are calculated.

In studying these results it is important to keep in mind that all the tests were conducted with existing installations of 4-in. pipe and for a limited number of pressure combinations. To obtain complete information concerning the friction factor for the flow of a flashing mixture of water and steam through pipes, it would be necessary to investigate the flow through several sizes of pipes, with several pressures in the low-pressure receiver for each of a large number of initial pressures in the high-pressure receiver, and with various quantities for each pipe size and each pressure combination. To conduct such a test, it would have been necessary to build special test equipment involving the expenditure of more time and money than was believed warranted by the importance of the authors' particular problem. A value of 0.0120 for the friction factor will give results that are sufficiently accurate for many design purposes.

Design of Pipe Lines to Carry a Flashing Mixture of Water and Steam

Past practice in the design of pipe lines to carry a flashing mixture of water and steam has depended more upon the judgment of the designer than upon any actual information. For instance, some designers have chosen pipe sizes to give a certain water velocity, neglecting the effect of steam forming in the line, while others have gone to the opposite extreme and chosen excessively large pipes. A line designed by the latter would usually be unnecessarily expensive, while one designed by the former would be liable to troubles with erosion in the elbows and in some cases operating difficulties with float-operated drainers.

Erosion in Drain-Line Piping. The results of a study of the flow characteristics through several existing cascade drain lines are given in Table 4. It should be noted that not all of these lines have a critical pressure at the end of the line, and neither have all the lines had an elbow replaced. The cause of erosion in drain lines has not definitely been determined; however, there is some indication that it is the result of cavitation which occurs at the elbows due to the momentum of the flowing mixture. For instance, when a saturated mixture of water and steam flows around a bend, the increase in pressure at the outer wall, which results from the change in direction of flow, will cause steam bubbles to collapse, constituting the cavitation condition.

For design purposes it is important to be able to determine in advance whether a line carrying a mixture of water and steam will have a satisfactory life or whether it will wear out in a short time due to erosion. Three methods for correlating experience with erosion have been investigated, namely, (*a*) force on elbows due to the momentum of the flowing mixture $\left(1.414\,\frac{wv}{g}\right)$, (*b*) kinetic energy $\left(\frac{wV^2}{2g}\right)$, (*c*) the product of the velocity head and the density $\left(\rho\,\frac{V^2}{2g}\right)$. Of these (*a*) seems to give the most consistent results based on experience with existing lines, as shown by the data given in Table 4. For example, all the lines except three, having a force on the elbow at the end of the line of 75 lb or more, have had at least one elbow replaced. Two of the exceptions have been in service only a short time, while the other is subject to corrosion. All of the lines with a force below 75 lb have not as yet failed by erosion. The methods (*b*) and (*c*) do not give results that are consistent in all cases with experience, as the reader can observe by comparing the values for lines Nos. 4 and 8 in Table 4.

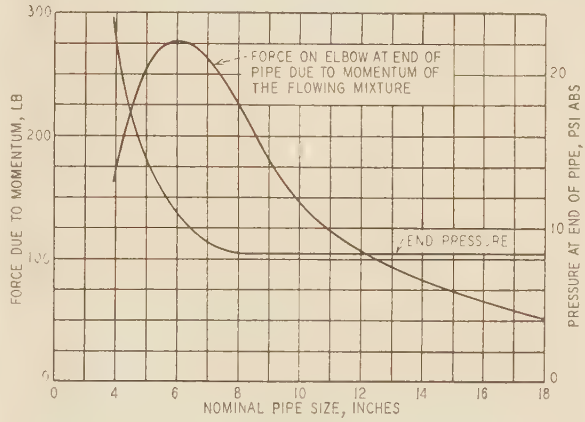

Fig. 9 Curves Showing Relation Between Downstream-End or Critical Pressure, Force Due to Momentum, and Pipe Size for Particular Design

(Case in which the weight of flashing mixture flowing is 22.2 lb per sec, and the initial saturation pressure of the water is 41.4 psi abs.)

It is important to note that in some cases increasing the pipe size will not always result in a lower velocity at the end of the line. As an example, take line No. 14 in Table 4, for which test data are given in Table 3. If the pipe in this line is increased from a 4-in. to a 6-in. size, the pressure at the end of the line will be about 11 psi abs or 2.5 to 3 psi above the pressure in the low-pressure receiver. The specific volume then is 2.56 cu ft per lb, the velocity is 285 fps, and the force due to the momentum of the flowing mixture at the end of the line is 277 lb.

Fig. 9 shows how the force due to momentum varies for different pipe sizes, as well as the pressures at the end of the line. From the standpoint of this force, it is seen that the 4-in. pipe is better than either the 6-in. or 8-in. pipe. Also in order to get the value of the force due to momentum down to about 75 lb it would be necessary to use a 14-in. pipe, as shown in Fig. 9. It

is probable, however, that the larger sizes of pipes, because of the greater projected area at the elbows, will stand a considerably greater total force than pipes ranging up to 8 in. diam. For this particular line, it would probably be necessary to use at least a 10-in. pipe to reduce the erosion to the point where it would not be objectionable.

In many lines it is desirable to use the smaller-size pipe and to resort to various schemes for retarding erosion. One scheme, which has been tried with only partial success, is to install tees in place of elbows in such a manner that the momentum of the flowing mixture will be partially dissipated against a blind flange. Another scheme is the installation of elbows with extra-heavy walls. In line with this it should be pointed out that cast-iron elbows, because of thicker walls, last longer than steel elbows. To avoid a forced shutdown of a turbine, telltales can be installed on the elbows to indicate by a leak when the wall is getting thin. Each telltale should be equipped with a valve which can be closed to permit the elbow or tee to be replaced at a convenient time.

Another scheme for minimizing erosion which has been considered is to separate the trap from its usual direct connection to the float operator, and move the trap proper to the downstream end of the drain line. The trap would then be actuated by the remote float through a mechanical or hydraulic linkage. This remote-control arrangement was not favored, however, because it would complicate the heater layout with additional control lines.

Whenever feasible the use of orifices[8] in place of float-operated traps for draining feedwater heaters offers another solution to the erosion problem. By installing the orifice near the end of the drain line so it will discharge into the low-pressure heater through a tee, as shown in Fig. 10, the erosion can be concentrated on the blind flange and in the tee, which can be examined and replaced if necessary whenever the turbine is down for inspection. This scheme has the additional advantage that smaller-size pipe can be used than would be possible if the orifice (or trap) were located at the beginning of the line.

[8] "The Flow of Saturated Water Through Throttling Orifices," by M. W. Benjamin and J. G. Miller, Trans. A.S.M.E., vol. 63, July, 1941, pp. 419–426.

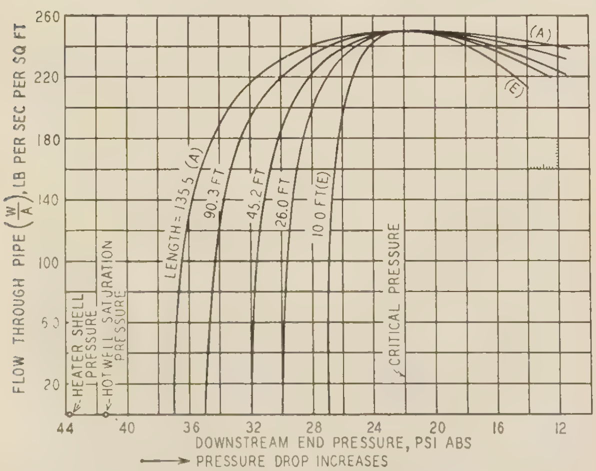

Fig. 11 Curves Showing Relation Between Pressure Following Trap, Downstream-End or Critical Pressure, and Length of 4-In. Drain Line for Constant Flow of 22.2 Lb Per Sec and Saturation Pressure of 41.4 Psi Abs in Hot Well of Upstream Heater

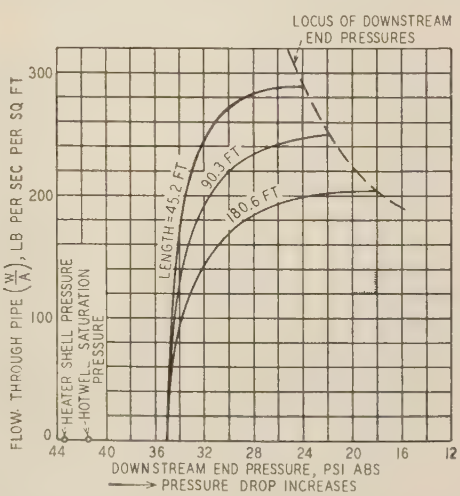

Fig. 13 Curves Showing Relation Between Capacity and Length of Pipe Following Trap, With Constant Initial Pressure After Trap and Constant Hot-Well Saturation Pressure in Upstream Heater

Effect of a Variation in Length on Flow Through Pipes. The effect on the flow characteristics of varying the length of pipe is mainly of interest in lines where the combination of flow and initial temperature is such that a critical-pressure condition will exist at the end of the line. If for example several lengths are assumed for the drain line, shown in Fig. 5 (No. 14, Table 4) while maintaining a constant flow of 22.2 lb per sec it is seen in Fig. 11 that the critical pressure is constant, but the pressure at the beginning of the line (immediately following the trap) varies from 27 psi abs for a length of 10 ft to 37 psi abs for a length of 135.5 ft. This variation of initial pressure with length is also shown in Fig. 12 along with the pressure drop available for forcing the water through the trap. For instance, for a length of 90 ft, which is the installed equivalent length of this line, the available drop is 8.4 psi. The trap as originally installed did not function properly at high loads on the turbine. An investigation showed that, because of the head required to push the water from the heater hot well to the trap, the float chamber on the trap was only half-full, or the trap valve was only half-opened, when the heater flooded, and the available pressure differential of 8.4 psi was not great enough to overcome the friction in the half-opened valve. This trouble was overcome by connecting the float chamber directly to the hot well of the heater, thus making the float respond directly to the water level in the hot well. There were two other possible solutions to this problem, however. One was the readjustment of the linkage between the float and the valve so that when the float chamber was half full of water the valve would be wide open. This solution was discarded mainly because it necessitated the installation of a stop to prevent the valve from lifting out of the seat. The other solution was to install 6-in. pipe or larger in place of the 4-in. pipe. With a 6-in. pipe the pressure following the trap valve would be about 19 psi abs, giving a pressure drop across the valve of approximately 25 psi. However, this scheme has the disadvantage of being subject to even more severe erosion than exists in the 4-in. pipe, as shown in Fig. 9.

If the initial temperature of the saturated water and the pressure of the mixture immediately following the trap are held constant, an increase in length of pipe results in a decrease in capacity and critical pressure. This relationship is illustrated in Fig. 13, for the drain line shown in Fig. 5 (No. 14, Table 4). It is interesting to note that the curves in Fig. 13, are similar to those for steam, showing the relationship between pressure drop, length of pipe, and weight of steam flow.[9]

Conclusions

For practical purposes a flashing mixture of water and steam flowing through a pipe can be treated as an elastic fluid. The results of tests show that a critical-pressure condition can exist in the end of a pipe carrying a mixture of water and steam, which is similar to the critical-pressure condition that will exist in a line carrying steam (or any other elastic fluid), in which the pressure drop in the pipe is sufficient to produce an acoustic velocity. Whether or not the velocity of a mixture flowing through a pipe having a critical-pressure condition is the acoustic velocity is a question that cannot be answered until more is known about the velocity of sound through a mixture of a liquid and vapor. The existence of a critical-pressure condition in a pipe carrying a mixture of water and steam depends upon the combination of the following factors: (*a*) The initial saturation temperature of the water leaving the high-pressure receiver; (*b*) the quantity flowing; (*c*) the size and length of the pipe; (*d*) the pressure of the receiver into which the pipe discharges.

It is important to keep in mind that the data presented in this paper are not complete, and the authors hope that other investigators who have the proper testing facilities will be encouraged to gather more information concerning this subject. The data obtained in the authors' tests, however, are useful in making calculations from which pipe lines carrying a flashing mixture of water and steam can be designed to minimize erosion in the elbows, while avoiding the use of unnecessarily large pipe. Similarly, the data are helpful in determining the loss of pressure in the piping adjacent to an orifice or float-operated trap, so that a proper size of orifice can be provided, or so that sufficient pressure differential across the trap is assured.

While the data presented in this paper concern only the flow of a flashing mixture of water and steam, it seems probable that the analysis given here would be applicable to the flow of any flashing mixture of a liquid and its vapor. For the latter, however, it might be necessary to determine new values for the friction coefficient.

q = quality of steam
t = temperature, F
v = specific volume, cu ft per lb
v_m = specific volume of mixture of water and steam, cu ft per lb
V = velocity, fps
w = flow of mixture of water and steam, lb per sec
x = distance to any point along pipe, ft
ρ = density, lb per cu ft

Keenan and Keyes Steam Table nomenclature for Table 5.

Example to Illustrate the Solution of Equation [4]

In order to solve the equation

$$\left(\frac{w}{A}\right)^2 \times \frac{1}{2g} \times \frac{1}{144} = \frac{\int_{p_1}^{p_2} - \rho dp}{\log_e \left(\frac{\rho_1}{\rho_2}\right)^2 + \frac{KL}{D}}$$

the densities of the mixture for various pressures must first be determined. Table 5 shows the method of calculating the densities for constant-entropy expansion for an initial temperature 269.3 F, or saturation pressure of 41.4 psi abs (see Table 3). Fig. 14 shows how these densities vary as the pressure decreases.

The integral $\int_{p_1}^{p_2} -\rho dp$ can best be evaluated arithmetically, since, to integrate directly, it would be necessary to find the equation of the curve in Fig. 14. The arithmetical integration is shown in Table 6, together with the solution of Equation [4]. This shows that, for an initial pressure, following the trap, of 35 psi abs and a downstream-end pressure of 22 psi abs, the value of $\left(\frac{w}{A}\right)^2 \times \frac{1}{2g} \times \frac{1}{144}$ is 6.64 (see also Fig. 8), which corresponds to a flow of 22.2 lb per sec through a 4-in. pipe.

It should be pointed out that it usually requires at least three trials to find a solution. For instance if the initial pressure p_1 had been chosen as 36 psi abs the maximum value of $\left(\frac{w}{A}\right)^2 \times \frac{1}{2g} \times \frac{1}{144}$ would have been greater than the required value of 6.64.

Discussion

W. T. Bottomley.[10] The Society has granted the writer permission to discuss, in conjunction with this current paper, a paper[11] which the authors previously presented.

Dealing first with their previous paper, the authors do not appear to have fully understood the data which the writer gave in his paper,[7] or they would have realized that their inference, that there is no evidence of a critical pressure in sharp-edged orifices when passing saturated water, is probably not correct.

The orifice the writer used was not sharp-edged but was a converging nozzle, having a cold-water discharge coefficient of nearly unity and was formed by drilling a hole in a $^1/_2$-in. plate, forming a well-rounded entry.

The pressure at the discharge side of the orifice, as measured by the temperature of the water, was not atmospheric pressure but was about 45 to 50 per cent of the initial saturation pressure.[12] Although the final discharge pressure at the other side of the heat exchanger was atmospheric pressure, the resistance through the heater, because of the large volume of flashing steam and water, accounted for the high back pressure at the nozzle discharge.

The writer did not assume that there was a critical pressure at the throat but deduced the fact from the results of the experiments. The last line in Table 1 of the writer's paper[7] gives the estimated throat pressure calculated from the discharge rate, assuming no vaporization before the throat and shows that the throat pressure was well above the pressure on the discharge side. The initial pressures were 48 to 64 psi abs, and the calculated critical pressure at the throat was about 67 per cent of the initial pressure.

Although these conditions were different from those of the authors', yet Fig. 2, of their paper, shows that the maximum discharge rates are in agreement; but for the sharp-edged orifice, it was necessary to drop the back pressure to zero to obtain the maximum discharge; whereas, with a nozzle the maximum discharge was obtained with a much higher back pressure.

At first sight, it may appear that the agreement of the maximum flow of saturated water through converging nozzles, with the maximum flow through sharp-edged orifices, is a coincidence, but the writer proposes to show that it is an indication there is a

[11] "The Flow of Saturated Water Through Throttling Orifices," by M. W. Benjamin and J. G. Miller, Trans. A.S.M.E., vol. 63, 1941, pp. 419–426.

[12] Second, third, and last lines of Table 1, reference 7.

critical pressure at the throat of the flow through the sharp-edged orifice.

The authors point out that, when the back pressure on the discharge side of the sharp-edged orifice is nil, the illustrations in Fig. 11 indicate that flashing occurs close to the downstream face. From this it may be inferred that no vena contracta is formed and therefore the discharge coefficient of the orifice under these conditions is practically unity. From the flows given in Fig. 7 for different initial pressures, when the back pressure is nil, the critical pressure at the throat can be calculated by Equation [1], assuming unity discharge coefficient, and is found to be from 63 to 69 per cent of the initial pressure, and is the same as that obtained at the throat of the nozzle.

The same argument applies to the flow of steam through sharp-edged orifices and nozzles, as shown in Fig. 12 of the authors' first paper.[11] It is not a coincidence that the maximum discharge is the same, but it indicates the same critical pressure at the throats.

If there is a critical pressure in the flow through sharp-edged orifices, the formulas in Equation [2] for the flow and the discharge coefficient, shown in Fig. 13, do not apply when the back pressure is below the critical pressure.

It was suggested in the writer's paper[7] that the excessive flow obtained, compared with the flow indicated by theory assuming thermal equilibrium, was due to the effect of surface tension, and that the critical pressure obtained indicated that the size of the bubbles which form at the throat is of the order of 0.001 mm.

It is interesting to note that the additional experimental data given in the present paper agree with the test data which the writer gave and confirm the fact that the flow through pipes can be calculated from the theory, assuming thermal equilibrium, and assuming an average resistance coefficient of about 0.012. The theory indicates the presence of a critical pressure at the pipe discharge when the receiver pressure is low enough, which incidentally has no connection with the critical pressure at the throats of orifices.

The authors have not given general curves showing the sizes of pipes required on the discharge side of orifices, such as are shown in Fig. 11 of the writer's paper.[7] It is necessary to note that the pipe sizes, shown in Fig. 11, apply to the pipes on the discharge side of orifices in the form of nozzles. For practical purposes, orifices with well-rounded entry are preferable to sharp-edged orifices, because they simplify the design of the layout.

Since the writer's paper[7] was presented in 1936, several power stations have been erected in this (England) and other countries which are operating satisfactorily with nozzle plates instead of traps in the feed-heater drains. These nozzle plates are generally about $1^1/_2$ to 2 in. thick, and the throat areas are made large so that they are capable of passing double the designed quantity of water at maximum output.

Only one case is known to the writer where erosion has occurred in elbow pipes, and this was at a bend immediately after the orifice. In this case, the orifice was lightly loaded and was above the receiver; the bend was in a downward direction close to the discharge side of the orifice.

In general, we have avoided erosion troubles at bends after orifices by placing the orifice below the receiver, so that the discharge side of the orifice is submerged. The water lying in the discharge pipe forms an effective buffer which dissipates the kinetic energy of the mixture issuing from the orifice.

The authors appear to be more concerned with erosion at the elbow near the pipe discharge. So far, we have not experienced this trouble. On checking the pipe sizes given in Table 4 of the present paper with those which we would have installed, based on Fig. 11 of the writer's paper,[7] it is discovered that pipe lines Nos. 2, 5, 7, 8, and 14 in Table 4 are too small to be used after nozzle plates.

Pipe line No. 6 is on the border line and we would have made it larger. Except, therefore, for pipe line No. 1, we would consider all those pipe lines, having replaced elbows, in Table 4 to be too small, and it is possible that this may account for our freedom from erosion trouble at the discharge elbow.

Pipe line No. 1 is a common condition in this country and, as we have not experienced trouble with it, the writer is unable to account for the erosion experienced by the authors. The authors say that the data for pipe line No. 1 were obtained from test results; but the writer cannot find these test results in Tables 1 to 3 and shall be glad if the authors will give a diagrammatic sketch of it similar to Fig. 5.

The writer is not satisfied with the authors' suggestion that the criterion for erosion is the total momentum force on the elbow and would expect the erosion to depend upon the intensity of the force on the surface area at the bend, in which case, it should depend rather upon the velocity head multiplied by the density either of the mixture or of the solid water.

It is to be noted that the arrangement shown in Fig. 10 of the paper can only operate when the water level in the previous receiver is above the orifice, in order to provide sufficient gravity head to overcome the resistance in the connecting pipe. The gravity head is necessary because the pressure in front of the orifice will be the same as the vapor pressure in the previous receiver.

A. G. Christie.[13] It was the writer's privilege to design some of the earlier drainage systems for bleeder heaters. These were designed on the basis of solid water flow with a liberal allowance for velocity and were generally large. When these did not function properly, larger pipes were used. In the early days, difficulties would frequently arise with the drainage traps; some of which troubles were quite unexplainable with the knowledge then at hand. These were remedied by cut-and-try methods.

The first suggestion that flashing of the water in the trap and piping might be the cause of the trouble was made by one of the officials of C. A. Parsons & Co., England, who were having trouble with heater drainage. It is understood that this company at a later date made some tests on this problem but, other than the paper by Bottomley,[7] none of these tests were made public.

The tests reported by the authors furnish the first concrete data on this rather baffling problem. The method for determining the critical pressure as presented by the authors is complicated and time-consuming. Probably some mathematician can develop a simpler method. It would also be of interest to determine whether this critical pressure at the end of the pipe corresponded to the acoustic velocity of the water-steam mixture.

The authors conclude that the momentum of the mixture causes the erosion at the elbows. The use of tees with blank flanges is recommended to enable easy replacement. The mass of steam and water must enter the lower pressure heater at high velocity and considerable momentum, which would cause erosion of the baffle that may be placed in this heater. Few heaters are designed with provision for the renewal of this baffle should such erosion occur.

Quite aside from the value of this paper in fixing conditions in piping from bleeder heaters, there is the suggestion that similar phenomena subject to the same analytical methods may exist in the side wall tubes of boiler furnaces. Certainly, similar flashing of water into steam will obtain in the blowoff pipes of boilers. While erosion has not been serious in either of these

[13] Professor of Mechanical Engineering, Johns Hopkins University, Baltimore, Md. Past-President A.S.M.E.

cases, the remedies proposed in this paper may find application in plants where there have been erosion troubles.

The authors suggest that further data should be secured by other observers. Let us hope that such data are soon made available. An interesting phenomenon has been carefully studied and the authors have made a notable contribution to our technical knowledge.

G. M. Dusinberre.[14] The suggestion has been made that the solution of the authors' problem would be simplified by the use of a suitable chart. The writer has constructed such a chart, Fig. 15, with a range covering several of the authors' examples. Similar charts could be made for higher and lower pressure ranges.

The best co-ordinates appear to be entropy versus specific volume. A uniform volume scale simplifies the construction, as the constant-pressure lines become straight. However, there are many advantages in using a logarithmic volume scale: (1) The chart is contracted and slide-rule accuracy is obtained throughout. The volume scale can be laid off conveniently directly from a slide rule. (2) If a density scale is desired, it need not be calculated but may be laid off by reversing the slide rule. (3) The logarithmic scale simplifies the authors' process of step-by-step integration. The quantity $\log_e(\rho_1/\rho_x)^2$ has to be evaluated a great number of times. With the use of Fig. 14, this is done as follows:

1 With dividers step off the horizontal intercept between the state points 1 and x.

2 Apply this on the scale of natural logarithms to obtain $\log_e(\rho_1/\rho_x)$.

3 Double this to obtain $\log_e(\rho_1/\rho_x)^2$.

The authors have measured condensate temperatures and then have expressed the data in terms of the corresponding saturation pressures. This seems an unnecessary complication. The saturation pressure does not exist in the system, except at some point in the drainer valve; nor is it used in the calculations except to determine the point on the liquid line at which the expansion process starts. For this purpose, the directly measured temperature serves as well. In design, the temperature would be estimated from the assumed heater shell pressure and the probable amount of subcooling. In the writer's Fig. 15, temperatures are shown on the liquid line.

The actual shell pressure must not be neglected since it is this, and not the saturation pressure, which determines the pressure ahead of the drainer valve. Hydrostatic pressure is often an appreciable factor.

The authors point out the fact, rather surprising at first thought, that there is little difference between the isentropic and the constant-enthalpy expansions in this situation. The writer has shown one constant-enthalpy line in Fig. 15 for comparison. The isentropic represents the limiting case of zero friction, and the constant-enthalpy line the limiting case of zero increase of kinetic energy. Neither of these conditions exists, and the actual expansion lies between.

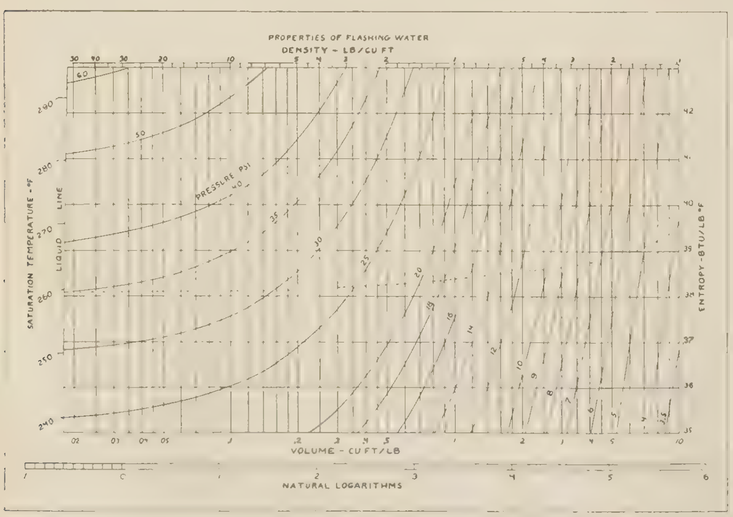

Fig. 15

H. W. Emmons.[15] In order to interpret their test results, the authors have set up a simple theory of what happens to water-steam mixtures as they pass through pipes. Before any reliance can be placed on the theory, and hence on the interpretation of the experiments, several of the authors' assumptions must be checked by test.

1 It was assumed that the water and steam were in equilibrium, having properties as given in the wet region of the steam tables. Such properties only apply for equilibrium when a plane interface exists between the water and steam. If the water is finely divided, as it may well be after the specific volume has increased 100- or 200-fold, the surface energy cannot be neglected, even if equilibrium exists. The authors missed an opportunity to shed a little light on this important question by failing to make simple pressure measurements at the same time they were making temperature measurements. If the pressure measurements had not agreed with the steam-table saturation pressures, the difference would have given an indication of what deviation from the simple equilibrium must be considered.

2 It was assumed that the water and steam were distributed uniformly over the pipe cross section and moved with the same velocity. Of course, this is approximately true only if the water occurs in very fine droplets. Note that assumptions 1 and 2 are mutually exclusive, that is, the equilibrium cannot be for a plane liquid-vapor interface and for fine droplets at the same time. If assumption 2 is not correct there are several alternative possibilities. The water may be finely divided but not moving with the same velocity as the steam. The water may be segregated in one portion of the pipe, say, the bottom, moving with a velocity probably different from that of the steam.

The analysis, to be correct, must be modified if either assumption 1 or 2 is not admissible. It might be argued that the quantities used in the theory represent "average" quantities. If the quantities vary considerably across the pipe cross section, these averages become very inaccurate. For example, the continuity equation requires the use of the "flow average velocity," while the energy equation requires the "flow average of the velocity cubed," which may differ considerably.

Before closing this discussion, it might be well to note the effect of two extreme water-steam distributions on the cause for a critical-flow condition. If it is correct to make the authors' assumption that the distribution is uniform then, by thermodynamics, it can be shown that the

[15] Graduate School of Engineering, Harvard University, Cambridge, Mass. Jun. A.S.M.E.

velocity at the end of the pipe must be equal to or smaller than

$$V = \left(\frac{\partial p}{\partial \rho}\right)^{1/2} = v\left(-\frac{\partial p}{\partial v}\right)^{1/2}$$

This is the speed of sound in the mixture. This velocity is easily found by calculating the slope of a *p-v* diagram for the change of state which actually occurs. For example, the square root of minus the slope of the authors' curve, Fig. 2, multiplied by the abscissa gives the maximum velocity for each state assuming an isentropic-equilibrium change of state. On the other hand, if the water is flowing essentially along the bottom of the pipe, the critical condition would occur, for a steam velocity equal to the speed of sound in the steam, and a water velocity equal to the maximum velocity in streaming.

In closing, the writer wishes to compliment the authors for the care with which they have stated their assumptions. It is certainly excusable, in the solution of a practical problem needing immediate attention, to make whatever assumptions seem adequate. To make such work useful to others, however, it is important that the assumptions be stated as clearly as possible.

G. T. Hutchison.[16] Previous papers have developed the theory that, when saturated water passes from one pressure to a region of lower pressure, the rate of flow through a restriction is governed by the increase in volume due to flashing of the liquid and the acceleration of the mass resulting from the reduction in pressure. It has also been established that the rate of flow increases with a reduction in the lower pressure to an optimum point, beyond which any decrease in pressure has no effect upon the rate of flow. This point is called the critical pressure and has been defined by the authors as being reached when the increase in energy made available by an increment drop in pressure balances the resulting increase in kinetic energy and the increase in friction. In their work, reported in a previous paper,[11] the authors found that no critical-pressure condition existed when using a thin-plate orifice as a throttling device. Tests run by the writer's company in 1934 and 1938, upon a nozzle with a rounded approach, and an approximate ratio of length to diameter of 8 to 1, definitely showed critical pressures to exist at the throat of the nozzle, as determined by pressure measurements. Additional tests, run by the company within the last 3 months, on a $^1/_2$-in. inverted bucket trap proved definitely the existence of a critical pressure, since variation of the back pressure below a certain point had no effect upon the capacity of the trap with constant initial conditions.

The existence of a critical pressure at the downstream end of a pipe, handling a mixture of saturated water and its vapor, is shown clearly by the authors' tests. Had these tests been run with the length of pipe as the only restriction to flow, and water at the saturation temperature supplied to the inlet of the pipe, rather than a mixture of vapor and water, the authors would also have found that a critical-pressure condition exists at the outlet end of the pipe.

It is also interesting to note that various tests indicate different critical pressures for identical initial conditions, depending upon the design of throttling device tested.

The logical deductions from the test data at hand may be enumerated as follows:

1 Design of the throttling device determines the order of a lower pressure which regulates the amount of flow from the initial conditions. For saturated water, the head available for producing flow varies approximately as the square root of the pressure differential in one extreme design, when the throttling device is a thin-plate orifice with no other factors to influence the flow. In the other extreme, where the design is such as to produce a critical pressure, the flow varies approximately directly with the first power of the absolute pressure, providing, of course, the back pressure is below the critical pressure in that design of throttling device.

2 Properties of the fluid considered, which might affect the order of the critical pressure for any particular design of throttling device, are surface tension, viscosity, and the thermodynamic properties of the fluid.

3 Characteristics of the throttling device affecting the order of the critical pressure are:

(*a*) Any features producing turbulence in the flow stream which aid in overcoming the resistances to a change in phase. This effect may be produced by irregularities in castings in traps, change in the direction of flow in pipe fittings and trap bodies, and simple wall friction, as may be found in a nozzle, or length of pipe.

(*b*) Time elements involved in passage through a throttling device.

Consideration must be given to each of these deductions in any attempt to anticipate the flow of a saturated fluid through a throttling device.

Future experimental work might well be directed toward determining the factors affecting the critical pressure in the design of throttling devices when handling saturated water. It is suggested that tests be run on a small-diameter nozzle of appreciable length to determine capacity and order of critical pressure, and shorten the nozzle in subsequent tests until it becomes a thin-plate orifice. An analysis of results may show useful relationships to exist between initial conditions, critical pressure, flow, length, hydraulic diameter, nozzle wall friction, time, and such properties of the fluid as may affect the transition from the liquid to the vapor state. In test work of this nature, it would be more accurate to determine pressures by actual pressure measurements, rather than temperature readings converted to pressures, since the absence of a critical pressure, when an orifice is the throttling device, indicates the possibility of a state of non-equilibrium.

The authors have developed a rather complete formula for flow of flashing liquids through pipes, which is based on the premise that flashing fluids behave much the same way as an elastic fluid. In applying Bernoulli's theorem or Goodenough's energy relation to the flow of flashing liquids, the authors have indicated the differential-friction head as varying directly as the square of the velocity. The variation in friction in a pipe line, handling a mixture of this nature, is sufficient material for considerable research and several papers. Future experimental work may indicate that the differential-friction drop varies as some function of the fluid density, as well as the velocity squared, since friction of both gas or turbulent liquids flowing in pipes is affected by the density. As the flow is turbulent during its passage through the piping tested, it would be expected that it would follow the laws of turbulent flow.

The authors reached the conclusion that a critical pressure can exist at the end of a pipe line draining saturated water. The test results and analysis made here prove conclusively that a critical pressure will always exist at the end of the line as long as the receiver pressure is below that critical pressure.

A. A. Markson.[17] The authors state that obtaining complete information concerning the friction factor would have necessitated the expenditure of more time and money than was believed warranted by their particular problem. This is often the case in engineering. The thermodynamics of this particular

[16] Cochrane Corporation, Philadelphia, Pa. Jun. A.S.M.E.

[17] Research Engineer, Consolidated Edison Company of New York, New York, N. Y. Mem. A.S.M.E.

problem presents some extraordinary difficulties which are not lessened by any means by the fact that they are dealing with a two-phase mixture. Therefore, it would be captious to criticize the thermodynamics of this paper from an engineering point of view. The writer believes it would have been better if the authors had restricted the generality of their friction factor to its use in the particular method of integration which they found to be convenient in solving this problem. Further, another series of tests not requiring a great amount of time or expense should be run on both solid water and saturated steam flowing through their lines so that the relationship, of the coefficients which they found to the isothermal friction coefficients usually considered, could be seen. The coefficients they report are of the form $4f$, where f is the conventional way of basing the coefficients on mean hydraulic radius. The magnitude of their coefficient is somewhat below anything predicted for isothermal friction in ordinary pipes. Therefore, the test on water is very necessary to be sure whether the difference is due to the method of integration employed or to a different friction mechanism.

It is to be noted that there is apparently no systematic treatment of inlet and exit losses in such a system and the authors should clarify this point.

The method of computation of the state of the mixture is cumbersome, which is no fault of the authors, simply because there are no adequate diagrams such as the Mollier or Ellenwood which cover the wet-vapor region. It is to be hoped that this deficiency in a field of increasing technical importance will be remedied by those whose function is the production of graphical charts of steam properties. For a constant-enthalpy expansion this has been partially done[18] in a series of charts giving the enthalpy volume and pressure for very wet steam. It should also be done for the isentropic.

What is most important is that to engineers this paper represents a practical way of solving a theoretically complex problem. Their refusal to misrepresent the "scientific" rigor of their solution warrants a special word of commendation.

Authors' Closure

In preparing this paper for publication, the authors hoped to stimulate interest in the study of the flow of a flashing mixture of a liquid and its vapor and are therefore pleased with the discussions contributed and the interest which is thereby indicated to exist among engineers. The authors are particularly pleased to have a discussion from W. T. Bottomley; his paper offered considerable assistance to the authors in their work.

The first part of Mr. Bottomley's discussion refers to the authors' earlier paper,[11] and the comments immediately following apply to this part of his discussion.

With reference to Mr. Bottomley's remarks concerning critical pressures in the orifice, the authors would first like to state that in their opinion the terms "orifice" and "nozzle" are too loosely applied. For instance, there have been found several references to flow through nozzles when the so-called "nozzles" were either orifices or short tubes. Also short tubes are often called orifices. Actually, there may be considerable difference in the way these two devices perform.

Whether or not a critical-pressure condition can actually exist in a sharp-edged orifice, the authors are not prepared to say. However, it seems that before this question can definitely be settled, many data will have to be obtained from very carefully conducted tests. For all practical purposes saturated water flowing through sharp-edged orifices follows the same law as cold water; and the illustrations for all cases except those with high pressure differentials show that the saturated water did not flash until it was through the orifice. Sometimes it was as much as 6 in., or more, from the orifice downstream face before flashing. For these cases the authors believe that no critical-pressure condition existed. So long as a decrease in back pressure with a fixed initial pressure results in an increase in flow, as Fig. 7 of the previous paper[11] indicates is the case for saturated water flowing through sharp-edged orifices, Equation [2] of that paper, together with the coefficients given in Fig. 13, applies equally well for the complete range of back pressures. It seems to the authors that this is also an indication that no critical-pressure condition exists in the throat of the orifices, since such a condition is essentially one of a maximum flow. This is not saying, however, that a critical pressure will not exist in nozzles or short tubes. In fact, the authors would expect such a condition to exist in the case of the latter devices, and the discussion by Mr. Hutchison supports this opinion.

The following remarks apply to Mr. Bottomley's discussion of the authors' present paper.

Because of the number of variables involved, the authors have not attempted to formulate any general curves to be used in the design of heater drain lines. Each drain line is an independent problem and should be treated accordingly. In the authors' opinion, the generalization that would be required in making up design curves might well make the problem appear more difficult than it really is. This does not say, however, that a simpler method of calculating flow through heater drain lines cannot be developed.

Three methods for correlating experience with erosion in heater drain lines are suggested in the paper. Among these three is the method $\left(\rho \frac{v^2}{2g}\right)$, suggested by Mr. Bottomley. It is pointed out in the paper under "Erosion in Drain-Line Piping" and in Table 4 that, of the three methods, the total momentum force seems to give the most consistent results based on experience.

Regarding Mr. Bottomley's remarks about the use of orifices for draining feedwater heaters, particularly the design shown in Fig. 10 of the paper, the authors would like to state that at present there are seven turbogenerator units in the authors' company utilizing orifices for controlling the drains from the feedwater heaters. On six of these units, the orifices are installed as shown in the design given in Fig. 10 and, contrary to Mr. Bottomley's belief, the water level in the upstream heater is not required to be above the orifice. These orifices are sized initially from heater performance data and finally sized in the field for some definite load (usually overload) on the turbine. At the maximum load for which the orifice is sized, the water level will be in the upstream heater hot well. For loads less than maximum, no water level will show in the upstream heater hot well, which means that a small quantity of steam is probably blowing through the drain line with the water. Heat-balance calculations indicate that the effect on cycle efficiency of by-passing this steam is slight. At Connors Creek, where orifices have replaced traps on four of the six modern units, no noticeable change in the plant efficiency can be ascertained.

As pointed out in the paper, the design of heater drain lines, given in Fig. 10, makes possible the use of smaller pipe. This has proved to be a distinct advantage in plants where the space available for feedwater heaters is limited. The orifice plates used so far in this design have been $^1/_4$ in. thick. In the later installations, the orifices are simply holes drilled in the center of the plate.

In response to Professor Christie's suggestion that the baffle would be eroded by the steam and water entering the low-pressure heater, the authors would like to point out that the condition of the mixture is practically the same with an orifice at the end of the line as it is with a trap at the beginning, because the end conditions in the heaters are the same in either case. The authors know of only one case where trouble with erosion was found inside

[18] Lefax Data Sheet, No. 41-11.

the heater, and this was due to faulty design of the baffle. It is believed that, if the mixture is permitted free expansion in all directions inside the heater shell and does not enter the shell near a tube support plate, little trouble will be experienced with erosion.

Professor Christie is quite right in suggesting that the same phenomena that exist in a heater drain line will also exist in a boiler blowoff line. The essential difference between these two types of lines is that in the latter the water does not go through a throttling device at the beginning of the line if all blowoff valves are wide open as they should be with intermittent blowdown. For continuous-blowoff lines, however, where the line may be throttled to get a given rate of blowdown, the condition is similar to the heater drain line. It should be pointed out here that the friction factor 0.012 given in the paper was determined from tests of heater drain lines which have normally much lower pressures and are comparatively larger than most blowoff lines. Whether this friction factor applies equally well in blowoff lines the authors are not prepared to say. However, the use of Equation [4] with $K = 0.012$ for designing boiler-blowoff lines probably is justified until more accurate data are obtained from actual tests of blowoff lines.

The authors are grateful to Professor Dusinberre for developing the chart in Fig. 15 accompanying his discussion. It is hoped that he or someone else may have time to prepare charts for the complete range of pressures in use today.

Professor Dusinberre's statement that the actual heater shell pressure must not be neglected is correct, but it should be pointed out that the amount of flashing in the line depends on the initial saturation pressure. The pressure drop across the trap, as shown in Fig. 12 of the paper, is the difference between the heater shell pressure and the pressure after the trap. The latter pressure and the amount of flashing, however, depend on the temperature (or saturation pressure) of the water entering the trap, which may be less than the saturation temperature corresponding to the heater shell pressure.

Regarding the discussion by Mr. Emmons, the authors would first like to point out that, at best, tests conducted on the heater drain lines of an actual turbine-generator unit leave much to be desired in so far as the testing procedure is concerned. The tests are only incidental to the operation of the unit and, therefore, must be made to a very great extent to fit the conditions as they exist. It is believed, however, that information obtained from such tests is much better than no information at all. The authors are well aware of the possible refinements pointed out by Mr. Emmons. It was hoped that the second and third paragraphs of the paper would indicate that no claims were being made beyond the fact that the data in the paper would be of assistance in the design of heater drain lines.

In the authors' tests for determining the flow of saturated water through throttling orifices,[11] both pressure and temperature measurements were taken in a line carrying a flashing mixture of water and steam. In all cases the saturation pressure corresponding to the temperature measurements checked the actual pressure measurements within 0.5 psi, which is well within the expected accuracy of the readings to be obtained on a commercial-size setup. While a rigorous scientific analysis might be derived from a delicate laboratory installation, it is questionable whether the laboratory results could be translated into actual practice with any greater satisfaction than is possible from the authors' tests.

The authors appreciate Mr. Hutchison's contribution to their paper and, in general, are in agreement with what he has said. It is hoped that he will find it convenient soon to publish the results of the tests by his company of flow of saturated water through nozzles.

With reference to Mr. Markson's suggestion that cold-water tests should have been carried out on the heater drain lines in question, the authors would like to say that this would have been impossible. The remarks about the friction factor are quite true and, because of this fact, the symbol K was used instead of the symbol f which is ordinarily used. No attempt was made to treat inlet and exit losses because, as already pointed out, all tests were conducted on drain lines of operating turbine-generator units and not on pipe lines which were especially designed for the tests.

The lack of suitable diagrams or curves for use in calculation has been partially taken care of by Professor Dusinberre.

In conclusion, the authors wish to express their appreciation to all the discussers for their interesting additions to the paper. It is hoped that further and more rigorous experimental investigations will be made and reported to the Society.

FIG. 1 SITE OF RIVERSIDE GENERATING STATION
(Scale 1 in. = 2215 ft.)

Wind-Tunnel Tests to Establish Stack Height for Riverside Generating Station

BY H. L. VON HOHENLEITEN[1] AND E. F. WOLF,[1] BALTIMORE, MD.

Because of its proximity to a residential area and to the municipal airport, the Consolidated Gas Electric Light and Power Company of Baltimore, in the construction of its new Riverside Generating Station, found it necessary to give careful consideration to the flue-gas problem and the height of stacks. The problem resolved itself into three distinct phases: (a) to establish the wind and weather conditions which would produce the most serious smoke annoyance; (b) to determine the effect of adding units to the plant; (c) to investigate all possible means for improving dissipation of flue gases. The model-test procedure followed, in studying these elements, in the wind tunnel of the Allied Aviation Corporation, the results attained in comparison with known data from the Westport Plant of the company, and the decisions reached in designing and arranging stacks at Riverside are thoroughly discussed.

THE Consolidated Gas Electric Light and Power Company is now engaged in the construction of its new Riverside steam-electric generating station on a site along the Patapsco River near Baltimore, between the Dundalk residential community and the Sparrows Point steel center. Work on the first 50,000-kw condensing unit is now in progress and the installation of a second unit of equal size has been authorized. Because of the proximity to the municipal airport, Fig. 1, height of structures was an important consideration in the design of this station. By careful study of mechanical arrangement, the height of the building itself was eliminated as a critical factor, and the stack remained as the sole point upon which a decision of height must be reached. The desired stack height, which had been de-

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

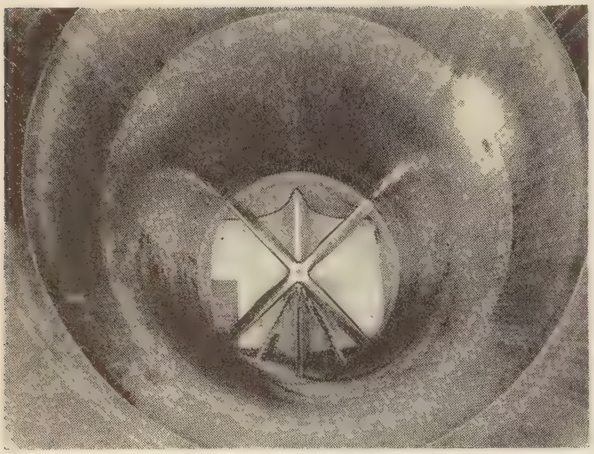

FIG. 2 WIND TUNNEL, LOOKING DOWNWIND

termined on the basis of past experience, was in excess of elevations suitable for this location.

There are several factors in the design of the Riverside stacks which are different from the usual problem. On account of the induced-draft-fan system, height is not required to produce draft, and with the Cottrell precipitator, the dissipation of flue gases rather than "smoke" is the primary consideration. It is usually desirable to have a stack sufficiently high to be free from smoke troubles under all normal wind conditions. At Riverside, it was necessary to select a stack height consistent with company requirements for reasonable dissipation of flue gases and yet satisfactory from the viewpoint of air navigation. It was concluded that the proper point of compromise between these contradictory requirements could be found only through the study of models in a wind tunnel.

ELEMENTS OF THE PROBLEM

Three distinct phases of this problem had to be analyzed: (*a*) It was necessary to establish what wind or weather conditions would produce the most serious smoke annoyance at this station, and, under these conditions, to determine the required stack height; (*b*) the effect of the addition of successive units to the plant had to be considered; (*c*) due to stack-height limitations, it was necessary to investigate all possible means of improving the dissipation of flue gases, such as stack design or arrangement, shielding of the stack or building, and increase of stack velocity.

Available Information. Prior to these tests, a study was made of available engineering information on the subject. Published reports of work carried on in England (1),[2] and to some extent in this country, on stacks with low-velocity output, indicate that a stack height 2.5 times the height of the building is desirable. There were no satisfactory data on height of stacks with high-velocity output directly applicable to the problem. However, it is known that the company's high-velocity Westport stacks which extend approximately 60 ft above the boilerhouse (or 1.46 times the height of the building) are sufficiently high to prevent troublesome downdraft at that location (Fig. 3). At Riverside, it was necessary to limit the stack height to an elevation less than that of the Westport stacks, but it was not known to what extent this

height could be reduced without experiencing smoke troubles.

Wind Tunnel. The wind tunnel in the plant now owned by the Allied Aviation Corporation at Dundalk, Md., was used for a 4-month period for this investigation. The tunnel, fan motor, and control equipment are installed in a separate brick structure. The tunnel is the recirculating type with double return paths from the discharge side of the fan to the intake end of the throat. A grid of vanes at the inlet end of the tunnel serves to straighten the air flow. The throat of the tunnel is 7 ft in diam. The open test space is 7 ft 6 in. long.

Air is circulated by a 12-ft-diam four-bladed wooden propeller fan, driven by a 175-hp variable-speed d-c motor at the downwind end of the tunnel, Fig. 2. Wind velocities from 5 to 100 mph are obtainable. The velocity is indicated by a pitot tube at the upwind end of the working space. Preliminary surveys showed that the uniformity of air flow within the test space was satisfactory.

Model Theory. Careful consideration was given to the reliability of model tests for smoke problems. Previous investigators have found that models satisfactorily predict the path of smoke from the prototype, provided the wind and flue-gas velocities are kept actual (2, 3, 4). This procedure was adhered to in the present experiments. In a Bureau of Standards report of 1926 (5, 6), it was stated that there is no error due to scale effect with sharp-edged models and this point now seems to be generally accepted. It was further stated, however, that there is some error due to scale effect with spherical, cylindrical, and streamlined models. With such curved objects, there is a critical value of the Reynolds number at which a change takes place in the flow phenomena. The model stacks used in these tests have a Reynolds number (17,000 at 20 mph) below the critical range, whereas, the actual stack will have a Reynolds number (2,040,000 at 20 mph) well above the critical range at normal wind velocities. Accordingly, there is a somewhat different partial vacuum distribution on the downwind side of the model stack than on the actual stack. This may cause slightly greater downdraft immediately back of the model stack. However, available data indicate that this should not produce a large experimental error.

Verification of Model Theory. Although theoretical considerations and previous work indicated that model investigations should produce sufficiently reliable results for predetermining required stack height, it seemed desirable to establish further proof of the validity of such tests. Accordingly, a simplified model of this company's Westport Station and surrounding property was tested to observe the relationship between the model smoke patterns and the actual smoke patterns of a familiar existing structure. It is the opinion of independent observers that the model satisfactorily reproduced the actual path of smoke from the Westport stacks. A comparison of the actual and model smoke paths under typical conditions is shown in Fig. 3.

The Westport model (scale 1 in. = 20 ft) showed no downdraft of smoke around the buildings or adjacent properties at 20 mph wind velocity in any direction, which is in accord with practical experience. A limited number of tests were conducted to determine the effect of low stack heights at this location for comparison with the Riverside model tests. When the No. 1 stack was lowered from 60 ft to 30 ft above the roof, objectionable downdrafts were observed. The downdraft from the "low" Westport stack was comparable with the downdraft from Riverside model stacks of equivalent height above the adjacent boiler room.

Tests on Riverside Models

Three models of the Riverside generating-station development were tested, namely, a single-unit, a three-unit, and a six-unit model. The last was regarded as the probable ultimate development at this location. The models were designed for maximum flexibility of operation so that desired test conditions could be obtained readily for the study or demonstration of the effect of any required variable. The models, constructed of wood, were placed on a turntable on a platform erected between the throat and bell of the tunnel. The platform was placed so that the horizontal diameter of the tunnel bisected the height of the models. The forward end of the platform was streamlined to minimize the disturbance of air flow.

The 1-in-ID brass-tube miniature stacks were adjustable in height and were equipped for variable discharge of air up to 70 fps. For the single unit, the "flue gas" was supplied through a 1-in-diam rubber hose from a blower, driven by a variable-speed d-c motor. The multiunit stacks were fed through a large plenum chamber. The velocity of discharge was controlled by individual supply-line valves. A scale of 1 in. = 10 ft was selected for convenience of size and ease of interpreting results. The six-unit model to this scale was in reasonable proportion to the diameter of the tunnel throat.

Procedure and Technique. In other investigations of smoke dissipation, it has been found that wind velocity and wind direction are the only meteorological phenomena which appreciably affect the downwash of smoke. Consequently, such factors as humidity, air temperature, and barometric pressure could be disregarded. It has also been found that stack-gas temperature has only a minor influence on the downwash for a given stack velocity (1, 2, 3). Therefore, this variable also was omitted, and the effect of elevated temperature was regarded as a small factor of safety.

For a complete analysis of this problem, it was felt that it would be necessary to make tests with each of the three models in the eight principal wind directions, at four wind speeds, five different stack heights, and three flue-gas velocities. If all combinations of variables were checked, this alone would have resulted in 1440 individual observations on the three models. This number of tests, together with the necessary preliminary work and special scheduled tests, was excessive. It was, therefore, imperative to determine how many of these individual observations could be safely eliminated. It was felt that a study of the turbulence produced by the models would enable differentiation between critical and noncritical variables.

Study of Turbulence. Previous work (2, 3) had indicated that, if downwash of smoke is to be avoided, smoke must be discharged at a sufficiently high elevation, or at a sufficiently high velocity, to be carried above the turbulent area set up by the structure. This consideration, together with the necessity of establishing the critical variables, led to a thorough study of the turbulence patterns.

When an obstruction is placed in the path of the wind, the flow of air is diverted in part around the sides of such obstruction and in part over the top. On account of this constriction of flow, the velocity of the wind immediately around and over the top of the building is increased. Since the pressure energy plus the velocity energy must remain constant (Bernoulli's theorem), the pressure is reduced in the high-velocity region on the top, sides, and back of the building and increased in the more or less dead air space directly in front of the structure. Vortexes are set up in the low-pressure areas immediately over the top, sides, and rear of the structure (6, 7). The nature of the vortexes or turbulent areas depends upon the configuration of the building, the wind direction, and the wind velocity. If the smoke stream is carried into one of these turbulent areas, it is dispersed and may be brought down to earth, Fig. 4. The stack also causes a disturbance. A cylindrical stack is known to set up two types of vortexes, namely, trailing vortexes and tip vortexes. Trailing vortexes of cylindrical shape with vertical axes originate along the vertical sides of the stack cylinder. These vortexes break off from the opposite sides

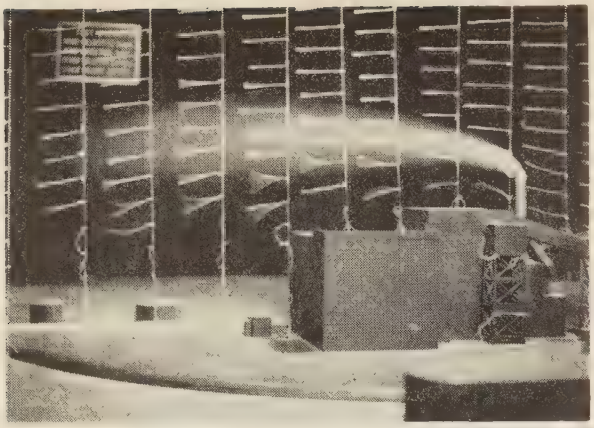

Fig. 4 Turbulence Pattern of Single-Unit Model
(20-Mph west wind.)

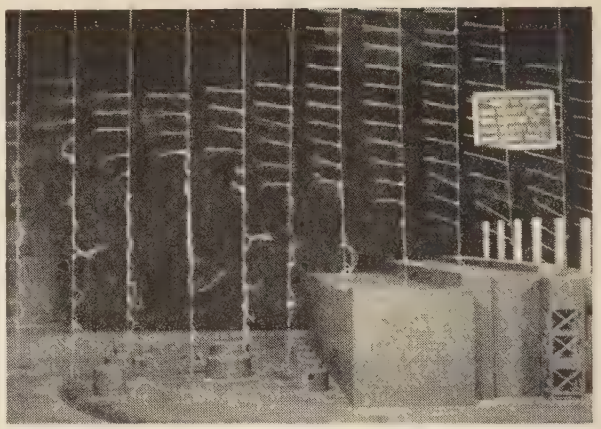

Fig. 5 Turbulence Pattern of Six-Unit Model
(20-Mph west wind.)

and travel downwind (Kármán's trail). The tip vortexes with horizontal axes in the direction of the wind form at the opposite sides of the top of the stack. These cone-shaped vortexes have a downward sense of rotation outside of the wake and an upward sense within the wake.[3] The effect of these tip vortexes may be seen in Fig. 3, where the smoke is leaving the stack in two separate cones. In high-velocity winds, these two types of vortexes tend to disperse the smoke and carry it downward, unless the discharge gas velocity is sufficiently high to overcome their effect.

Turbulence was studied by means of threads. Taut, vertical strings were set up at 6-in. intervals in line with the stack in a plane parallel to the wind direction. White silk threads, 5 in. long, were used as streamers tied at one end to the vertical strings at 2-in. spacings. The length and spacing were selected after a considerable amount of experimental work to determine the most suitable type and arrangement of threads which would follow the path of the wind. Photographs were taken of these string patterns, Figs. 4 and 5.

The area around the building was also explored by means of a fine silk thread on the end of an exploring rod. Flake mica (Christmas-tree snow) was distributed at points around the building. The path of the particles of mica showed the regions of turbulence, the direction of flow, and the character of the vortexes. The turbulence areas were also investigated by means of droplets of titanium tetrachloride placed at spots around the model. On the basis of the fixed and exploratory indicators, charts were plotted to show the turbulence patterns produced in line with the stacks.

Figs. 17 and 18 illustrate the effect of wind direction and wind velocity on the turbulence. The wind velocity affected the area of the turbulent zone to some extent, but did not in general affect the character of the turbulence pattern. The wind direction very markedly affected the area as well as the character of turbulence. The relative proportions of the building in the three planes is a vital factor. The surface of the single-unit building, exposed to north or south winds, is much greater than to east or west winds and, consequently, the turbulent zone extends higher with the north or south winds than with the east or west winds. Under the worst conditions, this turbulent zone extends as much as 70 ft higher than the building. In the six-unit plant, the proportions of the building are reversed and, consequently, the turbulence patterns are quite different. With a 20-mph west wind, the six-unit model set up a turbulent zone equivalent to 120 ft above the building, Fig. 5.

[3] The sense of direction reported here is opposite to that reported by Sherlock and Stalker (2, 3), and was demonstrated by direction of rotation of threads in the wind-tunnel tests, and confirmed by field observations.

(20-Mph west wind.)

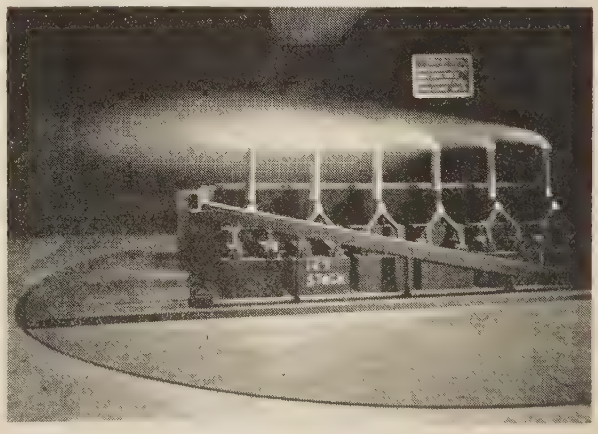

Fig. 7 Downdraft Caused by Wind in Line With Stacks

Smoke-Pattern Technique. In the Sherlock and Stalker investigation of the smoke problem for the Crawford Avenue Station, Chicago (2, 3), hydrogen sulphide was discharged from the model stacks and chemical indicators were used to detect the

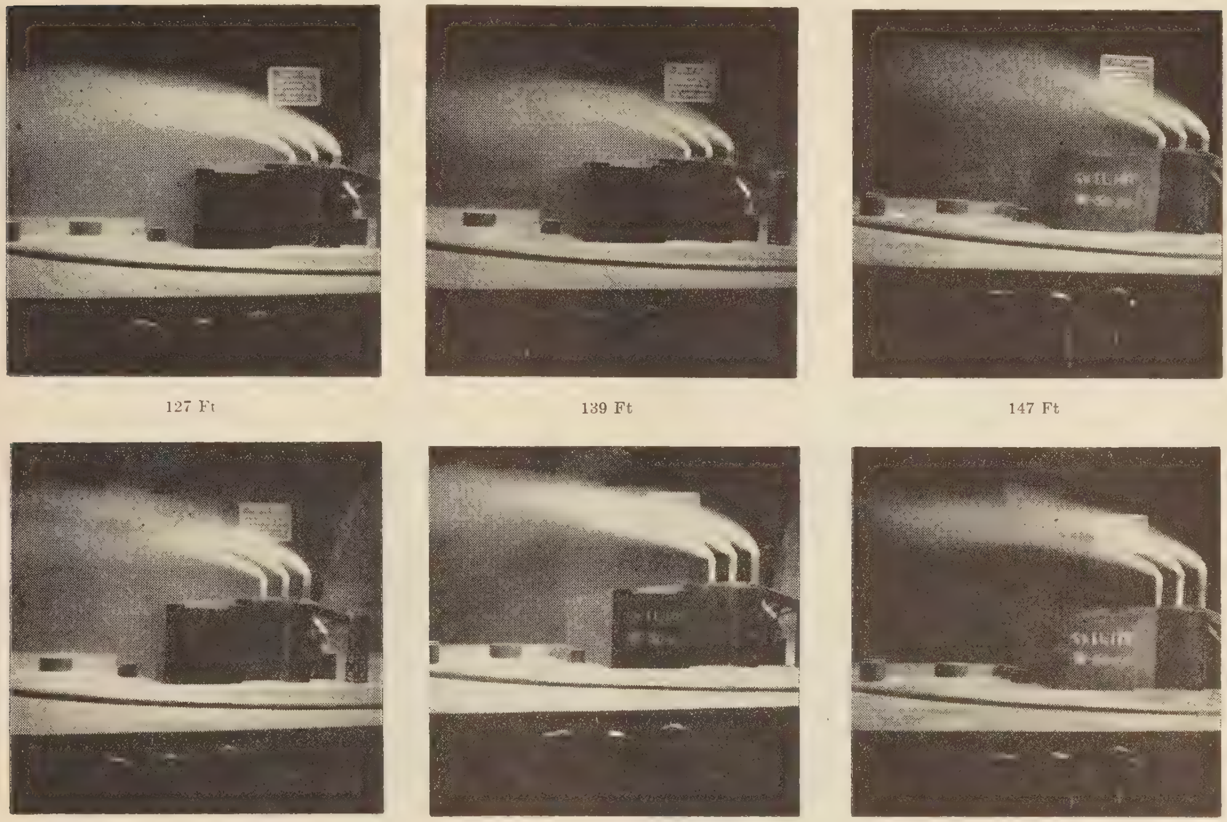
path of the gas discharge. This method was tried but found to be unsuitable in the present case. Since the working space in the tunnel was open, the exposure of the operator to the toxic hydrogen sulphide was objectionable. Furthermore, the indicators were not adapted to detecting the path of the smoke in more than one plane. Rapid evaporation of the chemical indicator made accurate recording difficult at the higher wind velocities. The same objection applied to the discharge of ammonia and other gases from the model stack.

Consequently, a technique was developed for the discharge of a dense white smoke from the stacks. Ammonium chloride was used for this purpose because of its relatively low toxicity and corrosiveness, high degree of visibility, and freedom from fire or explosion hazards. The ammonium-chloride smoke was found to



127 Ft 139 Ft 147 Ft

157 Ft 167 Ft 175 Ft

Fig. 12 Three Units; Effect of Stack Height

(Wind direction, west; wind velocity, 20 mph; stack height, as noted; stack velocity, 50 fps; No. 2 monitor roof.)

be quite satisfactory since it was possible to observe the path of the smoke in three planes and to see the vortexes around the building and stack structures. A satisfactory procedure was developed for making still and motion pictures of the smoke, which was generated by passing air from a compressed-air line through half-filled 1-gal bottles of concentrated ammonium hydroxide, and then neutralizing the ammonia-saturated air by passage through bottles of hydrochloric acid in a partially closed wooden box. The cloud of white smoke emanating from the hydrochloric-acid bottles was fed to the intake side of the blowers which supplied the stacks.

The smoke technique was found to be very useful, however, there are certain limitations in that some trouble is experienced from clogging of model stacks smaller than $^1/_2$ in. diam, or stacks with very low velocities.

Results of Investigation

Wind Velocity. The effect of wind velocity was investigated in the range of 5 to 40 mph. The tests brought out two conditions which may cause troublesome flue-gas concentration in the immediate vicinity of the plant, namely, extreme calm and moderately high wind velocities. In the almost complete absence of air movement, the stack-discharge gases rise more or less vertically from the stack and form a cloud over the building. This large mass of discharge gas tends to diffuse gradually downward. With wind velocities from 5 to 10 mph and stack velocities of the order of 50 fps, the discharge gases are carried in a gently curved arc upward clear of the surrounding property, with moderate stack heights, Figs. 9, 14, 21. From a practical consideration, wind velocities in the neighborhood of 20 mph cause the most concern. Winds in this range occur with considerable frequency in the Baltimore area, Table 1. With increasing velocity, the path of the smoke is carried lower. However, the rate of dissipation of smoke increases in proportion to the wind velocity, according to the investigation of Pearson, Nonhebel, and Ulander (1). Our own observations show that, at high winds, in the neighborhood of 30 to 40 mph, the downwash becomes very pronounced, but that the smoke is rapidly diluted. Although these higher velocities are relatively infrequent and the rate of smoke dissipation is also in our favor, we believe that with the stack heights under consideration, there will be some annoyance from smoke when these higher wind velocities do occur.

Wind Direction. The seriousness of the downdraft of smoke is very markedly affected by the wind direction, as indicated in the charts and photographs, Figs. 10 and 20. With the single unit, the north and south directions present a large area of building surface to the wind and create a particularly serious downdraft problem.

Fig. 13 Six Units; Effect of Stack Height
(Wind direction, west; wind velocity, 20 mph; stack height, as noted; stack velocity, 50 fps; No. 2 monitor roof.)

With a south southeast wind, there exist the combined effects of the large southern exposure of the building and the complicated turbulence patterns created by the partial exposure of the stack-and-breeching structure to the wind. This tends to cause a downwash around the induced-draft-fan structure.

With the three-unit and six-unit models, cumulative disturbances are set up when the wind is blowing directly in line with the stacks. The smoke is brought lower and lower with each successive stack, Fig. 7. With a south southeast wind, there is also a troublesome condition with the multiunit models. The successive disturbances of the stacks and the disturbance of the building itself combine to create a serious downdraft.

Stack Velocity. The path of the smoke as it emerges into the atmosphere is determined by both stack velocity and wind velocity. However, it should be pointed out that, at equal stack velocities and wind velocities, the smoke does not emerge at a 45-deg angle, as might be anticipated from a simple application of resultant forces. The problem is much more complicated and has been treated theoretically in the technical literature (8).

Under average weather conditions, high flue-gas velocity is decidedly beneficial in carrying the smoke upward, Fig. 11. A small-diameter stack creates less disturbance and high velocity tends to carry the smoke above the disturbed area. Under the conditions of Fig. 22, an increase in stack velocity from 15 to 50 fps raises the upper limit of the smoke path about 50 ft at the rear of the building. At wind velocities of the order of 30 to 40 mph, the effect of stack velocity is less pronounced. With wind velocities of approximately 20 mph and with low stack velocity, there is a very pronounced downdraft of smoke immediately along the downwind side of the stack. This phenomenon can be observed very readily on any windy day with the usual low-velocity industrial stacks.

Stack Height. As would be expected, the seriousness of the downwash of gas decreases with increased stack height, Figs. 8, 12, 13, 19. With a 127-ft stack elevation, which is approximately

equal in height to the boiler-room monitor, the lower portion of the smoke path sweeps over the model roof or swirls over near-by ground under a wide range of wind conditions. With a 139-ft stack, the smoke path is approximately the same, but the concentration appears to be somewhat less dense near the ground. With a 147-ft stack, the smoke path is raised somewhat but continues to swirl to the ground. At 157 ft, the downwash is still pronounced, even at a 10-mph wind velocity in some directions. Consequently, at this stack height smoke annoyance would be anticipated on a large number of days each year. At 167 ft, downwash is present within limited angles of wind direction at 20 mph, and quite general at 30 mph. It is the authors' opinion that this is the minimum height at which the smoke downwash would not be entirely excessive.

Even at the maximum elevation of 175 ft, set for this group of experiments, some smoke is carried downward close to the base of the model with unfavorable wind directions at the higher wind velocities.

Special Structural Treatments

Roof. No appreciable improvement could be obtained by variation in roof design within practical limitations. Several types of monitor roofs, flat roofs, and sloping roofs, all with the same maximum elevation, were studied. There was not sufficient difference in the smoke dispersion for this to be a deciding factor in the selection of the alternate roof plans.

Stack Arrangement and Design. One of the troublesome conditions which appeared with the three-unit and six-unit models has been mentioned previously. When the wind direction is approximately parallel to the line of the stacks, a disturbance originates at the first stack and is amplified by each successive stack which causes an increasing degree of downdraft. Tests were made to determine if a staggered arrangement would improve this condition. Since the stack, precipitator, and coal-conveyer structures are located comparatively close to the waterfront, there are practical limitations in the possible arrangement of the staggered stacks. The only available space for the location of the alternate stacks would have been on top of the boiler-room roof over the monitor. Stacks were arranged in this manner for tests, Fig. 16. Observations indicated that there are advantages in staggering, if it can be done in an ideal manner. However, with the arrangement which is possible at the Riverside location, there are no advantages. The stacks over the boiler-room roof produce especially troublesome downdraft of smoke. This test indicated that stacks which are placed directly on top of a building must be somewhat higher than stacks which are placed away from the main structure if the same degree of smoke dissipation is to be maintained.

Since the flow of smoke was not entirely satisfactory within the height limitations set for these experiments, considerable efforts were made to test all possible devices that might improve discharge conditions. A large number of stack nozzles, venturi jets, external flat-disk shields, streamlined shields, and flat and spiral vanes were tested. These devices were designed in an attempt to increase the gas-discharge velocity, break up the disturbance created by the stack, create a natural updraft outside the stack, or interfere with the downdraft of smoke back of the stack. The constricting nozzles, which increased the stack velocity, definitely raised the smoke path, but there are limitations to the use of such devices on account of the energy losses. Several of the shields produced improvement with critical adjustments under specific wind velocities and directions. Under other conditions, however, these devices not only failed to produce improvement but created new troubles.

Shielding. At the Riverside location, there are no other large structures near-by to create the effect of a streamlined approach to the plant. Consequently, the structure presents a somewhat abrupt exposure to the wind. The effect of streamlined shielding created by the coal pile was studied. Consideration was also given to the effect of long rows of trees along the property boundaries. Such shielding is beneficial to a limited extent only.

An effort was made to break up the very pronounced turbulent areas around the breechings and induced-draft-fan structures, Fig. 15. Such shields help to break up this local turbulence, but give no material aid in eliminating the smoke downdraft under most conditions.

Smoke-Dilution Analyses. An attempt was made to determine the degree of dilution of discharge gases. Samples were taken in a number of places on the roof and ground where there was visible downdraft of smoke. For this purpose, sulphur-dioxide gas in concentrations equivalent to the actual flue gases was discharged from the model stacks. Analyses for SO_2 content of the samples disclosed that even with low stack height, the dilution of flue gas was in excess of a hundredfold on the roof or ground. Studies elsewhere have shown that flue-gas dilutions of the order of a thousandfold are necessary to eliminate objectionable SO_2 odors (1). Since the tunnel was of the recirculating type, the entire atmosphere became permeated with traces of SO_2 rather rapidly. It was, therefore, impractical to measure greater dilutions than 1 part of flue gas per 100 parts of air in the stream of discharged smoke.

Conclusions

1 Following tests of the model of the Westport Plant, frequent observations were made of the smoke discharge from the actual plant. The model was found to reproduce actual conditions satisfactorily. These observations add further evidence that model tests furnish a reliable basis for judgment in predetermining necessary stack height for the dissipation of discharge gases.

2 Since it was necessary in this case to select a stack height consistent with requirements dictated by the proximity of the airport, and, at the same time, to insure reasonable freedom from a smoke nuisance, a compromise had to be reached. From practical considerations, it was felt that the performance at wind velocities of approximately 20 mph should govern. The reason for this selection is the large number of days during which wind velocities in the neighborhood of 20 mph occur. Velocities in excess of 20 mph will definitely produce a greater degree of downdraft, but these stronger winds occur with diminishing frequency.

3 With very low stacks, smoke is carried down around the

model and close to the ground at the prevailing average wind velocities. As would be expected, the amount of downdraft diminishes with increasing stack height. The model tests indicate that it is necessary to have a stack height of approximately 157 ft above ground (elevation 167 ft or 1.31 times the height of the boiler-room monitor) to reduce smoke nuisance to reasonable limits with a 20-mph wind. Even at this stack height, there is noticeable downdraft of smoke around the model within limited angles of wind direction. Also at this height, some annoyance from SO_2 can be expected on the days when very high wind velocities occur.

4 The benefits from high stack velocities are found to be distinctly worth while for flue-gas dissipation. The tests indicate that a stack velocity of 60 fps is desirable at this plant.

5 The annoyance from downdraft may be expected to increase somewhat with the addition of each unit.

6 None of the large number of special stack designs or shields showed sufficient merit to justify its use at this plant.

7 It is well to point out that the results obtained by model tests apply specifically only to that prototype for which the model is designed. The influence of surrounding structures greatly changes the turbulence pattern. Therefore, considerable care should be exercised in applying the results of one set of tests to other structures.

Acknowledgments

This investigation was carried out under the general direction of Mr. A. L. Penniman, Jr., general superintendent of the authors' company.

The authors wish to express their appreciation for the valuable comments which were made by the large number of engineers who witnessed the tests. Dr. P. L. Betz gave especially valuable assistance in developing special apparatus and test technique. Capt. L. M. Rawlins, Jr., and Mr. W. W. Pagon gave valued help in the investigation of special stack designs, and in developing additional methods of studying flow phenomena around stacks. A large part of the actual test work covered by this paper was carried out by Messrs. F. L. Griffith, Jr., and J. E. Goeller.

Problems in Water-Steam Cycle of Central Steam-Generating and Decentralized Control Systems, Parkchester

By S. T. POWELL[1] and J. A. DONDERO[2]

Parkchester, located in the Bronx, New York City, is the largest apartment community in the world, having 58 buildings, containing 12,273 apartments, which eventually will accommodate nearly 40,000 persons. The entire group of buildings is heated by a central steam-generating plant, and all condensate is collected at individual groups of buildings and returned to the central plant in an ingenious and novel collection system. To avoid corrosion of the distribution and condensate-return lines required the generation of steam of the highest quality. Numerous engineering problems were encountered and had to be economically solved in the basic design of the various structures. The project is now completed and the period of initial operation has demonstrated the soundness of the development. This paper presents a general discussion of certain problems which occurred in this development, emphasis being placed on the engineering aspects.

Introduction

Parkchester, located in the Borough of the Bronx, New York City, about four miles east of the George Washington Bridge, is the largest apartment community in the world. Its magnitude is indicated by the aerial view, Fig. 1, and by data given in Table 1. The development was conceived and financed wholly by the Metropolitan Life Insurance Com-

TABLE 1 STATISTICAL DATA—PARKCHESTER APARTMENT COMMUNITY

pany. Ground was broken in August 1938, and 3 years were required to complete the project. The last building was turned over to the operating management of the company on August 27, 1941.

This paper relates primarily to certain problems involved in the design, construction, and initial operation of the steam-heating system. The problems encountered with respect to corrosion and allied matters will be discussed under two major headings: (1) the selection of proper materials and equipment, and (2) the operating procedure followed for the control of water and steam quality.

Description of the Steam-Heating System

It will be noted in Fig. 2 that the Parkchester heating system consists of a single steam-generating plant from which feeder mains diverge underground to supply the various buildings. Steam at boiler pressure is distributed to 29 heat-control rooms strategically located throughout the development. Each of these control rooms houses a pressure-reducing station, duplicate hot-water generators, various pumps, and control equipment which automatically regulates the flow of steam throughout the building or buildings served by that particular control room.

The steam-generating plant houses four Foster Wheeler D-type boilers and auxiliary equipment. Each boiler has a normal rated capacity of 100,000 and a maximum capacity of 135,000 lb of steam per hr. Electricity is supplied to the entire project by the public utility; however, should future economic conditions warrant, turbogenerators may be installed, as necessary space has been provided for this purpose. The boilers have been designed to operate at a pressure of 500 psi, and provisions were incorporated to facilitate equipping them with superheaters. At present the boiler pressure has been limited

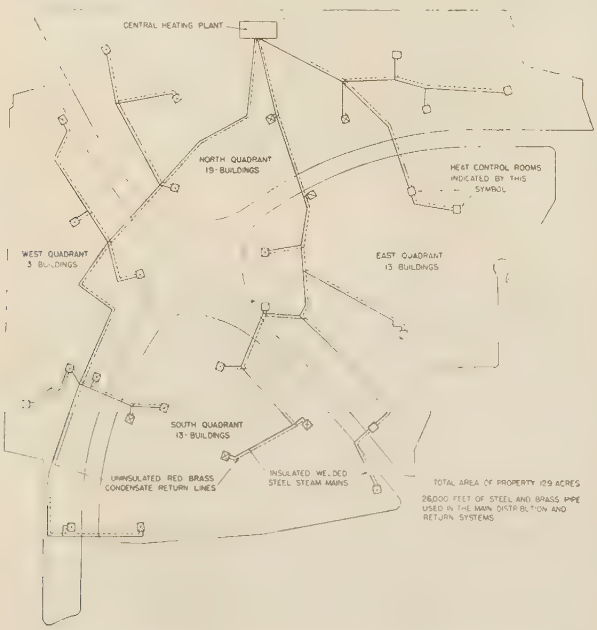

Fig. 2 General Diagram of Steam-Heating System

to 95 psi. In addition, the station has been so laid out that coal bunkers can be erected and pulverized-coal preparation and burning equipment installed, should conditions necessitate a change of fuel. The boilers are oil-fired at present and are equipped with waterwalls and air preheaters.

Operation of the boilers and auxiliaries is handled through a central panel board and automatic combustion control has been incorporated in line with modern practice.

The steam, at boiler pressure, is distributed through three transmission lines, two of which are 16 in. and one 14 in. in diameter. They are of welded steel construction, have packless stainless-steel bellow-type expansion joints, and are insulated with magnesia block, bound with copper sheathing. The condensate-return piping is of red brass connected by sweated fittings and provided with packed-type expansion joints. Approximately 13,000 ft of steel pipe and the same amount of red-brass pipe were required for the distribution and return mains.

Aside from the actual monetary value of the pipe involved, the relative inaccessibility of these underground mains would make replacement, in whole or part, a costly procedure and the protection of this portion of the heating system was the primary object that motivated the control measures adopted for the prevention of corrosion and deposition of solids.

The steam enters the control room at 80 lb pressure, allowing for a reduction of about 10 to 15 lb because of losses, passes through two reducing valves in series where the pressure is reduced to 5 lb, after which it is discharged to a low-pressure header for distribution. One line supplies two hot-water generators which are thermostatically controlled, maintaining the hot-water supply at 140 F.

These generators are copper-clad steel tanks with a copper-loop steam-heating element. As the water pressure is greater than the steam pressure, these generators must be regarded as potential sources of condensate contamination, although no actual cases of city water leakage into condensate have occurred to date.

The steam required for apartment heating next passes through an automatic electrically operated control valve, and the quantity admitted to the heating system is dependent upon two factors, i.e., the outside temperature and the amount of heat in the building.

In the radiation system[3] which was specially designed, the steam travels up bare pipe risers located in kitchens and bathrooms, heating these smaller rooms, and crosses over at the top floor of the building into adjacent downcoming banks of small cast-iron finned heat convectors. All condensed steam drains by gravity to the horizontal condensate-return line in the building basement where traps (one to each vertical convector bank) remove it from the radiation system proper.

The condensate is discharged through an accumulator tank to the vacuum pump, where the entrained noncondensable gases are evacuated, and the water is then delivered into the return mains leading to the storage tank in the heating plant.

The Water and Steam Cycle

Design and Installation Phase. It will be noted from the foregoing description of the mechanical aspects of the heating system and the diagram, Fig. 3, that the water-and-steam cycle is essentially a closed circuit. When designing the system it was estimated that the maximum loss of water and steam from this circuit would not exceed 3 per cent of the total steam output. The boiler feedwater would therefore consist of 97 per cent condensate returns and 3 per cent make-up.

The make-up supply, which is New York City water, consisting of either Catskill or a combination of Catskill and Croton

[3] Patented.

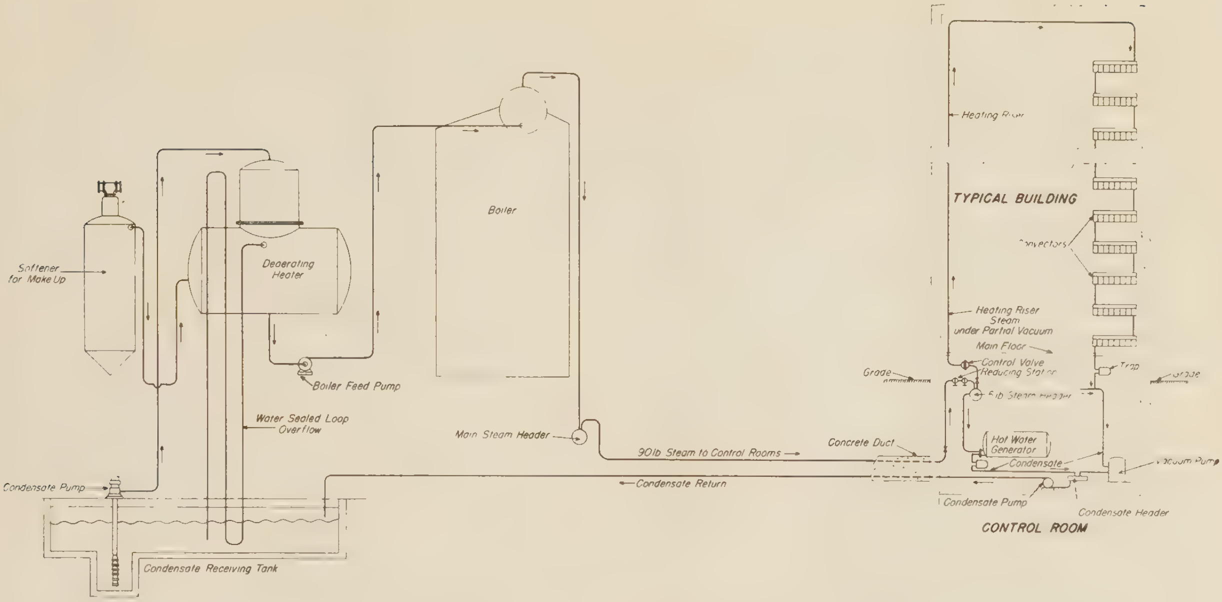

FIG. 3 MECHANICAL ARRANGEMENT OF STEAM-HEATING SYSTEM

water, is deaerated and treated in a hot-process softener using phosphates. The softener effluent is discharged into the storage tank of the feedwater heater where it mixes with the deaerated condensate. This method of treatment was selected by the designing engineers primarily to keep to a minimum carbon dioxide in the steam delivered from the boilers. A further design precaution was the inclusion of steam-purifying devices in the boilers in order to provide steam of a low total-solids content.

To protect the entire system, it was necessary to adopt additional measures, particularly with regard to corrosion. Since the heating system proper operates under high vacuum most of the time, slight leakage of air into that portion of the system is inevitable, and the condensate may actually take into solution oxygen and other gases. These gases will not be completely removed at the vacuum pump. Further, the condensate is exposed to pollution with air in the return lines, between the condensate pumps and the receiving tank in the plant, as the greater portion of the return piping is only partially filled with water and is under atmospheric pressure; hence the use of red brass to resist corrosion from these gases in the underground condensate return lines.

Careful consideration was given also to positive drainage of all piping, avoiding couples of dissimilar metals wherever practicable, and introducing numerous scale pockets to catch mill scale and debris left in pipe during construction.

Initial Operation. Steam generation began November 15, 1939, during the construction period, before the water-treating equipment was installed, which deficiency necessitated the use of untreated city water for a short period. An emergency chemical feeding system was hastily provided for protecting the boilers, the steam-distribution system, and the condensate lines against scale and corrosion.

It was originally planned to turn steam on the first buildings requiring heat and to flush the piping system to eliminate mill scale, dirt, and oil, which were known to be present to some extent in the system. After these lines had been cleaned, it was proposed to return the condensate to the boiler plant to be re-used as feedwater. During the first flushing-out period, the boiler feedwater was to consist of 100 per cent make-up; subsequent flushing-out operations progressively reducing the percentage of make-up required. Considerable delay was encountered in putting this plan into effect because of the fact that the condensate receiving tank was not completed until sometime after the plant was placed in operation.

The most aggravating operating problems encountered during the first few months of operation were the clogging of the steam-washer elements with solids and corrosive attack on steel nipples on the inlet manifold of the washer. The deterioration of these nipples was distinctly a case of oxygen corrosion due to lack of proper deaeration because of the unavailability of the deaerating heater. Although these problems were troublesome, they were of no greater magnitude than would usually occur in starting up a plant before construction had been completed and caused no permanent damage to the system as a whole.

Correction of Carry-Over. The boilers as originally installed were equipped with steam purifiers of the wet type, which provided for washing the steam with feedwater to lower the solids in the saturated steam. Difficulty occurred from deposition of solids in the washer elements because of the use of phosphate-treated feedwater. It was found necessary to replace the equipment with dry purifiers. This change effected a marked improvement in steam quality delivered from the boilers. The efficiency of the dry-type purifier over the wet type is shown in Fig. 4.

To provide an accurate check on steam quality, a permanent conductivity-recording assembly, embodying vacuum degasification of the sample was installed. This assembly consists of a combination condenser and tempering coil, a sample temper-

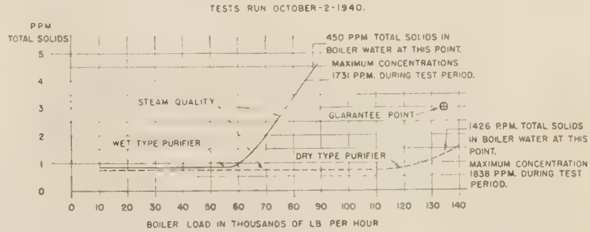

FIG. 4 GRAPH COMPARING PERFORMANCE OF STEAM PURIFIERS
(Tests obtained with both indicating and recording conductivity apparatus.)

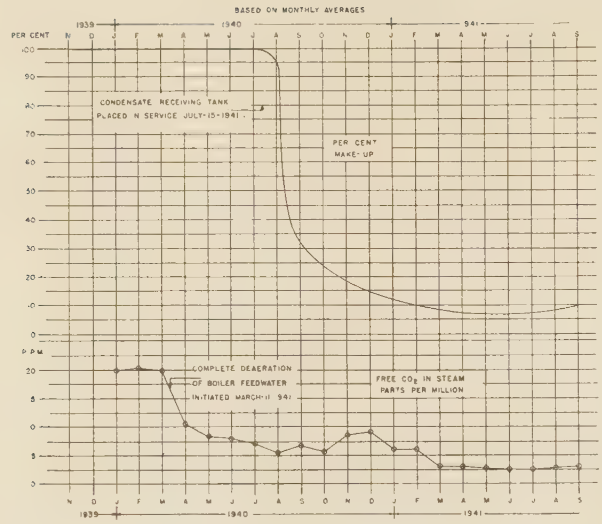

Fig. 5 Graph of CO_2 Content of Steam

ature-control device, a Pyrex flow vessel, two water-jet-type aspirators, and a Leeds and Northrup conductivity cell and recorder. Undesirable conditions, such as abrupt and sizable load increases and excessive concentration of solids in boiler salines, will be reflected on the chart by a rise in conductivity thus indicating a decrease in steam quality. One year of operation disclosed that the quality of the steam delivered into the main ranged from 0.6 to 1.5 ppm of total solids.

Reclamation of Condensate. Delayed condensate reclamation, enforcing the use of untreated city water introduced several undesirable factors; viz., the presence of free carbon dioxide in steam, high boiler-water turbidity, and slight deposition in parts of the feedwater cycle. However, most of these conditions have been either wholly or partially corrected.

The progressive reduction from amounts on the order of 20 to 30 ppm of CO_2 in the steam, which prevailed during the first four months of operation, to current values of 0.5 to 2.0 ppm is traceable in part to reductions in the amount of untreated make-up admitted to the system during the earlier stage of operation. The first reduction from over 20 ppm to about 10 ppm was due to better feedwater-heater performance. Most of the untreated city water was admitted to the boiler-feed system through the feedwater heater, therefore, the increased deaeration had an immediate effect on the carbon-dioxide content of the steam. These occurrences are illustrated graphically in Fig. 5.

One of the most troublesome factors still encountered in condensate reclamation has been the high turbidities that occur in the condensate over the first week or two of the heating season and recur to a somewhat lesser degree during the intermittent heating at the end of the season. When this condition arises the condensate is diverted to the sewer until it has cleared. Most of the suspended matter is undoubtedly rust, accumulating during extended periods of no flow, which, although present in minor amounts in the individual lines, collectively, over so large a system, imparts an appreciable turbidity to the condensate for a short period upon resumption of heating. This remains as one of the problems requiring solution, and as an initial step toward correction of the condition, a piping change is contemplated which will permit diversion of the condensate from the heating system proper to the sewer during start-up periods without affecting normal return of condensate from hot-water generators and other sources. It is estimated that in this manner from 20,000 to 40,000 lb of 130 F water can be saved per hour during these initial flushing periods.

Feed-Line Deposition. Difficulty was experienced from deposits which accumulated in the control valve of the Copes feedwater regulator. The analyses of these deposits showed them to consist largely of calcium and magnesium phosphates, some iron, and a small amount of copper. These deposits, which were quite hard, accumulated slowly during the period when it was necessary to use fairly large amounts of make-up, and although the mixture of condensate and treated water resulted in a relatively low hardness in the feedwater, still these deposits persisted. It was necessary to dismantle the equipment at intervals and remove the deposits manually.

These deposits occurred because of the presence of small amounts of calcium and magnesium phosphates which tend to precipitate as hard crystalline formations at pH values about 8.5 when the temperature of the water is moderately elevated. It is expected that by maintaining the pH value of the feedwater at 8 to 8.5, and by the use of a low percentage of treated make-up, the accumulation of such deposits can be greatly minimized.

Inspection and Maintenance of the Heating System

In so extensive a steam-distribution and condensate return system, periodic inspection and overhauling of certain portions of the equipment are essential to efficient and economical operation. During the summer all condensate traps are removed, cleaned, and tested. Necessary replacements of parts are made at this time. Scale pockets are opened and cleaned. Whether this operation will be necessary every 12 months can only be ascertained by future experience. It is quite probable that after all mill scale and debris have been removed from the system, some of the work will be required at less frequent intervals.

This maintenance program has provided an excellent means to ascertain the condition of the metal surfaces in the system and the last annual inspection, which covered about one half of the property, disclosed that out of a total of 2200 condensate traps, less than 0.5 per cent required replacement of parts due to deterioration incidental to normal operation.

The last inspection also disclosed that many of the scale pockets were entirely filled with mill scale and other dirt. Analysis of a sample of deposit (see Table 2) indicates that it consists of mill scale and silica-bearing construction debris, with traces of calcium and magnesium phosphates. The latter contamination occurred during the tuning up of the steam plant. Some of these scale pockets had been cleaned previously, which leads to the conclusion that purging of the piping still continued to a marked degree during the 1940-1941 heating season.

TABLE 2 ANALYSIS OF MATERIAL REMOVED FROM HEATER-HEADER DRIP TRAP, NO. 4 GARAGE

Constituent	Expressed as	Per cent
Silica	(SiO_2)	49.79
Iron	(Fe_2O_3)	30.14
Aluminum	(Al_2O_3)	10.96
Calcium	(CaO)	1.26
Magnesium	(MgO)	1.29
Phosphates	(P_2O_5)	0.50
Sulphates	(SO_3)	None
Copper	(Cu)	None
Zinc	(Zn)	None
Lead	(Pb)	None

Note: Analysis made on the dried sample which contained 36.60 per cent of water before drying.

Examination of steel piping adjacent to scale pockets and traps revealed only a small amount of general oxidation, adjudged by the condition of the metal and the presence of mere traces of red-iron-oxide film. From our observation metal deterioration has been practically absent in the steel pipe.

Additional evidence as to the apparent freedom from corrosion

in the building system was the excellent condition of the metal in one of the cast-iron convector elements. This element was taken from the bottom of a vertical convector bank, a point subject to maximum contact with hot condensate, after it had been in service 16 months.

Some general corrosion, indicated by a rust coating, has occurred in the 2-in. steel lines connecting the condensate pumps to the brass return lines. The total length of line which is so affected is relatively small. However, this point in the system is probably the most susceptible to attack because of the contact of condensate with air. It is probable that most of the rust which fouls the condensate returns during intermittent heating periods originates at these locations. It is interesting to note, however, that pitting has not occurred, and these deposits, when once formed, appear to be acting as an impervious coating retarding further aggressive attack. These points are being carefully observed, and should the condition warrant the pipe will be replaced with brass or other nonferrous material. In order to detect corrosion or deposition in steam-distributing mains and condensate return lines, the use of spool pieces as routine observation specimens is resorted to.

Idle Equipment

Experience in numerous boiler plants has demonstrated that serious corrosion is encountered during periods when equipment is idle. Heating plants are particularly subject to such action on account of the low steam demand during warm weather. At Parkchester three boilers are idle, one of which must be kept filled with water for stand-by service. Also considerable changing of boilers from active to idle or stand-by status is necessary in the summer on account of maintenance work.

To avoid corrosion, current practice is to keep the pH of the water in idle boilers at 10.8 or over, by addition of caustic soda, and also to maintain a sodium-sulphite residual of approximately 100 ppm to combine with any dissolved oxygen. Whenever practicable, idle boilers are filled to the vents, expelling all free air, the vents then being closed, and hydrostatic pressure of about 50 psi imposed to eliminate seepage of air into the unit.

Aside from boilers, consideration is being given to the problem of corrosion prevention in steel accumulator and vacuum-pump tanks. Just how far these protective measures should be extended we are unable to say at present.

Treatment of Make-Up

Supplementary Treatment. It was apparent from the period of initial operation that chemical deaeration utilizing sodium sulphite would be incorporated with the water-treating system as designed to assure the removal of traces of dissolved oxygen. The probablility of pH adjustment with caustic soda was also recognized, but subsequent experience with the hot-phosphate softener disclosed that this apparently would not be required.

Laboratory Control. To facilitate proper control of treatment in the water-steam cycle and to ascertain conditions in the various parts of the entire system, a chemical laboratory completely equipped for this type of work has been provided. Routine analyses are conducted which embrace samples and determinations, as given in Table 3.

TABLE 3 SAMPLING POINTS THROUGHOUT WATER-STEAM CYCLE WITH ROUTINE TESTS INDICATED FOR EACH POINT

Sampling points	Determinations
City water	Free CO_2, pH, total alkalinity, chloride, hardness
Softener discharge	pH, hydroxide and total alkalinity, chloride, hardness, turbidity
Condensate storage	Free CO_2, pH, hardness, phosphate, copper, iron
Boiler feed	pH, hydroxide and total alkalinity, chloride, hardness, phosphate, copper, iron
Boiler salines	pH, hydroxide and total alkalinity, chloride, hardness, phosphate, sodium sulphite, sodium sulphate, turbidity, estimated solids, copper, iron
Steam	Recorded total solids by electrical conductivity, free CO_2, pH, phosphate, copper, iron

Summary

Two years of operating experience and close observation of the entire heating system have demonstrated the foresightedness of the management and their designing engineers in the selection and use of materials for reducing corrosion of metals, and for preventing the deposition of solids, sometimes encountered in large-scale heating systems.

Radiation Configuration Factors Using Light in Furnace Models

By FRED ENGLAND[1] and H. O. CROFT[2]

In problems involving the exchange of heat energy by radiation between bodies, it becomes necessary to know what areas of the bodies in question "see each other." Those factors expressing mutual visibilities are known as "configuration factors." Configuration factors have usually been determined either by mathematical analysis and computation, or by actual experiment with bodies radiating heat energy. This paper introduces an experimental method of determining configuration factors by employing models of furnace cavities and utilizing the exchange of "light" energy instead of "heat" energy.

Nomenclature

The following nomenclature is used in the paper:

- A = area, sq ft
- B = correction factor for illumination, which is measured by a photoelectric cell when the angle of incidence is greater than zero (no units)
- B_{am} = arithmetic-mean correction factor (no units)
- B_{cm} = cosine-mean correction factor (no units)
- B_{tm} = true-mean correction factor (no units)
- e = emissivity of a body (no units)
- E_A = normal intensity of light, ft-c
- E_p = intensity of light, ft-c
- E/E_w = intensity factor; ratio of intensity of light at a point on furnace wall to average intensity of light from base of furnace (no units)
- F_c = configuration factor (no units)
- F_e = emissivity factor (no units)
- k = conversion factor of lumens to Btu per hr (5.1×10^{-3} Btu per hr per l)
- n = adjacent side of a right triangle whose angle with the hypotenuse is θ, the angle of incidence, ft
- q = energy transferred per unit of time, Btu per hr
- q_A = light energy in transit, l
- R = intensity of other forms of energy than light which cause photoelectric cell to respond, ft-c
- r = distance between centers of two radiating surfaces, ft
- T = absolute temperature of a system, deg R
- X = ratio of length of side of parallel planes to their distance apart (no units)
- Y = ratio of length of unique side on which heat-transfer equation is based to length of common side (no units)
- Z = ratio of length of unique side of other rectangle to the length of the common side (no units)
- θ = angle of incidence, deg
- λ = wave length of electromagnetic phenomenon, mu
- σ = Stefan-Boltzmann constant (0.173×10^{-8} Btu per sq ft per deg R^4 per hr)

Introduction

Since "the phenomena of light are inherently the same as those of radiant heat, although the wave lengths are of different frequencies,"[3] the possibility of the use of light in lieu of radiant heat for the determination of configuration factors for radiation in furnace models is discussed.

A great amount of work has been done on configuration factors from a theoretical viewpoint, involving certain assumptions which may not be strictly valid. Very little work has been done from the practical side, however, because of the difficulty of measuring the high temperatures usually involved in radiation, and because of the difficulty of obtaining equilibrium conditions.

This investigation involves measuring the intensity of light in various parts of furnace models which have a constant light source instead of a radiant-heat source, and, from the intensities of light, calculating the configuration factors which might be used in industrial-furnace design.

Furthermore, it was desired to compare the configuration factors determined experimentally with some determined by purely mathematical means.

When heat is transferred by radiation from a completely enclosed body to the enclosing body, the Stefan-Boltzmann equation is used in its usual form

$$q = \sigma A(T_1^4 - T_2^4) \qquad [1]$$

where q is the heat transferred per unit time, σ is the Stefan-Boltzmann constant, A is the area of the enclosed body, T_1 is the absolute temperature of the enclosed body, and T_2 is the absolute temperature of the enclosing body.

In many cases of heat transmission by radiation, one body is not enclosed by another; thus all of the radiation from one body is not intercepted by the other body, except in the case of infinite parallel planes. Therefore, for radiant-heat transfer between two black bodies which do not directly intercept all of the radiation of each other, another term F_c, the configuration or shape factor, must be placed in the Stefan-Boltzmann equation, which then takes the form

$$q = \sigma A F_c(T_1^4 - T_2^4) \qquad [2]$$

The configuration factor is simply a constant, never greater than unity, which represents the fraction of the areas of the bodies, involved in the transfer of heat, that are "seen" by each other.[4]

Configuration factors have been determined geometrically by use of the principles of illumination. If radiation takes place between two infinitesimal surfaces dA_1 and dA_2, which are small in

comparison to their distance apart, the configuration factor can be determined by assuming the Lambert cosine law and the square-of-the-distance law to hold. The Lambert cosine law states that the radiation from a given area in a direction at an angle to the normal to the surface is proportional to the cosine of the angle. The square-of-the-distance law states that the intensity of radiation from a point source decreases with the square of the distance from the point source. Referring to Fig. 1, it is

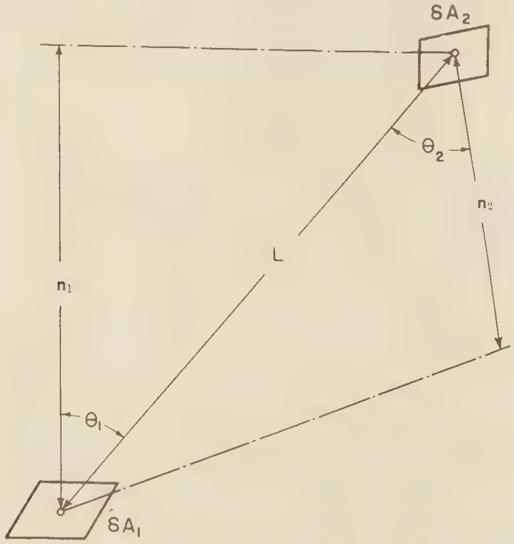

Fig. 1 Radiation Between Surfaces Small in Comparison to Their Distances Apart

seen that the black-body radiation between dA_1 and dA_2 will follow the equation

$$q = i(dA_1 \cos \theta_1)(dA_2 \cos \theta_2)/L^2 \ldots\ldots\ldots\ldots [3]$$

where q is the heat transferred between the infinitesimal elements of areas dA_1 and dA_2, i is the normal intensity of radiation, $dA_1 \cos \theta_1$ is the area of the surface dA_1 which is "seen" by dA_2, $dA_2 \cos \theta_2$ is the area of the surface dA_2 which is seen by dA_1, and L is the distance between the centers of dA_1 and dA_2. Since $\cos \theta_1$ may be written as n_1/L and $\cos \theta_2$ as n_2/L, Equation [3] may be written

$$q = idA_1dA_2(n_1\, n_2)/L^4 \ldots\ldots\ldots\ldots [4]$$

where, as shown in Fig. 1, n_1 is the perpendicular distance from dA_1 to a plane through the center of dA_2 parallel to dA_1, and n_2 is the perpendicular distance from dA_2. Since πi, the total forward radiation from a surface, is equal to σT^4, Equation [3] may be rewritten

$$q = \sigma dA_1 \cos \theta_1 dA_2 \cos \theta_2 (T_1^4 - T_2^4)/\pi L^2 \ldots\ldots\ldots [5]$$

Therefore, if Equation [5] is based on surface dA_1, the configuration factor is

$$F_c = dA_2 \cos \theta_1 \cos \theta_2/\pi L^2 \ldots\ldots\ldots\ldots [6]$$

Hottel[5] has derived equations for the configuration factors for radiant-heat transfer between rectangles in perpendicular and parallel planes. Hottel and Keller[6] determined mathematically and proved experimentally the effect of reradiation on heat transmission in furnaces and through openings. In their mathematical derivations, they assumed reradiating nonconducting walls which emitted as black bodies, and they determined the fraction of the radiation given off by one surface which is received by a parallel surface when the two surfaces are connected by nonconducting reradiating walls.

When the surfaces are not black bodies, another term F_e must be inserted in the Stefan-Boltzmann equation, which assumes the form

$$q = \sigma A F_c F_e (T_1^4 - T_2^4) \ldots\ldots\ldots\ldots [7]$$

The term F_e depends upon the emissivity e of both bodies involved. In the case where one body is small in comparison to the distance to the other body, F_e is equal to e_1e_2. Since the emissivity is equal to the absorptivity, the assumptions can be made that the emission from the first surface is e_1 times as much as that from a black body, and that the absorption of the second surface is e_2 times as much as that of a black body. Therefore, the amount of radiation $(1 - e_2)$ will be reflected in all directions from the second body, and a negligible fraction of this will reach the first body. For cases where a large amount of $(1 - e_2)$ is intercepted by the first body, F_e is not equal to e_1e_2. Hottel has shown that for infinite parallel planes

$$F_e = (e_1^{-1} + e_2^{-1} - 1)^{-1} \ldots\ldots\ldots\ldots [8]$$

For concentric spheres and concentric infinite cylinders, Hottel has proved that

$$F_e = [e_1^{-1} + A_1A_2^{-1}(e_2^{-1} - 1)]^{-1} \ldots\ldots\ldots\ldots [9]$$

where A_1 is the area of the enclosed body, and A_2 is the area of the enclosing body.

Analogy Between Light and Radiant Heat

An interesting analogy between radiant heat and light can be drawn by comparing the properties of each. Temperature is an intensive property of heat which tells the direction of the flow of heat, while the foot-candle is an intensive property of light. A foot-candle is the intensity of illumination upon a surface at a point which is 1 ft from a source of 1 c of standard light intensity, the surface being perpendicular to the light rays at that point. The quantity of the flow of heat is the British thermal unit per hour, which is the quantity of heat required to raise the temperature of 1 lb of water from 39 to 40 F in 1 hr, whereas, the extensive unit of light is the lumen, which is the quantity of light falling on a surface which has an area of 1 sq ft when every point of the surface is 1 ft from a point source of light of 1 c.

If a perfectly diffusing body, which absorbs none of the light energy coming to it, is reflecting this energy, then

$$q_A = E_A dA \ldots\ldots\ldots\ldots [10]$$

represents the amount of energy coming to and diffusing from the body. In Equation [10], term q_A is the energy in lumens, E_A is the normal intensity in foot-candles of the light energy diffusing from the body, and dA is a small element of area in square feet.

If a black body is radiating the same amount of energy as this perfectly diffusing reflector, then

$$q_B = \sigma T_B^4 dA = k\, q_A = kE_A dA \ldots\ldots\ldots\ldots [11]$$

where q_B is the energy radiating from the black body in British thermal units per hour, σ is the Stefan-Boltzmann constant, T_B is the absolute temperature of the black body, and k is the factor for the conversion of lumens to British thermal units per hour,

[5] "Radiant Heat Transmission Between Surfaces Separated by Nonabsorbing Media," by H. C. Hottel, Trans. A.S.M.E., vol. 53, 1931, paper FSP-53-19b, p. 270.

[6] "Effect of Reradiation on Heat Transmission in Furnaces and Through Openings," by H. C. Hottel and J. D. Keller, Trans. A.S.M.E., vol. 55, 1933, paper IS-55-6, p. 39.

the numerical value of which is 5.1×10^{-3} Btu per hr per l. Thus it is seen that

$$E_A = \left(\frac{\sigma}{k}\right) T_B^4 \qquad [12]$$

In other words, if a perfectly diffusing nonabsorbing body is reflecting the same amount of energy as a black body is emitting, then the intensity of the light energy coming to or diffusing from the reflector is proportional to the fourth power of the absolute temperature of a black body which is emitting the same amount of energy.

A hot body gives off radiations of different wave lengths. Those waves which produce heating effects are called heat waves, and those which are sufficiently short to affect the optic nerve are called light waves.[7] Fig. 2 compares the relative sensitivity to various wave lengths of the eye and of the Type 1 Weston Photronic cell.[8] From this illustration, it can be seen that the photoelectric cell is more sensitive than the eye to nearly all wave lengths of visible light, and also responds to some wave lengths which do not affect the optic nerve. Therefore, the photoelectric cell measures not only light but also other forms of energy. Thus, if a photoelectric cell is used to measure the energy coming to and diffusing from the nonabsorbing perfectly diffusing reflector, Equation [12] must be rewritten as follows

$$(E_A + R) = \left(\frac{\sigma}{k}\right) T_B^4 \qquad [13]$$

where the term $(E_A + R)$ is the intensity of the light and other

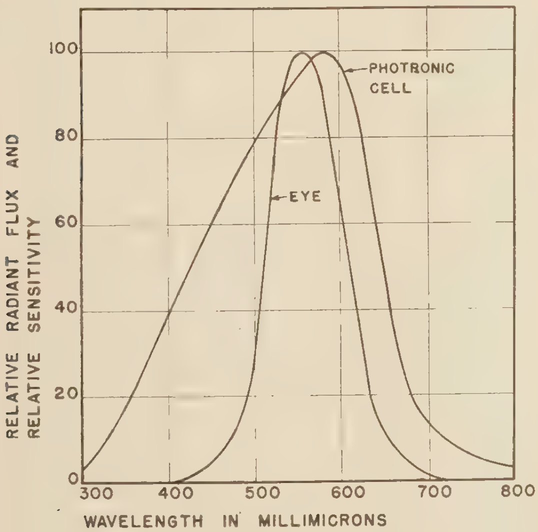

Fig. 2 Relative Spectral Sensitivity of Photronic Type 1 Cell and Average Eye

forms of energy which cause a response on the photoelectric cell. If this term is replaced by E_p, then the equation may be written

$$E_p = \left(\frac{\sigma}{k}\right) T_B^4 \qquad [14]$$

Rather than invent a name for E_p, the intensity of radiation from a light source as determined by a photoelectric cell, it seemed more expedient to redefine light as that form of energy to which the photoelectric cell responds.

Referring to Fig. 2 again, and assuming the square-of-the-distance law to be strictly valid, it is seen that doubling the distance from the source of the light for which the curve for the photoelectric cell is plotted causes the intensity for all wave lengths to be one fourth as great. Therefore, since the area under the curve is the total amount of energy received by the cell from

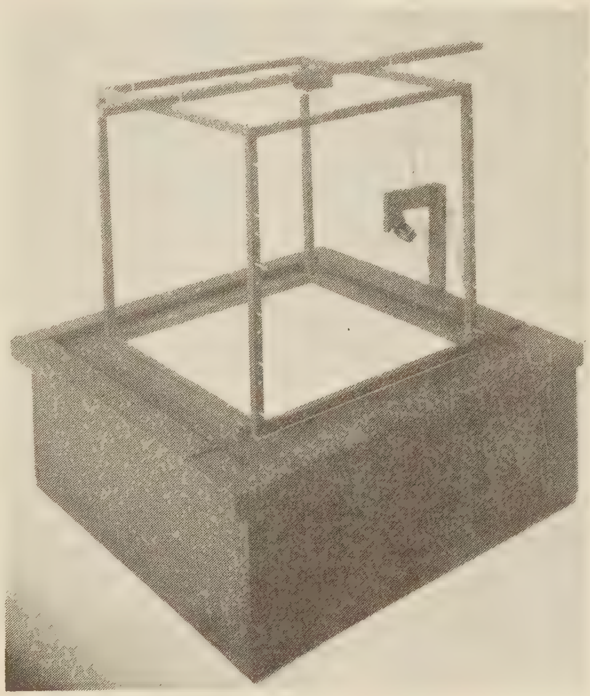

Fig. 3 Model Furnace No. 1 and Constant Light Source Enclosure

the source of light, this area, and therefore the energy received when the distance is doubled, will be one fourth as great.

Experimental Apparatus

The apparatus consisted of a constant light source, a specially mounted photoelectric cell, a standard photoelectric cell, a potentiometer, four model furnaces, a darkroom, a Weston illumination meter, and a standard reflector of magnesium carbonate.

The source of light was nine bulbs mounted in a box. The box was 3 ft wide, 3 ft long, and 1 ft high, and was made of 1-in. white pine. It was painted with flat white paint on the inside and flat black paint on the outside as shown in Fig. 3. The cover of the box was movable and was also painted with flat black paint. In the center of the cover was a piece of pure white opal glass, $^1/_8$ in. thick, 2 ft long, and 2 ft wide.

A Weston Photronic cell, No. 594, Type 1, was used as a standard cell to check the intensity of light from the constant light source. It was placed in a convenient position with respect to the light source. In Fig. 3 the standard cell is seen on the side of the light source, while, in Fig. 4, it is seen above both the model furnace and the light source.

Fig. 3 is an illustration of furnace No. 1 on the constant light source. It is a frame without any walls and represents a furnace with total-absorbing walls. The frame was constructed from $^3/_4$-in. $\times$ $^3/_4$-in. white pine; it has a square base 24 in. $\times$ 24 in. and is $23^1/_4$ in. high. Thus, the inside of this frame is a $22^1/_2$-in.

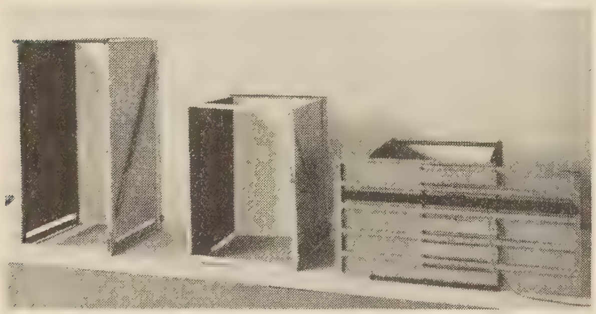

Fig. 5 Model Furnaces Nos. 4, 3, and 2

cube. As shown in Fig. 3, stud bolts were used to fasten the traversing bar, holding the measuring cell in the correct positions. This frame was painted with flat black paint, which absorbs 95 per cent of the light. Model furnace No. 1, Fig. 3, corresponds to a furnace with total-absorbing walls and top.

Model furnace No. 2 is shown in Figs. 4 and 5. It has four walls, no top, and is made of $^1/_4$-in. plywood. The inside of this furnace is a 2-ft cube. The front wall is 4 ft long and may be slid horizontally to the desired position. In the front wall are five holes with templates; thus the cell may be placed into the desired hole for traversing the side wall.

Model furnaces Nos. 3 and 4, Fig. 5, are identical with model furnace No. 2, except for the fact that they are, respectively, 1.4 times and 2 times as high as No. 2. The inner dimensions of No. 3 are 24 in. × 24 in. × $33^5/_8$ in., while those of No. 4 are 24 in. × 24 in. × 48 in. Furnace No. 3 has seven holes in its sliding front wall, while furnace No. 4 has ten.

Method of Conducting Experiments

The photoelectric cell used for measurements was calibrated in the following manner: A 200-w bulb in a lamp with no reflector and 1 ft 6 in. high was placed in the circuit used by the constant light source, described in the previous section. This lamp was placed in the darkroom, and the standard photoelectric cell was placed in a position near and to the rear of the lamp. The standard cell was kept at a constant reading on the potentiometer. The temperature of the room was maintained at 82 F, since the current of photoelectric cells is a function of temperature. The "measuring" cell was fastened to the front of furnace No. 1, so that it faced the lamp and was at the same height as the bulb in the lamp. To make sure that the cell was parallel to the lamp at all times, a string was hung horizontally across the darkroom at a height of 1 in. above both the lamp and the photoelectric cell. Thus, since the cell was attached to the front part of the furnace,

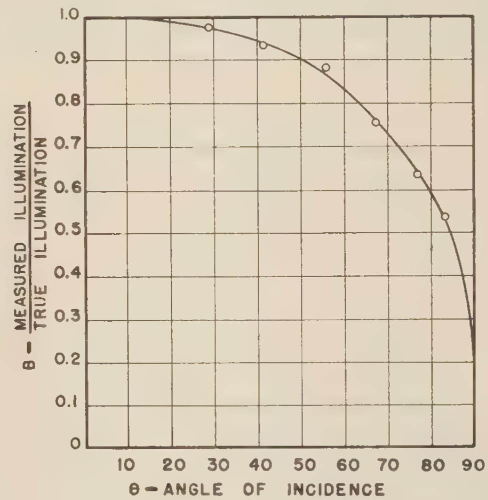

Fig. 6 Effect of Light Incidence on Illumination of Special Photoelectric Cell at Constant Illumination

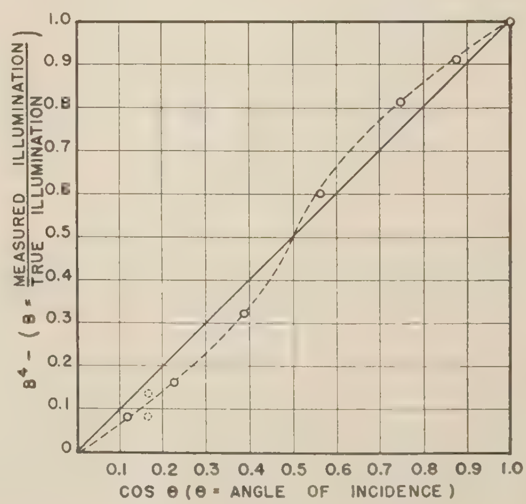

Fig. 7 Relation of B^4 to Cos θ

the cell was perpendicular to the light rays when this suspended string extended over the lamp, the photoelectric cell, and a point on the rear of the furnace, corresponding to the position of the cell on the front part of the furnace.

When the lamp had sufficient time to reach its equilibrium temperature, the current in the measuring cell was determined, while the current in the standard cell was held constant by keeping the illumination from the light source constant by means of the rheostats. When the readings for the current in the measuring cell became constant, this value in microamperes was recorded. Then the distance of this cell from the lamp was measured. The illumination at this cell was next found by means of a Weston illumination meter. This procedure was repeated for various distances of the photoelectric cell from the lamp.

Fig. 6 is a curve showing the relation of the correction factor to the angle of incident light. An interesting relation between the fourth power of the correction factor and the cosine of the angle of incident light is shown in Fig. 7.

Procedure for Model Furnace No. 1[9]

The distribution of illumination on the sides of model furnace No. 1 was determined in the following manner: The light in the light source was turned on, and the room temperature was held at 82 F for 2 hours prior to conducting the experiment, to insure equilibrium conditions.

The current generated in the measuring cell, when it was placed in the center of each of the thirty-six equal areas into which the top of the furnace was divided, was measured. Before and after determining the current in the cell at each point, the illumination from the constant light source was checked by means of the standard cell. Then readings were taken for each of the centers of the thirty-six equal areas of the side of the furnace. Because the thickness of the opal glass on the constant light source varied slightly, the sides of the furnace received slightly different amounts of light. Therefore, readings were taken alternately for the thirty-six points on the top and the thirty-six points on the side for each of the four sides. This procedure was repeated for five furnaces, similar to model furnace No. 1, except for the fact that their heights were from $^1/_6$ to $^5/_6$ times as great as the height of model furnace No. 1.

[9] Corresponding to a furnace with total-absorbing walls and top, Fig. 3.

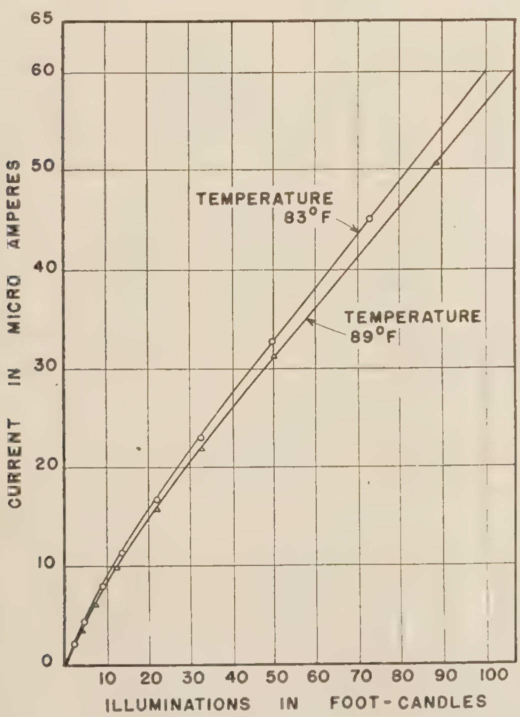

Fig. 8 Calibration of Photoelectric Cell Used With Model Furnaces Nos. 2, 3, and 4

Model Furnace No. 2, Procedure With Varied Absorption on Walls

Experiments were next conducted using model furnace No. 2, Figs. 4 and 5. A different light-sensitive element was used in the measuring cell and was calibrated in the same manner as before

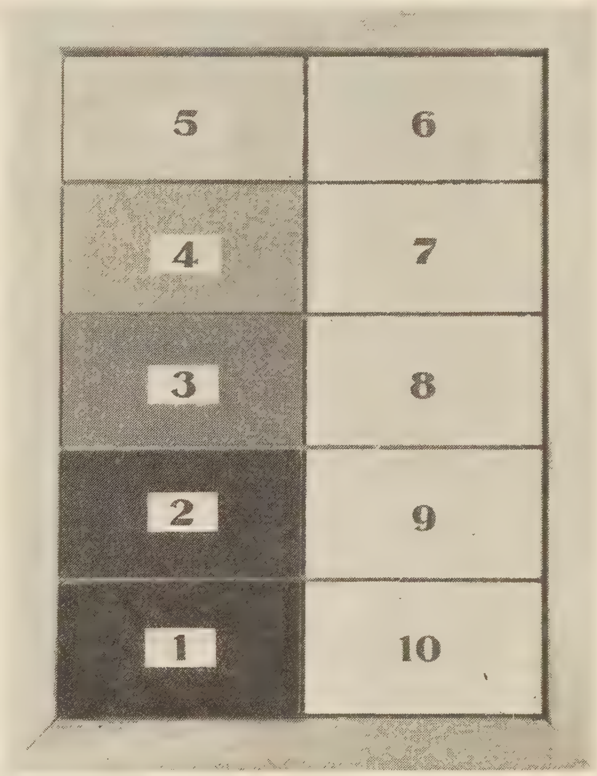

Fig. 9 Various Shades of Paint Used on Model Furnace No. 2

for temperatures of 83 and 89 F, as shown in Fig. 8. The sides of the furnace were first painted with flat black paint. A similar run was conducted as that described for model furnace No. 1. The intensity of the light was measured over the top and, by use of the sliding wall, on the front side of the furnace. To correct for the nonuniformity of the opal glass of the constant light source, it was found more convenient here to turn the opal glass clockwise 90 deg, and to take measurements for the top and the side four times. Then the four readings for each corresponding point were averaged and converted to foot-candles by means of Fig. 8. Next, the furnace was repainted with two coats of a flat paint containing 50 per cent flat white paint and 50 per cent flat black paint. The procedure described was repeated and the furnace repainted. The ten shades of paint which are shown in Fig. 9 varying from flat black paint to flat white paint were used.

The absorption of light on each of the paints was determined

by a method of Barrows[10] as follows: A flat block of c.p. magnesium carbonate was placed vertically a few inches away from the measuring cell. The current generated in the cell, when the light from a lamp trained upon the block was reflected to the cell, was read on the potentiometer. Then the current was measured when the magnesium carbonate was replaced by a piece of plywood painted with the desired paint. Since the reflection coefficient of light on magnesium carbonate is known to be 0.98, the product of the ratio of the light reflected from the paint to that reflected from the magnesium carbonate and 0.98 gives the reflection coefficient of the paint. The difference between unity and this value is the absorption coefficient of the paint. The data for the various paints are given in Table 3.

Procedure for Furnaces Nos. 2, 3, and 4

The next experiment consisted of runs on furnaces Nos. 2, 3, and 4, all having three walls painted with flat black paint and one wall painted with flat white paint to simulate a furnace with three waterwalls, one refractory wall, and absorbing tubes on top. These experiments were conducted in a manner identical with that described in the previous section for furnace No. 2, except that, since the walls are not alike as in the previous cases, a complete run had to be made having the white wall in each one of the three possible positions.

Results of Experiments

The configuration factor has been defined as a constant, never greater than unity, which represents the fraction of the areas involved in the transfer of heat that are "seen" by each other. Thus, the configuration factor for the top of model furnace No. 1 would be the ratio of the amount of light received by the top to the total amount of light received by the sides and the top. Similarly, the configuration factor for the side of this furnace would be the ratio of the amount of light received by the side to the total amount of light received by all sides and the top. These two cases constitute directly opposed parallel planes and adjacent perpendicular planes, respectively. The configuration factors determined for these two cases are shown in column 4 of Table 1, together with the values (column 3) calculated from Hottel's equations which were discussed previously.

Light striking the photoelectric cell at an angle of incidence greater than zero does not have as great an effect per unit of "effective" area (that area calculated from Lambert's law) as does light normal to the cell on the current generated in the cell. Therefore, to obtain the correct value for the illumination at each of the thirty-six points on the top and each of the thirty-six points on the side, it is necessary to use a correction factor for each point. Fig. 6, which was discussed previously, shows the relation of the correction factor B to the angle of the incident light. The light-emitting surface was divided up into thirty-six equal areas, and the angle of incidence from each of these thirty-six equal areas to each of the thirty-six equal areas on the top and to each of the equal areas on the side (the number of which depended upon the height of the furnace) was found and used.

From Fig. 6 the correction factor B for each of these angles of incident light was determined. Thus, each point on the top and each point on the side had thirty-six correction factors, for which factors it was necessary to find a correct mean. Since it is usually assumed that light intensity varies inversely with the square of the distance from its source, it is obvious that the light, coming from points closer to the point under consideration, should have more influence in determining the true-mean correction factor than points which are further away. Therefore, the true-mean correction factor, based upon the true-mean values B_{tm}, is expressed by the following equation

$$B_{tm} = \frac{(B_1/L_1^2 + B_2/L_2^2 + \ldots + B_{35}/L_{35}^2 + B_{36}/L_{36}^2)}{(1/L_1^2 + 1/L_2^2 + \ldots + 1/L_{35}^2 + 1/L_{36}^2)} \qquad [15]$$

where B_1, B_2, etc., are the correction factors, read from Fig. 6, for each of the angles of incidence of each of the thirty-six points on the light-emitting surface to the point under consideration, and where L_1, L_2, etc., are the distances from each of the thirty-six points on the light-emitting surface to the point under consideration. There are six dissimilar points on the top surface and eighteen dissimilar points on the side surface of model furnace No. 1. Both the true mean $B(B_{tm})$ and the arithmetic mean $B(B_{am})$ were determined for each point on the top and each point on the side of model furnaces 1a, 1b, 1c, 1d, 1e, and 1f, which furnaces have the following values for Z (the ratio of the height of the furnace to the length of the square base): 1, $^5/_6$, $^2/_3$, $^1/_2$, $^1/_3$, and $^1/_6$, respectively, Table 2. Fig. 7, which is a plot of the relation of B^4 to the cosine of the angle of incident light, shows an S curve which approaches a straight line. Another mean value of $B(B_{cm})$ was found by assuming B to be equal to $\cos^{1/4}\theta$ as in Equation [16].

$$B_{cm} = \frac{(\cos^{1/4}\theta_1/L_1^2 + \cos^{1/4}\theta_2/L_2^2 + \ldots + \cos^{1/4}\theta_{36}/L_{36}^2)}{(1/L_1^2 + 1/L_2^2 + \ldots + 1/L_{36}^2)} \quad [16]$$

The results indicate that the average B_{am} is 3.71 per cent larger than the average B_{tm}, whereas, the average B_{cm} is only 0.618 per cent larger. The difference between the B_{am} and the B_{tm} is that the coefficient of each B in the equation for the arithmetic mean is 1, whereas, the coefficient for each B in the equation for

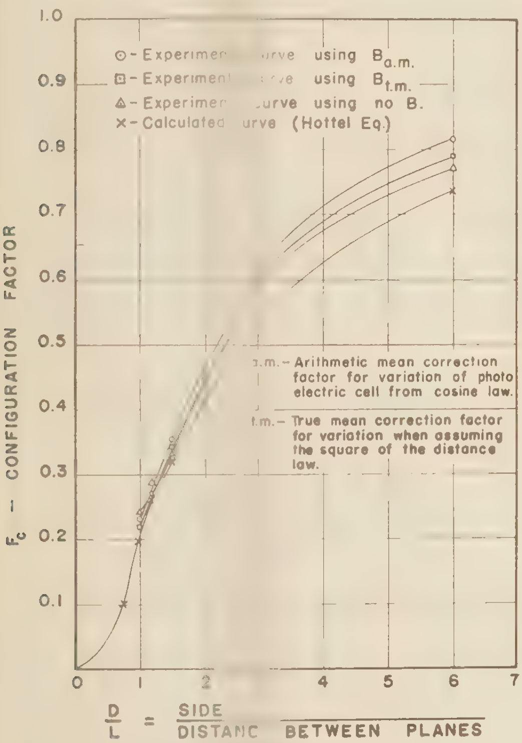

Fig. 10 Configuration Factors F_c, for Parallel Surfaces Directly Opposed

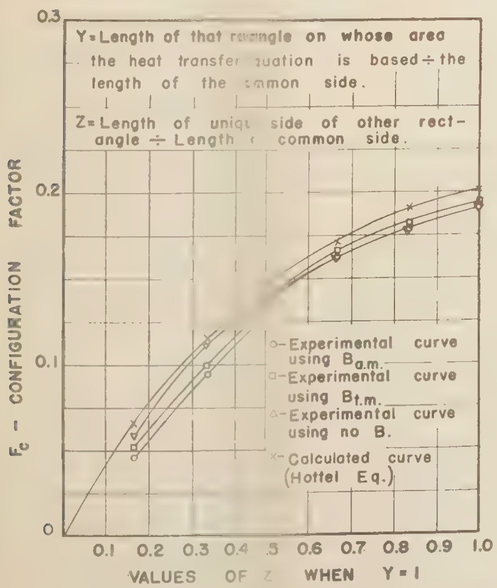

Fig. 11 Configuration Factor F_c, for Adjacent Rectangles in Perpendicular Planes

the true mean is $1/L^2$, and in both cases the divisor is the sum of the coefficients, which is 36 in the first case and

$$\sum_{L=L_1}^{L=L_{36}} 1/L^2 \text{ in the second.}$$

New configuration factors were, therefore, redetermined for model furnaces Nos. 1a, 1b, 1c, 1d, 1e, and 1f, using B_{tm} and B_{am}. To find the correct illumination at the points on the side or on the top, the values were divided by the appropriate correction, in order to obtain the correct illumination. Configuration factors were redetermined as described and are given in columns 5 and 6 of Table 1. Figs. 10 and 11 show the relation of the configuration factors F_c to Z (the ratio of the height of the furnace to the length of the square base) for both the top and the sides of model furnaces Nos. 1a, 1b, 1c, 1d, 1e, and 1f. The curves in Fig. 10, relating the configuration factor for directly opposed parallel planes to the ratio of the height of the side to the distance between the planes, show that the experimental values of the configuration factors are in all cases higher than those predicted by Hottel's equation. The curves in Fig. 11, for the configuration factors of adjacent rectangles in perpendicular planes, show lower values than those predicted by Hottel's equation.

Deviation From Square-of-the Distance Law

It is known that the square-of-the-distance law is not strictly valid, unless the distance between the emitting and the absorbing bodies is great in comparison with the size of the bodies. Schack[11] states: "The intensity of radiation from sources that are neither points nor can be considered as infinitely extended surfaces varies with a power of the distance ranging from zero to two, depending upon the size of the source of radiation relative to the distance r." Thus, since Hottel has assumed the square-of-the-distance law in his derivations, it might be that his values for the configuration factors for parallel planes are lower than the true values, and that his configuration factors for adjacent perpendicular planes are higher than the true values. If the square-of-the-distance law were strictly valid, the curves, using the true mean correction factor B, should be the same as the curves calculated from Hottel's equations. The curve using the arithmetic-mean correction factor does not assume the square-of-the-distance law, i.e., it assumes that the intensity of the light is independent of the distance from the source. Thus, according to Schack's statement, the true configuration factors should lie somewhere between the experimental curve, using the arithmetic-mean correction factor, and the curve, using the true-mean correction factor. It is also probable that, where the parallel planes are far apart, or where the adjacent perpendicular plane is large in comparison to the energy-emitting plane, the experimental curves, using true-mean correction factors, are approached. Conversely, when the parallel planes are close together, or when the adjacent perpendicular plane is small in comparison to the energy-emitting plane, the experimental curves, using the arithmetic-mean correction factor, are approached.

Deviation From Lambert's Cosine Principle

Hottel and Keller[12] state: "An assumption implicit in the basic equation is the validity of Lambert's cosine principle. Actually, the intensity of radiation from all surfaces in directions at large angles from the normal is different from that required by the cosine principle. The data that are yet available as to the

[11] "Industrial Heat Transfer," by A. Schack, translation by Hans Goldschmidt and E. P. Partridge, John Wiley & Sons, Inc., New York, N. Y., 1933, p. 178.

[12] Reference 6, p. 41.

deviation, however, indicate that the over-all error introduced by assuming the correctness of the cosine principle is not great." Therefore, unless the departure of the radiation, from the surfaces involved in the radiant-heat transfer, from Lambert's law is known as a function of the angle of incidence, the experimental curves in Figs. 10 and 11, using no correction factor, are probably the best to use.

Configuration Factors for Furnaces With Radiating Walls

The definition of the configuration factor, as given early in this paper, has to be modified when reradiating walls are involved, and might read as follows: The configuration factor is a constant, never greater than unity, which represents the fraction of the areas involved in the transfer of heat that are "directly or indirectly seen" by each other. Thus when a furnace has reradiating walls, part of the heat from the base of the furnace is absorbed by the walls and reradiated to the top of the furnace, and part of the heat is radiated directly from the base of the furnace to the top. That part of the energy, which is intercepted directly by the absorbing top, divided by the net amount of radiation given off by the bottom of the furnace, is the fraction of the top and of the bottom areas of the furnace which are directly seen by each other. That part of the energy which is reradiated by the walls to the top of the furnace, divided by the net amount of energy given off from the bottom of the furnace, is the fraction of the top and of the bottom areas which are seen indirectly by each other.

Determination of Configuration Factor for Model Furnace With Total-Absorbing Top and Partial-Absorbing Walls

To simulate a furnace with reradiating walls, it was found convenient to paint the walls of model furnace No. 2 with flat paints possessing a range of absorption coefficients as described in Table 3, and displayed in Fig. 9. Thus, the assumption was made that diffuse reflection was identical with reradiation. Therefore, the configuration factor for the top of a furnace, having a total absorbing top and partially absorbing walls, would be the ratio of the light absorbed by the top to the light absorbed by all of the walls and the top. Since none of the light coming to the top was reflected, all of it was absorbed, and, since the absorption coefficient for the paint on the walls was known, the amount of light absorbed by the walls was the product of the amount of light coming to the walls and the absorption coefficient of the paint. Hence, the configuration factor for the top is the ratio of the light absorbed by the top to the light absorbed by the walls and the top. The configuration factor for the walls is the ratio of the light absorbed by the walls to the light absorbed by the top and the walls. Configuration factors, found for both the top and the sides, are given in Table 3, and plotted in Figs. 12 and 13.

The intensity factor (E_w/E) is the ratio of the light intensity at any point on the furnace wall to the average intensity of the base of the furnace. The light intensity at any point on the furnace wall is the product of the reflection coefficient for the wall and the intensity of light received by the point. Thus, to find the intensity factor, the average intensity for each row for the sides is multiplied by the reflection coefficient of the wall and is divided by the average intensity of light from the base. The intensity factors (E_w/E) for the five points on the wall of model furnace No. 2 are given in Table 3, and are plotted in Figs. 14 and 15.

Discussion of Results

It will be noticed that the extrapolation of the curve of Fig. 12 to zero absorption gives a value equal to unity for the configuration factor F_c for parallel planes separated by reradiating black-body walls (diffusely reflecting walls). The Hottel and Keller value for a furnace similar to model furnace No. 2 with nonconducting reradiating black-body walls is 0.535. Also, from Fig. 12, it can be seen that a furnace with a configuration factor of 0.535 would have to possess walls which absorb 26 per cent of the energy coming to them. As previously stated, it was assumed in this investigation, that diffuse reflection from the walls is comparable to reradiation from the walls. For example, if two planes are separated by diffusely reflecting walls, part of the energy from the energy source will strike the wall and be reflected equally to all points in an enclosing hemisphere; if the two planes are separated by nonconducting reradiating black-body walls, part of the energy from the energy source will strike the wall, be absorbed by the wall, and be reradiated in its entirety, since the walls are nonconducting. Thus, in both cases, the energy absorbed by the wall is returned to the system in an almost identical manner. Hence, it seems logical that since all of the energy, which is received by a nonabsorbing diffusely reflecting wall or a nonconducting reradiating wall, is given back to the

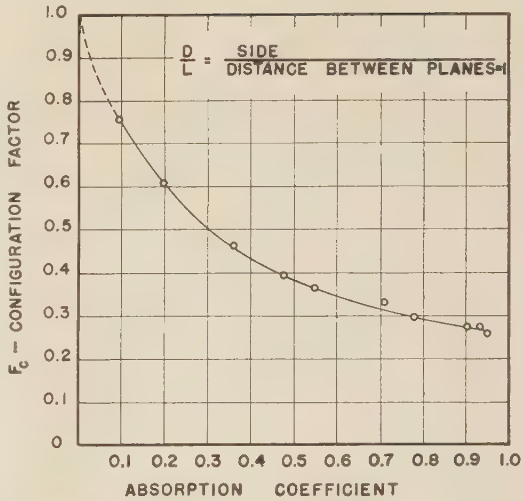

Fig. 12 Configuration Factor F_c, for Directly Opposed Parallel Planes Which Are Connected by Absorbing Walls

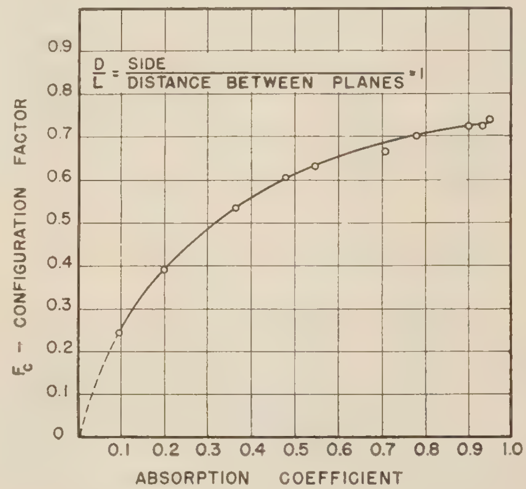

Fig. 13 Configuration Factors F_c, for Absorbing Walls Which Connected Directly Opposed Parallel Planes

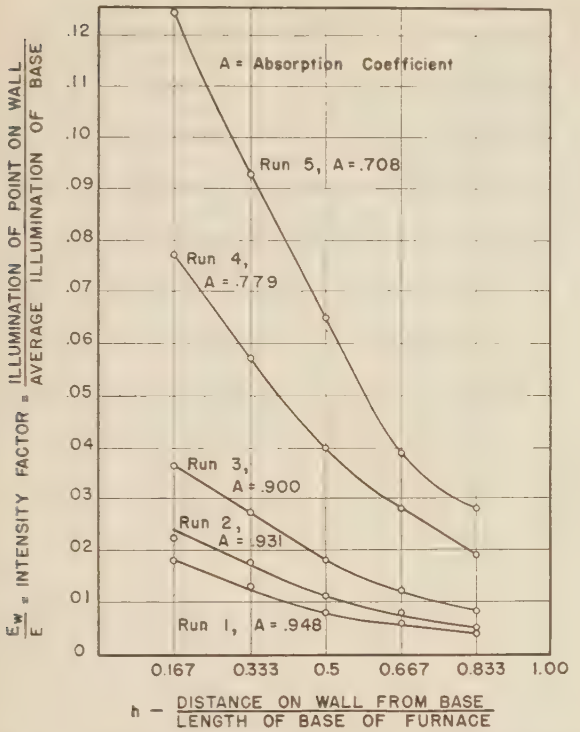

Fig. 14 Relation of Intensity Factor to Distance From Base of Cubical Furnace

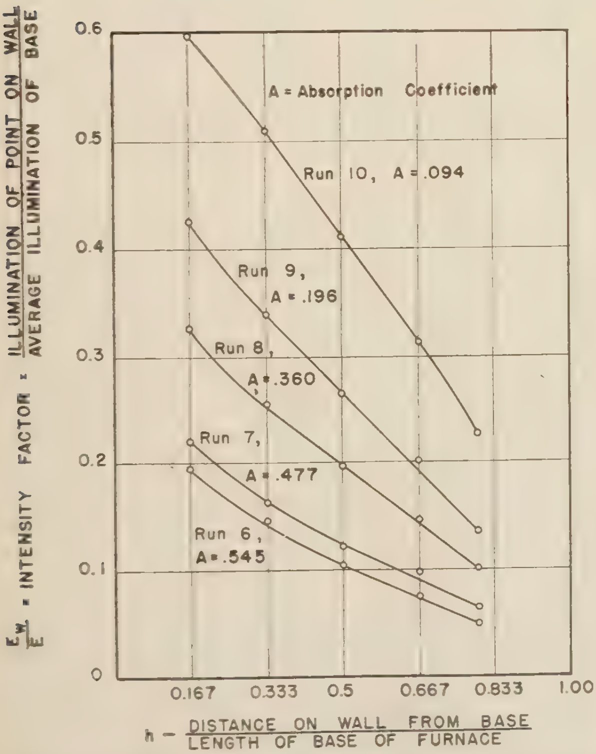

Fig. 15 Relation of Intensity Factor to Distance From Base of Cubical Furnace

system and is finally absorbed by the top, the configuration factor for the top should be unity, and the configuration factor for the sides should be zero, as extrapolated from the curves in Figs. 12 and 13.

The amount of light reflected from the walls is a function of the amount of light they receive and of the reflection coefficient. Thus, since that part of the wall which is closer to the energy source receives more light, it should reflect more. It has been shown that, if a perfectly diffusing nonabsorbing body is reflecting the same amount of energy as a black body is emitting, then the intensity of the energy coming to or from the reflector is proportional to the fourth power of the absolute temperature of a black body which is emitting the same amount of energy. Therefore, the intensity factor E_w/E, where E_w is the intensity of light leaving the wall at any point, and E is the average intensity of light leaving the light source, should be the same as T_w^4/T^4,

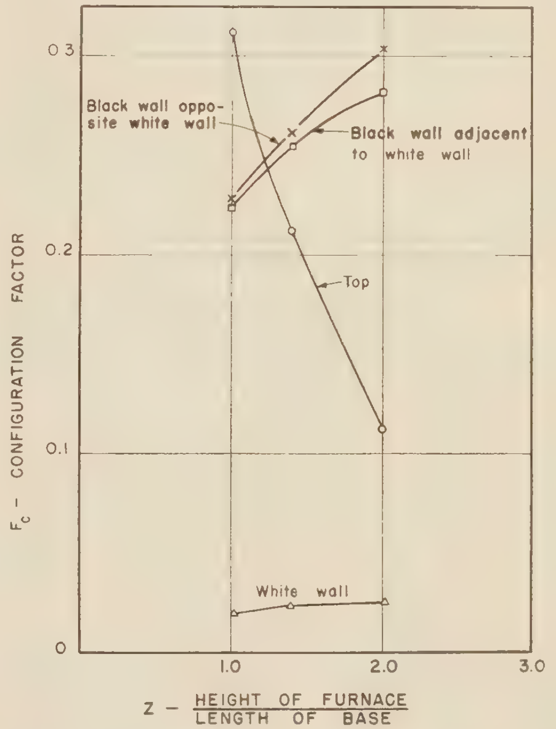

Fig. 16 Configuration Factors F_c, for Directly Opposed Parallel Surface With a Total-Absorbing Top, Three Connecting Black Walls, Representing Waterwalls, and One Connecting White Wall, Representing a Refractory Wall, and Configuration Factors for the Various Walls

where T_w is the absolute temperature of the furnace wall at any point, and T is the average absolute temperature of the base of the furnace.

Inspection of Figs. 14 and 15 makes it obvious that, for every different absorption coefficient, a different series of E_w/E or T_w^4/T^4 will be obtained on the wall. Thus, as the absorption coefficient becomes greater, the E_w/E becomes smaller, and the slope of the line decreases. Hottel and Keller[13] give a curve, derived for the radiation loss through a round hole in a furnace wall, assumed to be a nonconducting reradiating black body. Their curve falls just above the curve given in Fig. 13 for an absorption coefficient of 0.094. Their curve has a slope of —0.5, whereas, the curve cited from Fig. 13 has a slope of —0.6. If

[13] Reference 6, p. 46.

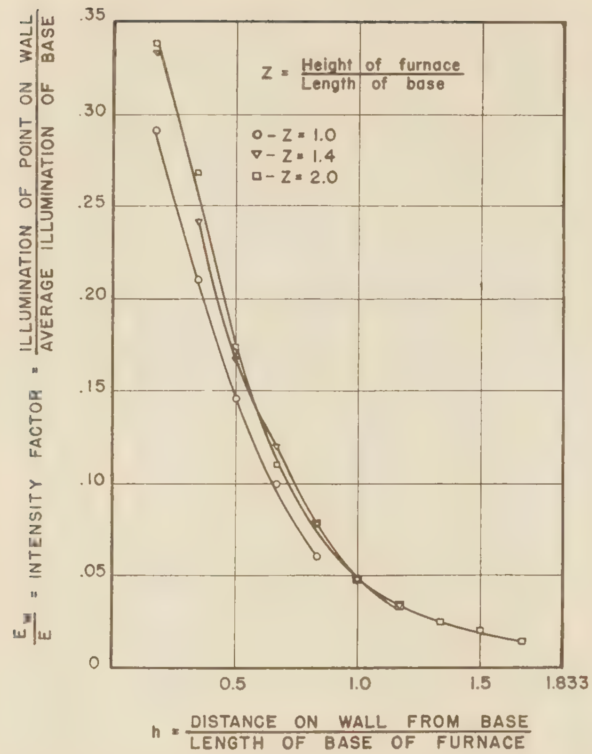

Fig. 17 Relation of Intensity Factor for White Wall to Distance From Base of Furnace With Three Black Walls and One White Wall

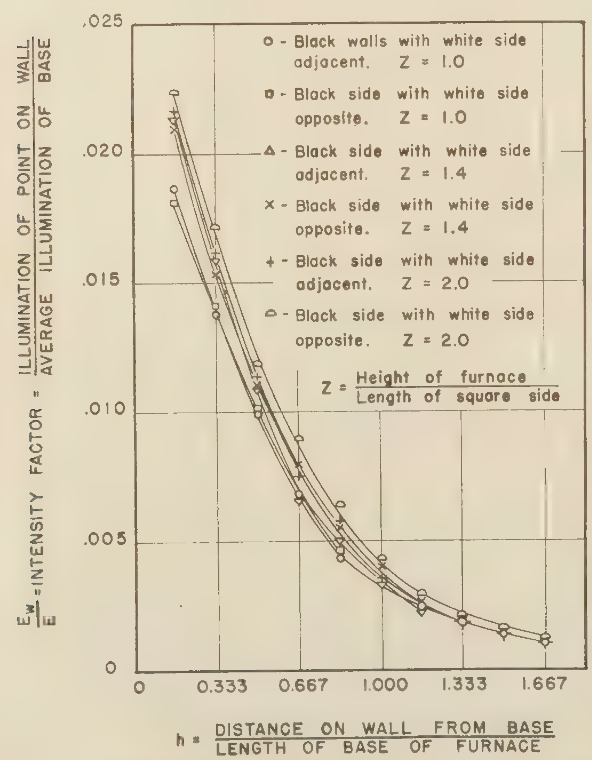

Fig. 18 Relation of Intensity Factor for Black Walls to Distance From Square Base of Furnaces With Three Black Walls and One White Wall

it were possible to use a flat paint which has an absorption coefficient of zero on the walls of model furnace No. 2, the other curves indicate that its slope would have a greater negative value than —0.6.

Model furnaces Nos. 2, 3, and 4, with three black walls and one white wall, represented furnaces with total-absorbing tubes on top, three completely exposed waterwall sides, and one refractory wall. Since the flat black paint on the walls absorbed 95 per cent of the light coming to them, the completely exposed tubes which they represent would probably be slagged up to such an extent as to reradiate 5 per cent of the energy coming to them. Since the flat white paint on the diffusely reflecting wall absorbs about 10 per cent of the light coming to it, the refractory wall which it represents would probably have some unexposed waterwall in it, or be not as thick as the usual furnace wall, so that more heat would be lost by conduction through the wall. The configuration factors were calculated for the white wall, for the black wall adjacent to the white wall, for the black wall opposite the white wall, and for the top of model furnaces 2, 3, and 4 in a manner identical with that described for the model furnace with total-absorbing top and partial-absorbing walls. These factors are plotted against Z (the ratio of the height of the furnace to the length of the base) in Fig. 16.

The intensity factors for the walls of each model furnace were also determined in the same manner as that described for the model furnace just mentioned. These are plotted against the ratio of the distance of the point from the base of the furnace to the length of the base of the furnace in Figs. 17 and 18. Since the intensity factor E_w/E for any point on the wall is equal to T_w^4/T^4 (the ratio of the absolute temperature for any point on the furnace wall to the average absolute temperature of the energy-emitting source), the temperature for any point on the wall of a furnace similar to one of the model furnaces can be found. Of course, this assumes that there is no heat transfer by convection or conduction to the wall. This also assumes that there is no radiation from luminous gases, nonluminous gases, or from particles of any kind. In most actual furnaces, these other heat-transfer agencies will be present, and each will have to be treated separately. However, in many actual cases, one of the means of heat transfer predominates to such an extent that the others may be allowed for or ignored without affecting the final result materially.

Effect of Reradiation

After the completion of the first portion of the experimental work, it was decided to determine, if possible, the reasons for the differences in the values for the configuration factors for a furnace with nonconducting reradiating walls, as determined experimentally, and as derived mathematically by Hottel and Keller. The experimental value for the configuration factor for this case was found to be unity, whereas the theoretical value as determined by Hottel and Keller, is 0.535. Since the walls of the furnace model are nonconducting and reradiating, no heat is absorbed by the furnace walls that is not emitted again; therefore the configuration factor for the walls of such a furnace must be zero. Since the sum of all configuration factors in a system must be equal to unity, it appears as though the experimental value is correct.

It was noticed during the experimental work that, in cases where a small portion of the light coming to the walls of the furnace model was absorbed, the amount of light given off by the bottom of the furnace was greater than that absorbed by the top and all of the sides. This difference resulted because part of the light which struck the walls of the furnace model was returned to the bottom of the furnace and was again given off by the bottom. Thus, the less absorbent the walls were, the brighter

was the light-emitting surface on the bottom of the furnace model. Therefore, the net amount of light given off by the bottom was the amount of light given off when no light was reflected back to the bottom, and the gross amount of light given off by the bottom was the amount given off when the furnace model had reflecting walls which reflected part of the light they received back to the bottom. It is seen that the amount of light absorbed by the sides and the top of the furnace model should be less than the gross amount of light given off from the bottom when all of the light received by the walls of the furnace model was not absorbed by them. Therefore, for furnaces with reradiating walls, it is necessary to include another term, the reradiation factor F_R, in the Stefan-Boltzmann equation

$$q = \sigma F_e F_c F_R A(T_1^4 - T_2^4) \qquad [17]$$

The reradiation factor is the ratio of the net amount of energy given off by the energy-emitting surface to the gross amount of energy given off by this same surface.

Reradiation factors and configuration factors were determined in the following manner: Furnace model No. 2 was painted, and

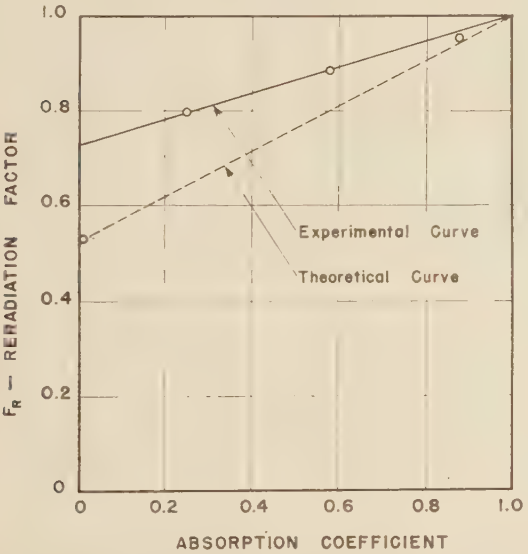

Fig. 19 Relation of Reradiation Factor to Absorption Coefficient of Walls of a Cubical Furnace With a Total-Absorbing Top

the absorption coefficient of the paint was determined as previously described. Then the illumination was measured on the top and the sides of the furnace. From these data, the configuration factor for the top was calculated. The photoelectric cell was next turned face upward, and the amount of light coming back from the walls to the bottom of the furnace model was measured. Then the furnace model was removed, and the illumination was measured at the center of each of twenty-five equal areas at a distance of 2 in. from the light-emitting surface. All of these measurements were taken in the darkroom, and the light from the light source was maintained constant, as previously described. Thus, the net amount of light emitted by the light source was that measured in the absence of the reflecting walls, and the gross amount of light given off was the sum of that measured in the absence of the reflecting walls and that measured with the cell facing upward. This procedure was followed using gray paints with the following absorption coefficients: 0.247, 0.581, and 0.878. Fig. 19 is a graph on which the experimentally determined reradiation factors are plotted against the absorption coefficients of the paints used on the walls of the furnace model.

Reradiation factors were determined only for furnace model No. 2, since in the case of furnace model No. 1 the walls were total-absorbing and therefore did not reradiate. In the case of furnace models Nos. 2, 3, and 4, in which three walls were painted black and one wall was painted white, the reradiation factor would be close to unity since only one wall reflected light back to the source, i.e., the average absorption coefficient here would be about 0.75 and, from Fig. 19, the reradiation factor would be 0.93. However, the value of the reradiation factor might be expected to be somewhat greater than 0.93, since the light reflected from the white wall to the black walls would less likely be reflected back to the light source than in the case where all the walls had an average absorption coefficient of 0.75.

Hottel and Keller determined a total radiation factor which corresponds to the product of the configuration factor F_c and the reradiation factor F_R as used in this work. Their total radiation factor was the sum of a direct radiation factor and a reradiation factor. Their direct radiation factor is the configuration factor F_c determined for directly opposed parallel planes; their reradiation factor, which was determined mathematically, represents the increase in the configuration factor, due to the presence of nonconducting reradiating walls. The dotted line, in Fig. 19, is an extrapolation from Hottel's value of 0.535 for the total radiation factor for a cubical furnace with nonconducting reradiating walls. Thus, it is seen that the product of the configuration factor and the reradiation factor, as determined in this investigation, is about 35 per cent greater than the total radiation factor, as determined by Hottel and Keller.

Hottel and Keller state: "If the walls were perfectly reflecting (or absorb none of the radiation), the total radiation factor would be increased to unity for all openings, and the opening would be equivalent to a freely exposed diaphragm."[6] This statement is correct if the reflection is perfectly specular; however, this work shows that, with perfectly diffuse reflection, the total radiation factor would not be unity. Thus, with diffusely reflecting nonabsorbing walls, part of the radiation from the warmer (or brighter) surface is returned to it by the walls, thereby keeping it at a higher energy-emitting level than the cooler (or less bright) surface.

Possible Sources of Error

It was assumed that the light from all parts of the constant light source was equal, however, the measurement of the intensities of light at a distance of 2 in. above the light source shows that the average intensity of light in the outer perimeter is about 3 per cent less than the over-all average intensity. However, this error is small and would have slight effect on furnaces, the sides of which are so close to the energy-emitting source that the intensity of light is independent of the distance from the source.

In the data for model furnace No. 1f, only six readings were taken to find the average illumination for the side of that furnace. These values might not represent the true-mean values if the light intensity varies with some function of the distance. However, since the light intensity at these points probably varies with some function considerably less than the square-of-distance function, the error here likely would be small.

In the experiments with model furnaces Nos. 2, 3, and 4, it was assumed that the reflection from the flat paints was perfectly diffuse. Barrows[14] has shown that for glossy surfaces specular reflection takes place, and for nonglossy and flat-painted surfaces perfectly diffuse reflection is approached. Thus, since the reflection from the flat paints was not perfectly diffuse, a certain amount of specular reflection took place. This specular reflection

[14] Reference 3, p. 11.

simulates the reflection which takes place from a non-black body, the emissivity e of which is less than 1. The diffusely reflected part of the light from the painted surfaces was probably about 90 per cent, which corresponds to an emissivity of 0.9 for the actual heat-transfer surfaces which the painted surfaces represent. No calculations for model furnaces Nos. 2, 3, and 4, were made for the variance of the illumination due to the effect of the angle of incident light on the photoelectric cell, because actual surfaces are known to vary also. Thus, it is thought that the configuration factors, given in Figs. 12, 13, and 16, approach the true values of those required in practice.

Conclusions

1 A new method was devised for determining configuration factors for radiation by the use of light energy instead of radiant heat.

2 Configuration factors for radiation between directly opposed parallel planes, Fig. 10, and for radiation between perpendicular adjacent planes, Fig. 11, have been determined and are found to conform fairly well with the theoretical values obtained by mathematical derivation.

3 Configuration factors have been determined for model furnaces with diffusely reflecting walls (reradiating walls). The data indicate that a furnace, with nonconducting reradiating black-body walls, would have a configuration factor for the top of the furnace of unity, Figs. 12 and 13.

4 Configuration factors have been determined for model furnaces having three black walls (waterwalls), one white wall (refractory wall), and a total-absorbing top (exposed tubes), Fig. 16.

5 Intensity factors have been found for the walls of model furnaces having various absorption coefficients, and for model furnaces having three black walls and one white wall, Figs. 14, 15, 17, and 18.

6 Another term F_R, the reradiation factor, has been inserted into the Stefan-Boltzmann equation, namely, Equation [17]. The reradiation factor corrects the Stefan-Boltzmann equation for discrepancies due to reradiation from the furnace walls to the energy source, Fig. 19.

Discussion

V. Paschkis.[15] The authors of this paper have developed a very interesting technique. It has, however, one difficulty in common with the mathematical analysis by H. C. Hottel, quoted by the authors, namely, the necessity of assuming a wall of nonconducting material.

This simplification will in some cases be undesirable. Therefore an electric-analogy method, previously published[16] might be of interest. In that method, the thermal conduction in the structures emitting and receiving heat can be duly considered. The method consists briefly in the breaking up of the total radiation in a number of radiation paths, each of which is represented by a resistor. The resistance of each element is so adjusted that it is true to the Stefan-Boltzmann law.

The geometry of small elements of the radiating areas is so simple that the radiation can easily be calculated for each element. Conduction in the radiating material is represented by additional fixed resistors.

Correlation of Coefficient of Friction With Drilling Torque and Thrust for Different Types of Cutting Fluids

By A. O. SCHMIDT,[1] W. W. GILBERT,[2] and O. W. BOSTON[3]

The authors report results of a series of tests made to determine the lubricating effects of a wide variety of cutting fluids on the forces involved in drilling. The investigation was conducted in the metal processing laboratories of the University of Michigan. Torque and thrust, from which the coefficient of friction was obtained, were measured on a special lubrication dynamometer and recorded graphically. Brief specifications are given for the cutting fluids used. The technique for carrying out lubrication tests and the results obtained are discussed, as well as those for the drilling tests. A comprehensive series of graphs showing test results accompanies the paper, and clearly defined conclusions are drawn from the investigation.

In ORDER to determine the lubricating effect of cutting fluids on the forces involved in drilling, a series of tests was conducted for the purpose of investigating this quality in cutting fluids of a wide variety of types. The coefficient of friction of these oils was obtained when they were operating under conditions of lubrication and seizure. Values of torque and thrust were recorded, as the load, applied to a special type of dynamometer, was periodically increased in uniform increments. The results of these friction tests are correlated with values of torque and thrust obtained from drilling tests in a manner to show how cutting fluids act and where they are most beneficial in actual metal cutting. Torque and thrust under cutting conditions were determined by drilling in such a way that their values could be determined for the drill point as a whole, the cutting edges, the margin, and the chisel-edge point, each independently.

The Lubrication Tests

Torque and thrust, from which the coefficient of friction was obtained, were measured on a special lubrication dynamometer. This friction device, shown in Fig. 1, was designed to simulate the sliding of a ductile chip over the face of a single-point tool cutting continuously. The torque and thrust were recorded graphically on a sheet mounted on a slide moving with the spindle. A typical graph is shown in Fig. 2. A test plate was held on the top of the dynamometer inside of a cup. The test plate, made of S.A.E. 2340 steel normalized and annealed, was surface-ground before each test in order to eliminate any previous seizure marks. It was submerged in the cutting fluid. Bearing on the plate were three high-speed-steel pins having a diameter of 0.125 in. at their rubbing ends. The area of contact of the pin-end rubbing surfaces was kept small in order that high unit pressures might be obtained. These pins were mounted axially in a body connected to the driving Morse-taper shank by means of a universal joint. They were spaced 120 deg apart on a circle having a radius of 1 in. In operation, the test pins were first run over a flat abrasive stone, and then on fine emery paper to insure their being flat and smooth. The spindle of the drill press was rotated at 225 rpm to give a rubbing speed of the lower ends of the pins on the upper ground face of the plate of 118 fpm, similar to normal metal-cutting speeds. Pressure was applied on the pins through the spindle of the drill press. The thrust was kept low enough at the start of the tests so that no seizure occurred. It was increased in steps until seizure was obtained, or until the capacity of the dynamometer was reached. The coefficient of friction was then computed as follows

$$\text{Coefficient of friction} = \frac{\text{Force of friction}}{\text{Normal force}} = \frac{12\ \text{Torque}}{r \times \text{Thrust}} = \frac{12\ \text{Torque}}{\text{Thrust}}$$

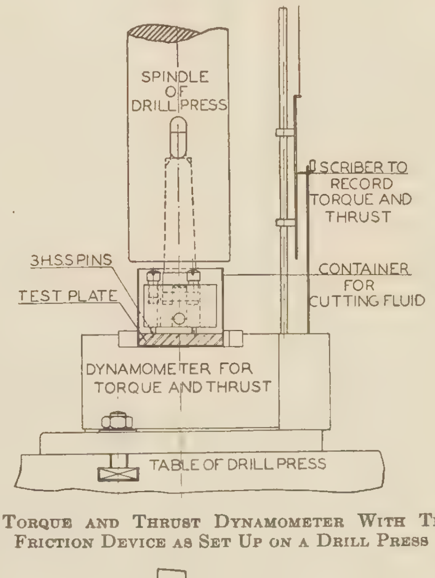

Fig. 1 Torque and Thrust Dynamometer With Three-Pin Friction Device as Set Up on a Drill Press

Contributed by the Special Research Committee on Cutting of Metals and presented at the Annual Meeting, New York, N. Y., December 1–5, 1941, of The American Society of Mechanical Engineers.

As r, the working radius of the rubbing pins, was 1 in., the torque is in pound-feet, and the thrust is in pounds. These results are then plotted against the thrust or load in pounds per square inch for analysis.

Cutting Fluids Used

Distilled water, two plain mineral oils, five sulphurized mineral-lard oils, and two emulsions containing sulphur were used, as follows:

Oil sample *A*	100 per cent Gulf coast pale mineral oil of 150 viscosity at 100 F, with 0.15 per cent natural sulphur
Oil sample *B*	100 per cent mid-continent mineral oil of 165 viscosity at 100 F, with 0.2 per cent natural sulphur
Oil sample *C*	96 per cent mineral oil, plus 1 per cent fatty oil and 3.5 per cent sulphur; viscosity 135 at 100 F
Oil sample *D*	95 per cent mineral oil, plus 0.5 per cent fatty oil and 3.6 per cent sulphur; viscosity 155 at 100 F
Oil sample *E*	45 per cent mineral oil, plus 47 per cent lard oil (sulphurized), and 7.7 per cent sulphur; viscosity 180 at 100 F
Oil sample *F*	77 per cent mineral oil, plus 19 per cent lard and tallow oils and 4 per cent sulphur; viscosity 130 at 100 F
Oil sample *G*	83 per cent mineral oil, plus 17 per cent lard and tallow oils and 1.33 per cent dissolved sulphur; viscosity 175 at 100 F
Emulsion 1:50	1 part sulphurized soluble oil to 50 parts water
Emulsion 1:10	1 part sulphurized soluble oil to 10 parts water

Results of Lubrication Tests

When light thrusts were applied there was no seizure. However, as the thrust was increased, seizure marks became visible on the test plate. In the case of dry cutting, or when using water or plain mineral oils, a further increase in thrust would induce seizure, and metal to a depth of 0.005 in. would actually be removed through the heavy rubbing action of the pins. The thrust or load in pounds as read from the chart, Fig. 2, was divided by the combined area of the three rubbing pins to give the applied pressure in pounds per square inch. The coefficient of friction is plotted over these pressures in Figs. 3 to 5, inclusive.

The range of seizure for a variety of the cutting fluids is indicated in Fig. 3. When seizure occurred, there was an appreciable increase in the coefficient of friction and a change in surface quality of the rubbing surfaces. The friction tests on the various types of cutting fluids of Fig. 3 proved that cutting dry, or with water, or mineral oil *A*, allowed seizure under relatively light pressures and caused actual metal removal with very high values of coefficient of friction. The compounded oil *E*, which is a sulphurized mineral oil plus a fatty oil, had a low coefficient of friction under both nonseizure and seizure conditions. When slight seizure occurred, this oil had a smoothing or nonwelding characteristic which prevented further seizure, and also any further increase in the coefficient of friction. The emulsions which contained a sulphurized soluble oil also exhibited these smoothing characteristics. There was only slight increase in coefficient of friction during the range of seizure. It was noticed that the emulsions formed a strong oil film on the plate where the pins were rubbing, which actually gave a decrease of the friction coefficient under pressures between 1500 and 7500 psi. The pressure at seizure was approximately 500 psi for dry cutting, 1200 to 1300 psi for water and mineral oil, 5000 to 6000 psi for the 1:50 emulsion, 8000 to 10,000 psi for the 1:10 emulsion, and 11,000 to 13,000 psi for the compounded sulphurized oil *E*.

The effect of sulphurizing the cutting oils is indicated in Fig. 4. The 3.5 per cent sulphur in mineral oil *C* gave a marked decrease in the coefficient of friction. The pins began to leave seizure marks on the plate at a pressure of about 5800 psi. Lower coefficients of friction were obtained with oil *D*, which contained 3.6 per cent sulphur where seizure marks became visible at 8750 psi.

The friction tests comparing the sulphurized and the sulphur-

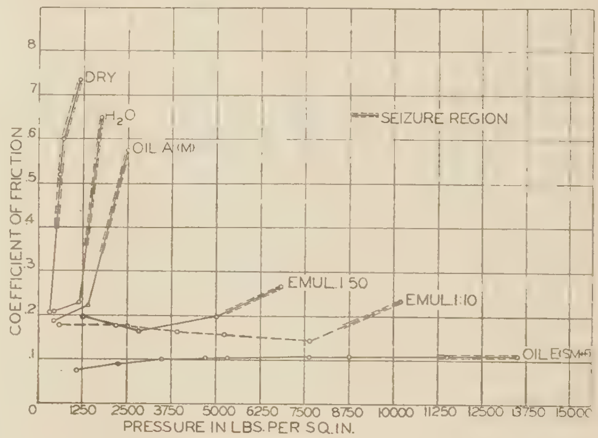

Fig. 3 Friction Tests of Various Fluids

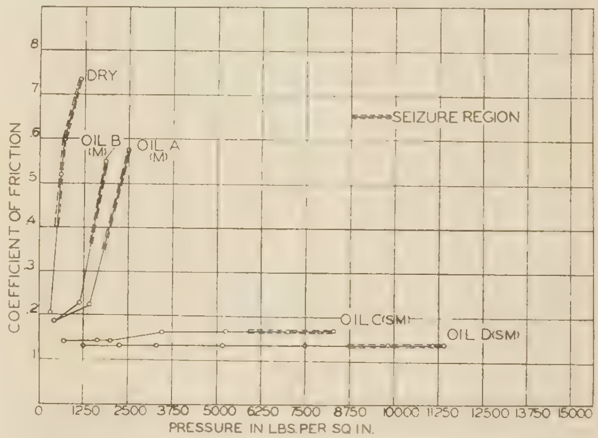

Fig. 4 Friction Tests, Showing Effect of Sulphur

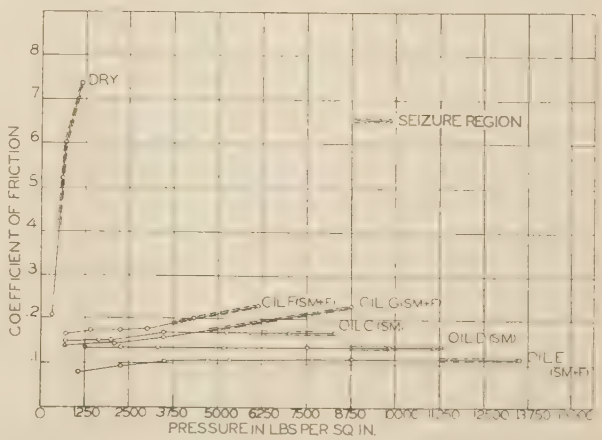

Fig. 5 Friction Tests, Comparing Sulphurized and Sulphurized Fatty Oils

ized fatty oils are reported in Fig. 5. All the oils, C, D, E, F, and G, gave a low coefficient of friction, but the lowest was obtained with oil E which had the highest sulphur content of 7.7 per cent, and a lard-oil content of 47 per cent. With oil E, pressures up to 11,000 psi left no seizure marks on the test plate, and even at 13,500 psi seizure marks were only 0.0005 in. deep. The other oils produced seizure marks varying in depth between 0.001 and 0.003 in.

The coefficient of friction divided by the pressure at the beginning of seizure gives a value representing the performance of the oils just prior to seizure. Fig. 6 brings out clearly the poor performance of the dry tests, the reduction of friction by water and pure mineral oils, and the very marked frictional decrease of the oils and emulsions which contain sulphur and lard oil.

Drilling Tests

To check the behavior of these different cutting fluids under actual cutting conditions, a series of drilling tests was carried out

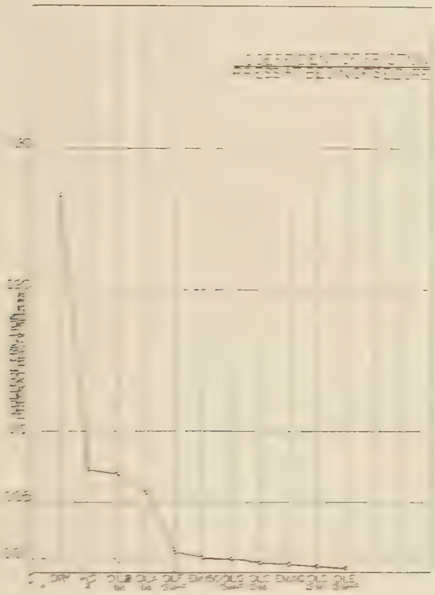

Fig. 6 Rating of Cutting Fluids in Friction Tests
(Values were obtained by dividing the coefficient of friction by the pressure in pounds per square inch at the beginning of seizure.)

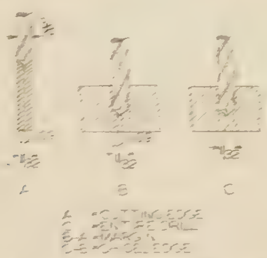

Fig. 7 Test Bars for Drill Tests

on a drill press. The procedure followed in the drilling tests was to use essentially the same test equipment, shown in Fig. 1, except that the friction pins and the test plate were replaced by a twist drill and screw stock, as shown in Fig. 7. The material drilled was S.A.E. 1120 cold-finished steel. The drills used were of high-speed steel having a helix angle of 28 deg 30 min, a point angle of 118 deg, chisel-edge angle of 120 deg, and a relief angle of 12 deg. These drills had a web thickness of 0.062 in., but it was necessary to use a pilot drill of 0.109 in. diam for conditions A and B of Fig. 7 to remove the effective working area of the chisel edge. The drill and work were completely flooded with cutting fluids during the tests. A preliminary test was made by varying the cutting speeds of the drill, and it was found that the cutting fluids were most effective at slow cutting speeds. Therefore the tests were run at 143 rpm or 13 fpm with feeds of 0.004 and 0.006 in. per revolution.

Fig. 7 shows how these tests were made. At A is shown the cylindrical test bar of $^{11}/_{32}$ in. diam with a pilot hole in the center.

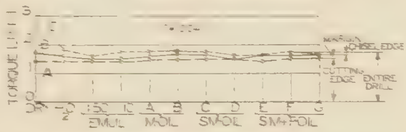

Fig. 8 Effect of Cutting Fluids on Drilling Torque
(Material, S.A.E. 1120 cold-finished steel; speed, 143 rpm; feed, 0.004 in. per revolution.)

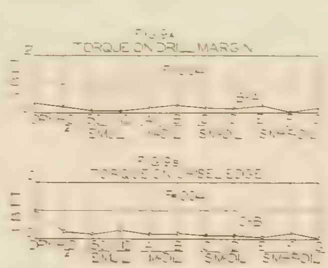

Fig. 9 Torque Caused by Friction on Drill at Feed of 0.004 In. per Revolution

When drilling the test bar with a $^{5}/_{8}$-in. drill, cutting was confined to the cutting edges. This eliminated the effect of the chisel-edge point and the margin of the drill. At B, the pilot hole was drilled in a test bar, and then a larger hole was cut of the same diameter ($^{11}/_{32}$ in.) as the test bar at A. This eliminated the forces on the chisel-edge point. The third cutting condition illustrated at C consisted of drilling a hole $^{11}/_{32}$ in. diam into the solid material, in which the whole drill was in action. By subtracting the test results of A from B, it was possible to show the frictional piloting action of the margin; by subtracting B from C, it was possible to isolate the action of the chisel-edge point.

These three zones may react differently under the influence of cutting fluids. The actual cutting edge on the lip of the drill is heavily stressed, and the chip pressures are so high that lubricants have but little effect. The margin on the drill, which is the cylindrical portion forming the outside diameter, actually does no cutting, but merely pilots the drill due to its rubbing on the side of the hole drilled. The bearing pressures are low when the drill is properly ground, but may become quite high if the drill operates off-center. The chisel edge acts as a blunt cutting edge with negative relief. The stress is so high that under normal conditions approximately 60 per cent of the thrust on the drill is localized at this point, and bearing pressures are very high.

Fig. 8 shows the effect of the various cutting fluids on the value of torque at a feed of 0.004 in. The graph for the whole drill, line C, shows that the torque was highest for dry cutting, that water and mineral oil reduced the torque somewhat, but that the emulsions and the sulphurized oils produced the lowest values. In test B, in which the effect of the chisel-edge point was eliminated, there was less friction and, therefore, less variation due to the cutting fluids. However, all the cutting fluids produced a decrease in torque. In test A, in which only the cutting edge of

the drill works, there was practically no difference between dry cutting and the cutting operations with cutting fluids.

In Fig. 9(*a*), only the amount of torque caused by friction on the margin is shown for the various cutting fluids; and in Fig. 9(*b*), only the amount of torque developed at the chisel edge is shown. The decrease in torque on the chisel edge, produced with the emulsions and oils, from that when drilling dry is very conspicuous.

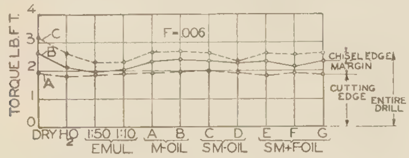

Fig. 10 Effect of Cutting Fluids on Drilling Torque at 0.006 In. per Revolution Feed

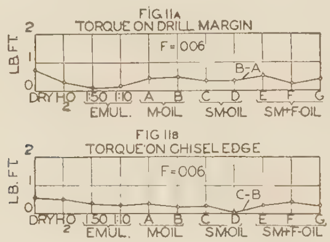

Fig. 11 Torque on Drill for Various Cutting Fluids at Feed of 0.006

A graphical representation of the torque developed during the drilling tests with a feed of 0.006 in. per revolution is shown in Fig. 10. There is a pronounced variation in torque for the different fluids in test *C*, where the entire drill point is involved. Test *B*, in which the chisel edge is eliminated, also produces considerable variation, but test *A*, involving only the lips, shows very little variation.

The torque on the drill margin with a feed of 0.006 in. per revolution is shown for the various cutting fluids in Fig. 11(*a*). A decrease of torque is effected by the use of liquids as against dry cutting. The sulphurized emulsions give the lowest values. Fig. 11(*b*) shows values of torque on the chisel edge. That for dry cutting is highest, while the cutting liquids reduce the amount of torque slightly. Sulphurized mineral oil *D* gives the lowest value. The torque usually can be reduced 25 per cent by using an appropriate cutting fluid. This reduction takes place only at the margin and chisel edge as there is no appreciable reduction on the cutting edges themselves.

The effect of the cutting fluids on thrust is graphically represented in Fig. 12. With a feed of 0.004 in. per revolution, the thrust was highest when cutting dry. The sulphurized emulsions

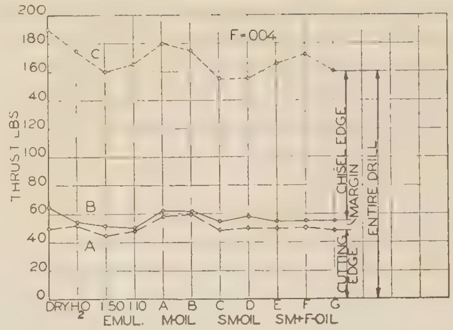

Fig. 12 Effect of Cutting Fluids on Drilling Thrust at 0.004 In. per Revolution Feed

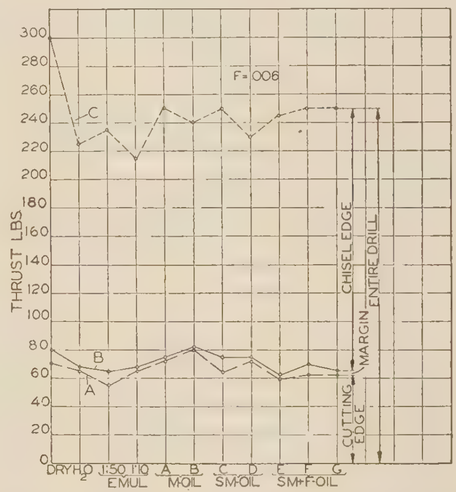

Fig. 13 Effect of Cutting Fluids on Drilling Thrust at 0.006 In. per Revolution Feed

and sulphurized mineral oils show the highest degree of reduction for the drill point as a whole. Water is even better than the oils. The thrust for condition *B* was highest for dry cutting, and slightly less for the plain mineral oils. The thrust for test *A*, involving only the cutting edges, shows much less variation for the cutting fluids because of less effect on the cutting edges. Most conspicuous are the values for the plain mineral oils, which in this case give values even higher than dry cutting. The chisel edge is shown to account for about 60 per cent of the total thrust. The sulphurized emulsions and oils effect the greatest reduction.

Fig. 13 shows the values of thrust from the drilling tests at a feed of 0.006 in. per revolution. For the entire drill, there is a decided decrease in thrust produced by all of the liquids, as com-

TABLE 1 RELATIVE VALUES AND DISTRIBUTION OF TORQUE, WHEN DRILLING $^{11}/_{32}$-IN-DIAM HOLE INTO S.A.E. 1120 STEEL

	Feed 0.004 in. per revolution				Feed 0.006 in. per revolution

Margin	8	2	1	4	3	1	1	1

pared to dry cutting. The most effective liquid, in this case, is the sulphurized emulsion of 1:10. In the tests involving only the cutting edges, there was very little difference between dry cutting and cutting with fluids. The cutting fluids had little effect upon the *B* tests, involving the cutting edges and margin. These graphs also show that the greatest proportion of the thrust is produced at the chisel edge.

Conclusions

1 The results of the friction tests show that under conditions of seizure, mineral oils and water produce approximately the same high coefficient of friction at relatively low pressures, and that considerable metal is displaced. When sulphurized oils are used under conditions of seizure, the coefficient of friction is greatly reduced, and there is very little metal displacement or seizure even at very high pressures. Emulsions containing active sulphur also reduce the coefficient of friction between the friction surfaces in the same manner as that produced by the sulphurized oils. Only at very high pressures was the sulphurized-oil film ruptured to permit metal-to-metal contact and seizure.

2 Cutting fluids, even those which possess high sulphur content, high antiseizure properties, and low coefficient of friction in the friction tests, will not decrease the cutting forces unless there is rubbing friction on noncutting surfaces where the antiseizure properties become effective.

3 When drilling a hole of $^{11}/_{32}$ in. diam into S.A.E. 1120 at a speed of 143 rpm, the relative values and distribution of torque are as given in Table 1, taking dry cutting as 100 per cent.

4 When drilling a hole of $^{11}/_{32}$ in. diam into S.A.E. 1120 at a speed of 143 rpm, the relative values and distribution of thrust are as given in Table 2, taking dry cutting as 100 per cent.

Acknowledgments

The lubrication dynamometer used in these tests was originally designed and made by Mr. Charles E. Kraus, a student assistant and later instructor in the department of metal processing, for experimental work to determine lubricating properties of cutting fluids. It has since that time been modified.

The work covered in this paper was done by Mr. A. O. Schmidt as a partial requirement for the degree of master of science in engineering (mechanical engineering) in the metal processing laboratories, under the supervision of Professors Gilbert and Boston.

Discussion

Hans Ernst.[4] This paper is of particular interest in that it represents a further attempt to correlate the results of tests in the field of friction with tests in the field of metal cutting.

In the friction tests (authors' Fig. 3), it is interesting to note the sharp rise toward high values for the coefficient of friction, under increase of load, in the case of the dry test and with water and plain mineral oil.

In an investigation of static friction made in the research laboratory of the Cincinnati Milling Machine Company, and reported in part in a paper[5] presented before the National Metals Congress in October, 1940, it was found that the coefficient of friction between extraordinarily clean surfaces of high-speed steel and S.A.E. 3145 at room temperature was approximately 1.0. With high-speed steel in contact with FM 18-8 stainless steel, the coefficient of friction was 0.92, while with S.A.E. 1112 it was 0.73. In view of these results and the theoretical analysis presented in the paper mentioned, it would seem likely that all of the curves of the authors' Fig. 3 would have reached limiting values in the neighborhood of 1.0, if the apparent pressures had been increased to sufficiently high values.

In stating that a rubbing speed for the pins of 118 fpm is "similar to normal metal-cutting speeds," the authors may have overlooked the fact that the rubbing speed of a chip on the face of a cutting tool is usually on the order of $^1/_3$ to $^1/_4$ of the speed of the tool relative to the work surface. Thus a chip rubbing speed of 118 fpm would normally correspond to a cutting speed of about 400 fpm, which is, in general, far too high for use with a high-speed-steel tool.

In view of the fact that the avowed purpose of this paper is the correlation of coefficient of friction with drilling torque and thrust, it is regrettable that the actual values of coefficient of friction were not calculated, where possible, from the data gathered in the torque and thrust tests. If this had been done, the small effect of the cutting fluids in reducing the coefficient of friction on the actual cutting edge of the drill would have been brought out even more clearly.

Referring to Fig. 14 of this discussion, which shows condition *A* of the authors' paper, it will be seen that the force perpendicular both to the cutting edge and to its path is

$$F_v = \frac{T}{2 \cos 31°} = 0.584\, T$$

where T is the thrust on the drill. Making the approximation, mean torque radius (R_m) equals mean cutting radius, then

$$R_m = \frac{0.109 + 0.343}{4} = 0.113 \text{ in.}$$

and thus the cutting force F_c, perpendicular to the cutting edge and tangential to its path, is equal to

$$F_c = \frac{\text{Torque (in lb-ft)} \times 12}{2 \times 0.113} = 53.1 \times \textbf{torque}$$

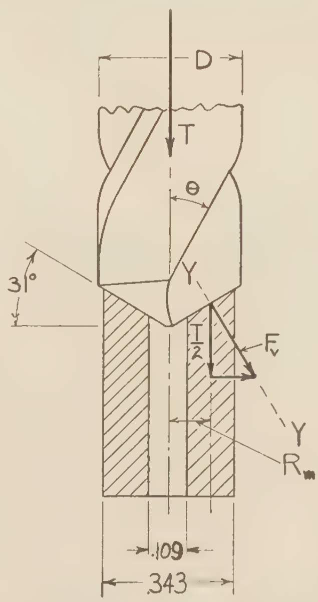

Fig. 14 Detail Showing Condition *A*, Fig. 7 of Authors' Paper

[4] Research Director, The Cincinnati Milling Machine Company, Cincinnati, Ohio. Mem. A.S.M.E.

[5] "Chip Formation, Friction, and High Quality Machined Surfaces," by H. Ernst and M. E. Merchant: "Symposium on Surface Treatment of Metals," American Society for Metals, Cleveland, Ohio, 1941, pp. 299–335.

As the mean true rake angle is very nearly equal to the true rake angle (α) at the mean cutting radius, then

$$\tan \alpha = \frac{2 R_m \cdot \tan \theta}{D} \cdot \cos 31°$$

where θ is the helix angle of the drill, and D is the outside diameter.

For the dimensions given in Fig. 14, therefore

$$\tan \alpha = 0.281 \text{ and } \alpha = 15° \ 42'$$

From Fig. 15 of this discussion (which is a reproduction of Fig. 8 of the aforementioned paper,[5] and which may be considered as a cross section through the line Y-Y of Fig. 14), it will be seen that the previously determined forces F_v and F_c form mutually perpendicular components of the resultant force R between the tool point and the work which, for simplification, is used to replace the distributed load on the tool face. This resultant force R may also be resolved into the mutually perpendicular components F and N which are, respectively, the friction force acting along the face of the tool and the force normal thereto.

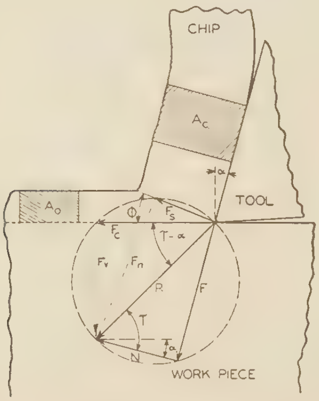

Fig. 15 Force Diagram, Showing Geometric Relationships Between Forces at Tool Point When No Built-Up Edge Exists

(Reproduction of Fig. 8, reference 5.)

From the geometry of Fig. 15, it is evident that

$$\frac{F_v}{F_c} = \tan (\tau - \alpha)$$

and that the coefficient of friction $= \mu = \dfrac{F}{N} = \tan \tau$

From the authors' data for condition A, when cutting dry at 0.004-in. feed, the thrust is 48 lb and the torque 1.4 lb-ft. From the relationships thus determined

$$F_v = 0.584 \times 48 = 28 \text{ lb}$$

and

$$F_c = 53.1 \times 1.4 = 74.3 \text{ lb}$$

$$\tan (\tau - \alpha) = \frac{28}{74.3} = 0.377$$

and

$$\tau - \alpha = 20° \ 40'$$

but

$$\alpha = 15° \ 42' \ \therefore \ \tau = 36° \ 22'$$

and

$$\tan \tau = \mu = 0.74$$

Similarly, for the worst case (mineral oil B), at 0.004-in. feed, where the thrust was 59 lb, and the torque 1.45 lb-ft, we find

$$\tan (\tau - \alpha) = 0.448$$

whence

$$\tau = 39° \ 50' \text{ and } \mu = 0.83$$

For the best case (1:50 emulsion) at 0.004-in. feed, the thrust was 45 lb, and the torque was 1.4 lb-ft. Consequently

$$\tan (\tau - \alpha) = 0.353$$

whence

$$\tau = 35° \ 09' \quad \text{and} \quad \mu = 0.70$$

It is interesting to note that the coefficient of friction with mineral oil B is even higher than for the case of dry cutting, where the "cutting fluid" is of course, air. This is not inconsistent with previous findings and may be due to the exclusion of air by the oil, thus preventing the formation of oxide or nitride films on the tool face and permitting even more intimate contact of chip and tool.

The fact that the coefficient of friction with even the "best" fluid was only slightly less than when cutting dry (0.70 as against 0.74, as contrasted with large differences found in the authors' friction tests) again indicates the extreme difficulty encountered by a cutting fluid in reaching the chip-tool interface. This should further dispose of the false idea, still widely held, that a crack normally precedes the nose of the cutting tool, thus permitting the cutting fluid to enter and form a wedge film against the tool face. Actually no such crack exists, and thus a substantial reduction of friction between chip and tool face can only be obtained by means of highly active fluids such as carbon tetrachloride which can, to some extent, penetrate the labyrinth of microscopic passageways separating the actual contact points of chip and tool, and react with the freshly ruptured chip material to form stable compounds of low shear strength. This is a mechanism quite remote from that of a lubricant in a common journal bearing, and thus it is evident that the term "cutting lubricant" (which is still often used in the shop) is a misnomer. Except for the questionable term "lubrication dynamometer," and the casual reference in the paragraph opposite Fig. 7, the authors have carefully and correctly refrained from associating the word "lubrication" with the reduction of friction between chip and tool through the use of cutting fluids.

H. L. Moir.[6] There are one or two points which might be suggested to help make a better understanding of the friction curves of the paper, particularly those which have been run with the sulphurized oils. It would be well to determine the ratio of active to inactive sulphur in these oils, instead of simply presenting the total sulphur content. It is believed that this information will help to explain the long seizure region of oil G in Fig. 5, as compared with the relatively short seizure region of oil E. We have found generally that active sulphur has the apparent effect of prolonging the seizure region by alternately healing and seizing, while a combined sulphur has a twofold effect both of lowering friction and producing a region of new seizure considerably in excess of active sulphur at higher loads. It might be well to have some qualitative means of determining the effect of the different cutting fluids upon these seizure regions at the same load, or at different loads, by weighing the small pins to determine the loss of metal due to abrasion.

The writer would like to comment upon some remarks[7] made by C. G. Williams, concerning tipped tools from an oil man's standpoint. There seems to be considerable confusion existing

[6] Asst. Chief Products Engineer, Pure Oil Mechanical Laboratory, Winnetka, Ill.

[7] "Oil for Carbides," by C. G. Williams, *American Machinist*, vol. 85, 1941, p. 1124.

in the industry at present as regards the so-called "vulnerability" of tipped tools when used with a sulphurized oil as a cutting fluid. This situation is quite analogous to the confusion which existed in the minds of many for a long time regarding the lubrication of hypoid gears when they were introduced in large-scale production in 1937. Apparently, the year 1937 was to many the date of the invention of the hypoid gear, in spite of the fact that the petroleum industry had successfully been lubricating many other automobiles which were equipped with hypoid gears prior to that time.

It is easy to understand the confusion which exists in the mind of an oil salesman when he is confronted with a turret operation which may have, for example, four tools in the head. Two of these tools may be tipped tools, while the other two may be solid tools, e.g., a drill and a tap. It is obvious that the best cutting-oil recommendation for the tap and drill will be a sulphurized oil. However, if the recommendation to use nonsulphurized oils or coolants, because of the tipped tool, is followed, the cutting speed for all of the tools will be governed by the safe cutting speed for the solid tool. In this manner it is easy to see that all of the advantages which tipped tools have will be nullified if a restriction is based upon the operation of tools which do not cut efficiently with certain cutting fluids, for example, soluble oils. The writer believes that this situation should be clarified promptly since a solution would be of threefold benefit; namely, to the user of tools and cutting fluids, to the tool manufacturer, and to the oil manufacturer.

Authors' Closure

The comments of the various discussers are greatly appreciated. Mr. Ernst has shown that the coefficient of friction, calculated from the torque and thrust loads, is greatest for the mineral oil and smallest for the sulphurized mineral oil and the emulsion. As shown in Table 3 of this closure, the coefficient of friction, determined from the torque and thrust drilling tests, has a maximum variation from 0.67 for the 1:50 emulsion to 0.84 for the mineral oil. This variation is exceedingly small when compared with the computed coefficients of friction of from 0.1 to 0.2, obtained with the three-pin friction device operating under nonseizure loads, as shown in Figs 3, 4, and 5 of the paper. It is thus seen that metal cutting must be considered to be in the seizure region of dry cutting, and therefore the general conception of cutting fluids, acting as lubricants between the tool face and chip, must be changed. However, as pointed out in the conclusions, some of the cutting fluids are effective in reducing cutting forces when they act on noncutting surfaces such as the margin or chisel edge of the drill, or on the outside surface of a continuous chip formed by turning. In turning, there is little change in cutting force for various types of cutting fluids.

TABLE 3 COEFFICIENT OF FRICTION WHEN DRILL IS CUTTING ON CUTTING EDGES ONLY

Cutting Fluid	Coefficient-of-friction feed in I.P.R. 0.004	0.006
Dry	0.76	0.77
H_2O	0.80	0.77
1:50	0.71	0.67
1:10	0.74	0.74
A (M)	0.82	0.80
B (M)	0.84	0.84
C (SM)	0.81	0.72
D (SM)	0.73	0.79
E (SM + F)	0.76	0.72
F (SM + F)	0.72	0.70
G (SM + F)	0.71	0.72

Mr. Moir's suggestions that the tests be continued, and that quantitative results be obtained by weighing the loss of metal due to abrasion, are very timely. It is felt that these tests should be run under conditions of greater pressure so that actual metal would be abraded from the test plate even when the sulphurized oils are used.

C. G. Williams[7] has questioned the use of sulphurized oils as cutting fluids for cemented-carbide tools. This objection is heard from many different sources, and is discussed by Mr. Moir. General commercial practice as to the use of emulsions on carbide tools varies. When high cutting speeds are used, the chips may prevent the coolant from functioning continuously, and as a result the tool is alternately hot and cold and, therefore, becomes cracked or damaged. If the flow on the tool cannot be maintained uniformly, it is better to cut dry.

Mr. Lange stated that 80 per cent of the carbide-tipped tools on Warner and Swasey turret lathes are cooled with emulsions. At high speeds sulphurized oils cause too much smoke. Mr. Lucht also added that emulsions are preferred to cool carbide turning tools.

Characteristics of Centrally Supported Journal Bearings

By E. O. Waters,[1] New Haven, Conn.

The primary purpose of the study reported in this paper is to determine the load capacity and friction of journal bearings having arcs of contact of 80 to 120 deg, eccentricity ratios ranging from zero to unity, length-width ratios ranging from zero to infinity, and central support. Essentially, it is a continuation of the work published by Needs,[2] which covered the range of eccentricities from 0 to 0.8, but with two important differences, i.e., (1) the results have been obtained by mathematical, rather than experimental, solution of the Reynolds equation for two-dimensional viscous flow in a thin channel; (2) the matter of negative pressures has been dealt with in the manner advocated by Swift.[3] In other respects, the treatment of the fundamental variables is akin to that which is found in the majority of journal-bearing- and fluid-film-lubrication papers, published by the Society, e.g., the journal radius, journal velocity, mean clearance, eccentricity ratio, and oil viscosity are assumed constant for any given bearing, and the oil channel is of rectangular plan form.

Nomenclature

The following nomenclature, in addition to other notations,[4] is used in this paper:

B' = angle between line joining centers of bearing and journal (line of centers) and trailing edge of extended bearing

F_0 = friction force per unit width of bearing, in an infinite-width bearing

m_n = characteristic number in solution of homogeneous form of Reynolds equation, associated with the nth order solution

$\bar{p}$ = pressure per unit of bearing area, averaged over the bearing width

p_x = pressure per unit of bearing area in a bearing of infinite width

Q_A = volumetric flow of oil into bearing at entering edge, per unit of time

Q_B = volumetric flow of oil out of bearing at trailing edge, per unit of time

Q_z = volumetric flow of oil out of bearing at one side, per unit of time

q = pressure drop per unit of bearing area, due to side leakage in a finite-width bearing

$\bar{q}$ = pressure drop per unit of bearing area, due to side leakage, averaged over the bearing width

r = ratio of bearing length to bearing width, in a terminal or preterminal bearing

r' = ratio of bearing length to bearing width, in an extended bearing

W_0 = load capacity per unit width of bearing, for an infinite-width bearing

z = co-ordinate of oil channel, perpendicular to x and parallel to axis of journal

β' = arc length of extended bearing

ϵ = arc increment of extended bearing; $\epsilon = \beta' - \beta$

ξ = modified angular co-ordinate of bearing, advancing from 0 at entering edge to π radians at trailing edge; $\xi = (\theta - A)\pi/\beta$

Introduction

If a bearing is specified by giving arbitrary values to the variables, journal radius, journal velocity, mean clearance, eccentricity ratio, and oil viscosity, it is possible to compute the local pressure at any point by direct solution of the Reynolds equation. Then, as a second step, the total capacity, coefficient of friction, and the direction of the resultant load line can be directly obtained by integration. However, if the direction of the load line is specified, with respect to the entering and leaving angles, while these angles themselves are unknown, it does not appear feasible to make a direct computation of the load capacity. This is certainly the case for infinite-width bearings, the properties of which are now well known, and is therefore all the more true when the bearing width is finite. Accordingly, the method adopted in this paper has been to find the properties of a field of bearings having specified entering and leaving angles, to compute the capacity and load-line direction of each, and then, by interpolation, to find the properties of those bearings whose arcs of contact are 80, 100, and 120 deg, and whose load lines come midway between the angle of entrance and the angle of exit. The chief disadvantage of this method is that a large number of individual cases must be computed, but this is balanced by the fact that, from the original cases, it is possible to make interpolation not only for centrally supported, but for offset bearings as well.

General Computation of Load Capacity, Friction, and Oil Flow of Partial Bearings

Calculations have been completed on 108 different bearings, having eccentricity ratios, entering and leaving angles, and length-width ratios as specified in Table 1. These are referred to in subsequent portions of the paper as "fundamental" bearings. The pressure distribution in each bearing has been computed by the method previously described by the author[5] and need not be repeated here. Briefly, this method employs, instead of the actual pressure p, a pressure function, equal to p multiplied by an arbitrary power of h, which can be developed in a convergent trigonometric series from $\theta = A$ to $\theta = B$.[4] Such a development

is desirable for fitting the boundary conditions of the particular solution of Reynolds equation (infinite-width case) to the boundary conditions of the homogeneous form of the equation, and overcomes the stumbling block encountered by Reynolds, who tried unsuccessfully to express the pressure in trigonometric series form for high eccentricity ratios. Once this pressure function has been evaluated, the remaining data (capacity, attitude, etc.) can be found by simple quadratures, which may be performed by the available formulas of integral calculus or by Simpson's rule, whichever is more convenient.

The Appendix contains an outline of the computations for a specimen bearing, for the benefit of those who wish to examine the application of this method in detail. Attention is called to Fig. 8, in this Appendix, in which $\bar{p}\Big/\frac{\mu U a}{\eta^2}$, the factor of mean pressure with respect to bearing width, is plotted against the bearing angle θ and the modified bearing angle ξ, for length-width ratios $r = 0, 1, 2, 3, 4$, $A_{\circ} = 70$ deg, $B = 190$ deg, and $c = 0.8$; compare the curve for $r = 0$ with the dotted curve, which is proportional to the mean-pressure function $\bar{p}h^{3/2}$ for the same value of r, and note the absence of prominent harmonics in the latter.

The final results which were obtained for these 108 bearings are assembled in Table 1, and represent the bulk of the arithmetical work. From the side-leakage factors in this table, graphical interpolations were made, from which Table 2 was constructed. The material in Table 2 affords a direct comparison with Needs's results for $c = 0.6$ and 0.8, $\beta = 120$ deg, $\alpha = 60$ deg, and may be used as a basis for determining bearing performance on the assumption that theoretical negative pressures may be neglected.

The values of oil flow in Table 1 furnish a convenient index of the accuracy of the boundary-value solutions obtained for the homogeneous form of Reynolds equation. Where the discrepancy between computed inflow and outflow is fairly large, it is believed that the error may be ascribed to two causes, i.e.

0.9 extrapolation from Table 1 is unreliable

(1) an insufficient number of iterations in arriving at the accepted value of the solution; (2) an inherent error in expressing the film thickness h, together with its reciprocal and derivatives, as a cosine series in ξ. Actually, h is a function of θ which is not a multiple or divisor of ξ, and accuracy, at least at the end points, requires the use of a complete sine-cosine series. In addition, the oil-flow data are of course obtained by a differentiation of p, which tends to magnify any errors already present in the solution for p. Terms W and F, on the other hand, are obtained by integration, which tends to minimize the effects of these same errors.

Interpolation for Terminal Bearings

The data in Table 1 furnish the raw material for determining the properties of centrally supported bearings. First, however,

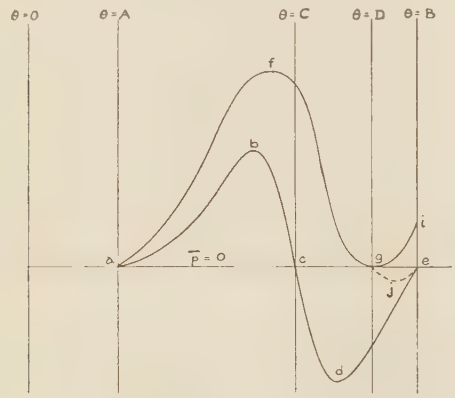

Fig. 1 Treatment of Negative Pressure

it is necessary to settle the matter of negative pressures, which appear in many of the computed cases where $B > 180$ deg. At least two ways of doing this have been proposed. Let us assume that a bearing extends in the lengthwise direction from $\theta = A$ to $\theta = B$, Fig. 1. Then, according to the first method, we take as our boundary conditions $p = 0$ at $\theta = A$, $p = 0$ at $\theta = B$, and obtain for $\bar{p}$ a curve such as *abcde*. Either we use this curve as it stands, on the assumption that the negative portion has little effect, or else we neglect the negative portion *cde* as being physically impossible, and determine the load capacity of the bearing, direction of the resultant line of support, friction, and oil flow, solely from the curve *abc*.

According to the second method, we first find whether $d\bar{p}/d\theta$ is positive or negative at $\theta = B$, on the basis of the same boundary conditions as for the first method. If negative, the pressure curve lies above the zero axis for the entire length of the bearing, and no consideration of negative pressure is necessary. If positive, we arbitrarily reduce the leaving angle until a value is found, say $\theta = D$, at which $d\bar{p}/d\theta = p = 0$. Then, using the boundary conditions $p = 0$ at $\theta = A$, $p = 0$ at $\theta = D$, we obtain the pressure curve *afgi* and, neglecting the portion *gi*, use the portion *afg* to determine the properties of the bearing.

This latter method for the treatment of negative-pressure cases has been advocated by Swift[3] and, after studying the relative merits, has been adopted by the author for the present paper. Swift's line of reasoning will be found fully expounded in his own paper; the following independent analysis, based on considerations of oil flow for an infinite-width bearing, may also be enlightening. First, assume that a bearing extending from $\theta = A$ to $\theta = B$, Fig. 1, by formal integration gives the pressure curve *abcde*. The same result is obtained by assuming that two bearings exist in tandem, and by performing separate integrations from $\theta = A$ to $\theta = C$ and from $\theta = C$ to $\theta = B$. Assume further that actual running conditions are represented by neglecting the theoretical pressure in bearing $C — B$, so that the effective pressure line is *abcge*. The oil discharge at the leaving end of bearing $A — C$ is then determined by the thickness of the clearance space and the negative pressure gradient at C. Since bearing $C — B$ is assumed to have the same clearance space at C, but no negative pressure gradient, it is unable to take the full volume of oil discharged by bearing $A — C$.

On the other hand, assume that formal integration gives the pressure curve *afgi*, g being located by Swift's criterion, this is equivalent to two bearings $A — D$ and $D — B$ in tandem, the first of which discharges at zero pressure, while the second discharges against a terminal pressure *ie*. But, obviously, there is no terminal pressure, which simply means that bearing $D — B$ is fully capable of taking all the oil, or more, that is supplied by bearing $A — D$. The pressure line in this case is theoretically *gje* for the full volume of oil that bearing $D — B$ is capable of handling, being negative because of the divergence of the clearance space, but in reality the pressure is maintained at zero by cavitation in the oil film. The hydrodynamic equations are satisfied by taking constant mass flow rather than volumetric flow for the oil film in bearing $D — B$, i.e., mass flow per unit time per unit width of bearing $= \left(\frac{Uh}{2} - \frac{h^3}{12}\frac{dp}{\mu dx}\right)\rho =$ constant, assuming that the density ρ decreases according to the law $\rho = \rho_0 h_0/h$, where ρ_0 and h_0 are, respectively, the oil density and the clearance at $\theta = D$. The same line of reasoning may be extended to bearings of finite width.

If a bearing of constant eccentricity ratio c and constant length $a\beta$, with $p > 0$ throughout, is given an increasing entering angle A, the pressure gradient at the leaving edge first increases from a negative value to zero. A further increase in A is no longer accompanied by an equal increase in the leaving angle of the effective film, even though the length of the bearing shell is maintained constant, and the pressure curve takes the form of line *afge*, Fig. 1. In this paper, all cases where the mean pressure gradient at the leaving edge of the bearing is zero are designated "terminal bearings." The local values of dp/dx across the bearing width need not equal zero for the same value of x; that is to say, the leaving edge of a terminal bearing may be a curve, rather than a straight line, but this possibility has been neglected as being of minor importance. In Fig. 1 bearing $A — D$ is a terminal bearing. All cases in which the entering angle is so great as to cause the point of zero pressure gradient to recede toward the entering edge, as from e toward or beyond g in Fig. 1, are designated "extended bearings." Actually, they consist of a terminal bearing, followed in tandem by a bearing ($D — B$, Fig. 1), which contributes nothing to load capacity, but doubtless adds a share to the velocity term of the friction. This extension also affects the attitude of the complete bearing with respect to the load line; if this is α/β for the terminal bearing, it will be $\alpha/(\beta + \epsilon)$ for the extended bearing, ϵ being the angular length of the inert extension.

Experience shows that the majority of centrally supported bearings with eccentricity of 0.6 or more lie in the extended range; hence it is desirable to know the properties of terminal bearings. This is done by first ascertaining the exit angle B, and then interpolating between values of the properties of those fundamental bearings having the same length, width, and eccentricity ratio as the terminal bearing in question. For example

$$\left.\frac{d\bar{p}}{d\theta}\right]_B = \left.\frac{dp_x}{d\theta}\right]_B - \left.\frac{d\bar{q}}{d\theta}\right]_B = 0 \text{ for terminal bearing}$$

$$\frac{6\mu Ua}{\eta^2}\left[\frac{1}{(1 + c\cos B)^2} + \frac{C_1}{(1 + c\cos B)^3}\right] - \left.\frac{d\bar{q}}{d\theta}\right]_B = 0$$

$$1 + c\cos B = -C_1 + \frac{\eta^2}{6\mu Ua}\,(1 + c\cos B)^3 \left.\frac{d\bar{q}}{d\theta}\right]_B = f(B)$$

Draw a curve for the left side of this equation versus B; and, using points calculated from a group of fundamental bearings, having a given c, β, and r (usually three in number), plot a curve for the right side of the equation. The intersection gives the value of B for the associated terminal bearing; the results, for the three series of bearing lengths, are shown in Fig. 2. As the eccentricity approaches unity, it becomes rather difficult to locate these terminal bearings by three-point interpolation, due to the suddenness with which the value of $dp/d\theta$ changes over a small range of B in the neighborhood of 180 deg. For this reason the curves in Fig. 2 have been faired without attempting to intersect plotted points, where these were obviously out of line.

The α/β values and side-leakage factors of all fundamental bearings in each group having the same c, β, and r were plotted simultaneously versus B. By using appropriate values of B from Fig. 2, the properties of the terminal bear-

* Uncertain, due to extrapolation.

ing pertaining to each of these groups were obtained by interpolation and entered in Table 3. Consider for example line 10 in Table 3; this represents the terminal bearing of eccentricity ratio 0.8, 80-deg span and length-width ratio 4:1, and was derived from the three starred lines in Table 1. The three B values in these lines of Table 1 are 170, 190, and 210 deg; from Fig. 2, B for the terminal bearing is 185.6 deg, which gives the interpolation interval. Accordingly, the three α/β values in Table 1, which are 0.6863, 0.5389, and 0.0507 give $\alpha/\beta = 0.578$ for Table 3. Similarly, the W/W_0 and F/F_0 values in Table 3, respectively, 0.08 and 0.792, are interpolated from the six side-leakage factors in the starred lines of Table 1.

Terms W/W_0 and F/F_0 in Table 3 are not true side-leakage factors for terminal bearings, since the value 0.08, for example, means that the capacity of a terminal bearing of length-width factor 4 is 0.08 that of an infinite-width bearing whose entering and exit angles are the same as those of the finite-width bearing, and such an infinite-width bearing is not terminal. To find the true side-leakage factor for load, 0.080 must first be multiplied by the load capacity for an 80-deg infinite-width bearing whose exit angle is 185.6 deg, and then be divided by the load capacity of an 80-deg infinite-width terminal bearing, i.e., $0.080 \times 7.3928/6.7200 = 0.088$. For the friction side-leakage factor, $0.792 \times 5.6421/6.0051 = 0.743$. The W_0 and F_0 factors, used in this corrective process, are interpolated from the appropriate values of $W \Big/ \left(\frac{\mu Ua^2}{\eta^2}\right)$ and $F \Big/ \left(\frac{\mu Ua}{\eta}\right)$ in Table 1.

The exit angles, α/β values, and load and friction factors entered in Table 3 for the case of $c = 1$, are in harmony with the negative-pressure theory adopted in this paper. According to this theory, the load line and line of centers become coincident in this limiting case, and pass through the leaving edge of the bearing, regardless of the value of the entering angle A. Obviously, any terminal bearing having $c = 1$ may be extended into a centrally supported bearing merely by doubling the length of the shell; all of the pressure in the oil film is developed in the convergent half, approaching infinity at the point of contact between journal and shell. In the divergent half, the pressure is zero.

No values for side-leakage factors have been entered in Table 3 for $c = 1$. When negative pressures are neglected, it has been customary to assume unity for both these factors, as well as for the coefficient of friction. However, with the interpretation here placed upon negative pressures, it is suspected that the side-leakage factors approach values lying between 0 and 1, and that the friction coefficient approaches zero. The author is at present making a detailed study of this region and expects to report his findings at a later date. Fortunately, this uncertainty does not appear to have a vital effect upon the determination of optimum bearings, at least in the range of minimum film thickness ordinarily used.

Properties of Centrally Supported Bearings

Ignoring for the present the terminal bearings with $c = 0.6$, most of which have, according to Table 3, noncentral support with $\alpha/\beta < 0.5$, it is possible to convert all the remaining examples into centrally supported bearings simply by adding an arc ϵ at the leaving edge of the shell, such that $\epsilon = (2\alpha/\beta - 1)\beta$.

* Uncertain due to extrapolation.

The complete bearing arc is then $\beta + \epsilon = \beta'$, and $\alpha/\beta' = 0.5$. At the same time, the length-width factor changes, becoming $r' = 2\alpha r/\beta$. The load factor $W \Big/ \left(\frac{\mu Uh^2}{a^2}\right)$ is unaffected by this addition to the bearing arc, since, as previously explained, the oil film which carries the load maintains the same arc β as before. The effect upon the friction factor is uncertain; the pressure term is zero, and the velocity term is indeterminate, due to the discontinuous nature of the oil in the portion of the bearing represented by arc ϵ. It has been assumed that this term is small

n comparison with the corresponding term for the load-carrying part of the bearing, and may be neglected.

Consider, as an example, the three infinite-width terminal bearings with $c = 0.8$ in Table 3, all of which have $\alpha/\beta > 0.5$. These may be extended into centrally supported bearings with $\alpha/\beta' = 0.5$, as follows

B, deg	A, deg	ϵ, deg	β', deg	$W\Big/\left(\frac{\mu U a^2}{\eta^2}\right)$	$F\Big/\left(\frac{\mu U a}{\eta}\right)$
197.0	117.0	2.88	82.9	6.7200	6.0051
198.3	98.3	12.00	112.0	9.168	7.1084
199.0	79.0	22.56	142.6	11.007	8.0607

Note that the load and friction factors have not been altered

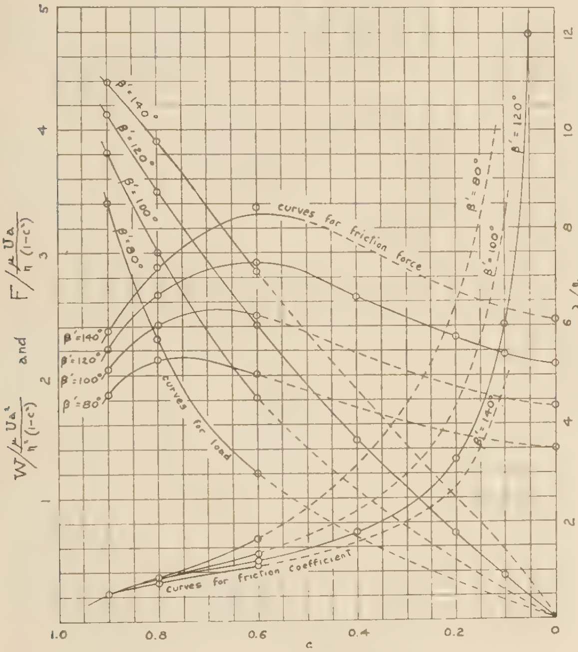

Fig. 3 Capacity and Friction of Infinite-Width Centrally Supported Bearings

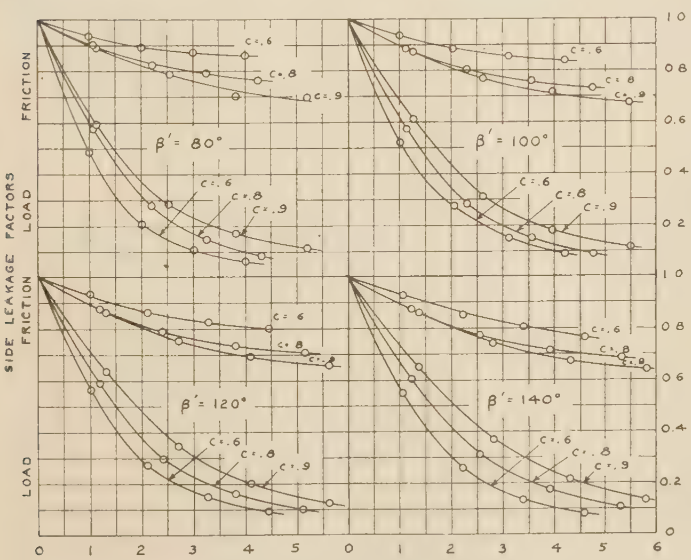

Fig. 4 Effect of Length-Width Ratio on Side-Leakage Factors

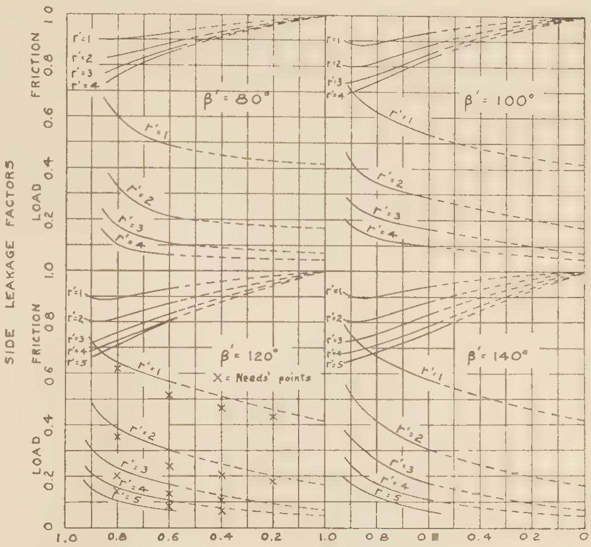

Fig. 5 Effect of Eccentricity on Side-Leakage Factors

by the addition of ϵ to the bearing arc. Now, by interpolating between these three rows of figures, the properties of any centrally supported bearing having $c = 0.8$, and a bearing arc in the range of 80 to 145 deg, may be ascertained. The interpolation is practically straight-line for all of the cases investigated, so that good accuracy is assured. The results are given in Table 4, and Table 5 contains similar data for finite-width bearings, with the inclusion of the corrected length-width factor r' and the substitution of side-leakage factors for load and friction factors.

As was noted previously, the terminal bearings with $c = 0.6$ lie on both sides of the line $\alpha/\beta = 0.5$, which means that, where $\alpha/\beta < 0.5$, the criterion for interpolation is a group of "preterminal" bearings, obtained directly from Table 1, whereas, if $\alpha/\beta > 0.5$, the criterion is a group of terminal bearings, as in the case just illustrated. In any event, the side-leakage factors in Table 5 refer to centrally supported infinite-width bearings of the same span β', regardless of whether they are terminal or preterminal.

Fig. 3 shows the load capacity, friction force, and coefficient of friction of infinite-width centrally supported bearings. The values for $c < 0.6$, $\beta = 120$ deg, have been taken from Needs's paper,[2] since in this range, there is no question of negative pressures; above $c = 0.6$, the load and friction factors tend toward infinity, and the coefficient of friction apparently tends toward zero. Fig. 4 shows the variation of side-leakage factors with length-width ratio, according to the data in Table 5, and Fig. 5 presents the same data as variation of side-leakage factors with eccentricity.

If crossplots are made to show the effect of varying the bearing length, the curves are slightly irregular at some points, showing the need of additional data to verify the interpolations. There is, however, a small but consistent increase in the side-leakage factor for load, and decrease in the factor for friction, with increasing bearing length, for all values of length-width ratio that were investigated. This can be seen by comparing the adjacent sections of Figs. 4 and 5.

If the mean clearance η is replaced by the minimum

clearance $h_0 = \eta(1 - c)$, Kingsbury[6] has shown that the load capacity and friction coefficient attain definite maxima and minima for any given value of h_0, bearing size, speed, and viscosity. Bearings operating at such points are said to be running under optimum conditions. Hitherto, this analysis has been based on the conventional neglect of negative pressures, and it would seem to be a matter of some interest to find what effect, if any, is produced by the principle of the exclusion of negative pressures, as contrasted with their neglect. Accordingly, Figs. 6 and 7 have

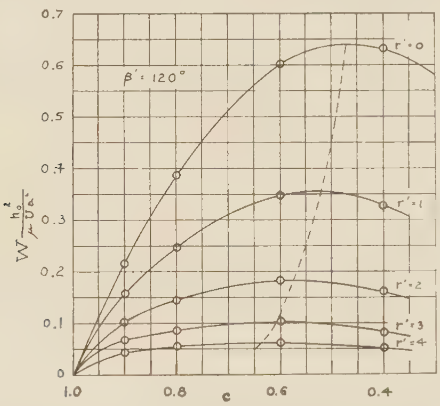

FIG. 6 OPTIMUM CONDITION FOR LOAD, 120-DEG BEARINGS

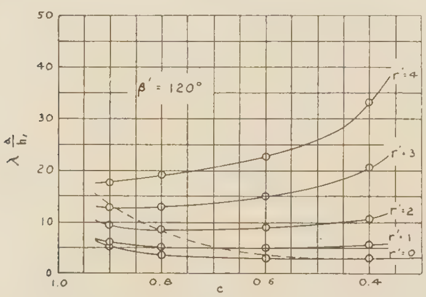

FIG. 7 OPTIMUM CONDITION FOR FRICTION, 120-DEG BEARINGS

been plotted from the data for 120-deg bearings. For $c < 0.6$, the curves for $r = 0$ were taken directly from Needs's paper[2] and the curves for $r = 1, 2, 3, 4$ were then obtained by using the tentative side-leakage factors given by dotted lines in Fig. 5 for this region.

COMMENTS AND GENERAL CONCLUSIONS

Table 2 indicates that the author's method of solution for the fundamental bearings gives results of the same order of magnitude as those previously obtained by experimental integrations, but the factors for load and friction both decrease more rapidly as the length-width ratio increases above unity. When $r = 4$, $c = 0.6$, $\beta = 120$ deg, the values are respectively 10.7 and 4 per cent lower, making the friction coefficient 6.6 per cent higher. When the criterion of bearings without negative pressure is introduced, there is no effect upon infinite-width bearings in the approximate range $0 < c < 0.6$; beyond this, the film arc β has to be reduced to eliminate the negative-pressure region, and the entering angle A has to be increased to maintain $\alpha/\beta' = 0.5$. The resulting bearings are offset in the sense that their point of support is not at the center of the oil film, but actually they are centrally supported, due to the effect of the nonloaded portion of the bearing shell. In the limiting case of a 120-deg bearing, with $c = 1$, β has shrunk to 60 deg, $A = 120$ deg, and the line of centers bisects the bearing arc. The entering half of the bearing then carries the entire load. The effect of these shifts is to increase $W \bigg/ \left(\dfrac{\mu U a^2}{\eta^2}\right)$ and decrease $F \bigg/ \left(\dfrac{\mu U a}{\eta}\right)$ in relation to the conventionally accepted values.

The side-leakage factors in Table 1 are all based on a comparison of the properties of a finite-width bearing with those of an infinite-width bearing with the same values of entering and exit angles. When the basis of comparison is altered to that of terminal bearings, having the same span, then the line of centers for each finite-width bearing undergoes a definite shift, and this has a decided effect upon load capacity in the range of eccentricities covered by the present paper. This explains the main reason for the discrepancy between the author's curves in Fig. 5 and the points determined by Needs[2] who considered it unnecessary to correct the side-leakage factors for shift of centerline angle. The terminal points of these curves, at $c = 0$, were computed by a simplified mathematical analysis for centrally supported bearings of small eccentricity, in which the expression for clearance, $h = \eta(1 + c\cos\theta)$, is expanded in ascending powers of c, and all terms of order higher than unity are neglected. According to this analysis, the side-leakage factor for load equals, to a first approximation, $1 - [(\tanh \pi/2r)/(\pi/2r)]$. The results agree exactly with those extrapolated from Needs's experimental points.

Figs. 5 and 6 indicate the existence of a definite relation between eccentricity and length-width ratio for maximum-capacity or minimum-friction coefficient on the basis of a fixed minimum clearance. However, the general flatness of the curves indicates that the eccentricity may be varied over a considerable range without much effect on capacity or friction. As r increases, the divergence between the eccentricity for greatest load and that for least friction becomes much more pronounced than is apparent from the work of Needs. A set of points for $c = 0.95$ is desirable for establishing this relationship definitely.

ACKNOWLEDGMENT

In conclusion, the author wishes to acknowledge his thanks for the very material aid that he has received from the Society's Special Research Committee on Lubrication.

Appendix

Outline Solution for Typical Fundamental Bearing

(1) Solution of Reynolds' equation

$$\frac{\partial}{\partial\theta}\left(\frac{h^3}{\mu}\frac{\partial p}{\partial\theta}\right)+a^2\frac{\partial}{\partial z}\left(\frac{h^3}{\mu}\frac{\partial p}{\partial z}\right)=6Ua\frac{dh}{d\theta} \qquad (1)$$

$p=p_x-q$, where p_x is a particular solution of

$$\frac{d}{d\theta}\left(\frac{h^3}{\mu}\frac{dp_x}{d\theta}\right)=6Ua\frac{dh}{d\theta} \qquad (2)$$

q is a general solution of the homogeneous equation

$$\frac{\partial}{\partial\theta}\left(\frac{h^3}{\mu}\frac{\partial q}{\partial\theta}\right)+a^2\frac{\partial}{\partial z}\left(\frac{h^3}{\mu}\frac{\partial q}{\partial z}\right)=0 \qquad (3)$$

Boundary conditions: $p=0$ when $\theta=70°$ and $190°$, for all values of z

$p=0$ when $r=2$, for all values of θ

Eccentricity ratio: $c=0.8$

Pressure function: $p(h/\eta)^{3/2}$

$$p_x(h/\eta)^{3/2}=(0.08323\sin\xi+0.003248\sin 2\xi+0.0005563\sin 3\xi+0.001690\sin 4\xi-0.0006310\sin 5\xi+0.0005756\sin 6\xi)\frac{6\mu Ua}{\eta^2(1-c^2)^{3/2}} \qquad (4)$$

by 6-ordinate harmonic analysis of conventional solution.

Let $q=\Sigma A_n\left[X_n/\left(\frac{h}{\eta}\right)^{3/2}\right]Z_n$, X and Z being functions respectively of θ and z only. Then, by separating the variables in (3),

$$\frac{d^2X}{d\theta^2}+\left[m^2-\frac{3}{2}\frac{d^2h/d\theta^2}{h}-\frac{3}{4}\left(\frac{dh/d\theta}{h}\right)^2\right]X=0 \quad \text{or}$$

$$\frac{d^2X}{d\xi^2}+\left[\frac{4}{9}m^2-1.3476+1.3814\cos\xi+0.1568\cos 2\xi-0.05126\cos 3\xi+0.01857\cos 4\xi-0.006684\cos 5\xi+0.01004\cos 6\xi\right]X=0 \qquad (5)$$

by Fourier theorem for cosine series.

Also

$$\frac{d^2Z}{dz^2}-\left(\frac{m}{a}\right)^2Z=0 \qquad (6)$$

The first six solutions for $q(h/\eta)^{3/2}$ are (by method of successive approximation):

$$\left.\begin{array}{llllllll}
 & & \sin\xi & \sin 2\xi & \sin 3\xi & \sin 4\xi & \sin 5\xi & \sin 6\xi \\
q_1(h/\eta)^{3/2}= & (A_1\cosh\frac{m_1 z}{a})[& +1 & +.2326 & +.02912 & +.00009687 & -.00009443 & -.00003807] \\
q_2(h/\eta)^{3/2}= & (A_2\cosh\frac{m_2 z}{a})[& -.2415 & +1 & +.1386 & +.01452 & -.0005453 & -.0003871] \\
q_3(h/\eta)^{3/2}= & (A_3\cosh\frac{m_3 z}{a})[& +.004015 & -.1383 & +1 & +.09819 & +.009347 & -.0005853] \\
q_4(h/\eta)^{3/2}= & (A_4\cosh\frac{m_4 z}{a})[& +.002216 & -.0003328 & -.09878 & +1 & +.07633 & +.006696] \\
q_5(h/\eta)^{3/2}= & (A_5\cosh\frac{m_5 z}{a})[& -.0002639 & +.001629 & -.001536 & -.07684 & +1 & +.06231] \\
q_6(h/\eta)^{3/2}= & (A_6\cosh\frac{m_6 z}{a})[& +.0001048 & -.0003539 & +.001238 & -.001774 & -.06230 & +1]
\end{array}\right\}(7)$$

$m_1=2.2522$ $m_2=3.4957$ $m_3=4.8329$ $m_4=6.2503$ $m_5=7.7010$ $m_6=9.1723$

$p_x-q=p=0$ at $z=w/2$; hence, equating to zero the coefficients of terms in (4) and (7) having the same multiple of ξ in $\sin\xi$, and letting $A_n\cosh\frac{m_n z}{a}=B_n$ when $z=\pm w/2$, also $\eta_1^2=\eta^2(1-c^2)^{3/2}$,

$$\left.\begin{array}{l}
\frac{\eta_1^2}{6\mu Ua}(B_1-.2415B_2+.004015B_3+.002216B_4-.0002639B_5+.0001048B_6)=0.08323 \\
\frac{\eta_1^2}{6\mu Ua}(.2326B_1+B_2-.1383B_3-.0003328B_4+.001629B_5-.0003539B_6)=0.003248 \\
\frac{\eta_1^2}{6\mu Ua}(.02912B_1+.1386B_2+B_3-.09878B_4-.001536B_5+.001238B_6)=0.0005563 \\
\frac{\eta_1^2}{6\mu Ua}(.00009687B_1+.01452B_2+.09819B_3+B_4-.07684B_5-.001774B_6)=0.001690 \\
\frac{\eta_1^2}{6\mu Ua}(-.00009443B_1-.0005453B_2+.009347B_3+.07633B_4+B_5-.06230B_6)=-0.0006310 \\
\frac{\eta_1^2}{6\mu Ua}(-.00003807B_1-.0003871B_2-.0005853B_3+.006696B_4+.06231B_5+B_6)=0.0005756
\end{array}\right\}(8)$$

Solving (8), $B_1=0.07955\left(\frac{6\mu Ua}{\eta_1^2}\right)$ $B_2=-0.01518\left(\frac{6\mu Ua}{\eta_1^2}\right)$

$B_3=0.0005190\left(\frac{6\mu Ua}{\eta_1^2}\right)$ $B_4=0.001796\left(\frac{6\mu Ua}{\eta_1^2}\right)$

$B_5=-0.0007350\left(\frac{6\mu Ua}{\eta_1^2}\right)$ $B_6=0.0006068\left(\frac{6\mu Ua}{\eta_1^2}\right)$

Since $\bar{q}_n=q\Big]_{w/2}\left(\frac{\tanh(m_n w/2a)}{m_n w/2a}\right)$ and $r=l/w=2$, we have

$$\left.\begin{array}{lll}
\bar{q}_1=q_1(\tanh\frac{1}{6}m_1)/\frac{1}{6}m_1=0.7015q_1 & \bar{q}_2=0.5190q_1 & \bar{q}_3=0.3902q_3 \\
\bar{q}_4=0.3047q_4 & \bar{q}_5=0.2478q_5 & \bar{q}_6=0.2082q_6
\end{array}\right\}(9)$$

Combining (7), (8) and (9), $\bar{q}=\Sigma\bar{q}_n=$

$$(0.05771\sin\xi+.005073\sin 2\xi+.000682\sin 3\xi+.000472\sin 4\xi-.000147\sin 5\xi+.000120\sin 6\xi)(\eta/h)^{3/2}(6\mu Ua/\eta_1^2) \qquad (10)$$

Subtracting (10) from (4),

$$\bar{p}(h/\eta)^{3/2}=(0.02552\sin\xi-0.001825\sin 2\xi-0.000126\sin 3\xi+0.001218\sin 4\xi-0.000484\sin 5\xi+0.000456\sin 6\xi)(6\mu Ua/\eta_1^2) \qquad (11)$$

$$\left.\begin{array}{l}
W_H=a\int_A^B\bar{p}\cos\theta\,d\theta=-3.1383(\mu Ua^2/\eta^2) \\
W_V=a\int_A^B\bar{p}\sin\theta\,d\theta=1.8877(\mu Ua^2/\eta^2)
\end{array}\right\}\text{from (11) by Simpson's rule for 12 equal intervals}$$

$\phi=\tan^{-1}\left(\frac{W_V}{W_H}=-0.6015\right)=148°58'$

$\alpha/\beta=(148°58'-70°)/120°=0.6581$

$W=W_H\sqrt{(W_V/W_H)^2+1}=3.662(\mu Ua^2/\eta^2)$

See Fig. 8 for graph of $\bar{p}$, p_x and $p_x(h/\eta)^{3/2}$

(2) Friction computation. $F=\int_A^B\frac{\mu Ua}{h}d\theta+\int_A^B\frac{h}{2}\frac{d\bar{p}}{d\theta}d\theta$

$=F_1+F_2$

$F_1=5.3273\mu Ua/\eta$

$$F_2=\frac{1}{2}\int_{\bar{p}_A}^{\bar{p}_B}h\,d\bar{p}=\frac{1}{2}h\bar{p}\Big]_{\bar{p}_A}^{\bar{p}_B}-\frac{1}{2}\int_{\bar{p}_A}^{\bar{p}_B}\bar{p}\,dh$$

$$=0-\frac{1}{2}\int_A^B\bar{p}\frac{dh}{d\theta}d\theta$$

$$=\frac{\eta c}{2}\int_A^B\bar{p}\sin\theta\,d\theta=\frac{\eta c}{2a}W_V$$

$$=0.7550\mu Ua/\eta$$

$F=6.0823\mu Ua/\eta$ $\lambda=F/W=1.6609\,\eta/a$

(3) Oil flow computation. $\frac{\partial q_n/\partial z\Big]_{w/2}}{q_n\Big]_{w/2}}=\frac{m_n}{a}\tanh\frac{m_n w}{2a}$,

and $\frac{q_n\Big]_{w/2}}{\bar{q}_n}=\frac{m_n w/2a}{\tanh\frac{m_n w}{2a}}$, hence $\partial q_n/\partial z\Big]_{w/2}=\frac{m_n^2 w}{2a^2}\bar{q}_n$

Combining this with (7), (8) and (9) gives $\partial q/\partial z\Big]_{w/2}=\Sigma\,\partial q_n/\partial z\Big]_{w/2}=$

$$(0.3064\sin\xi-0.03108\sin 2\xi-0.002970\sin 3\xi+0.02130\sin 4\xi-0.009755\sin 5\xi+0.01013\sin 6\xi)\left(\frac{w}{2a^2}\right)(\eta/h)^{3/2}\left(\frac{6\mu Ua}{\eta_1^2}\right) \qquad (12)$$

$$Q_z=-\int_A^B\frac{h^3}{12\mu}\frac{\partial p}{\partial z}\Big]_{w/2}a\,d\theta=\int_A^B\frac{ah^3}{12\mu}\frac{\partial q}{\partial z}\Big]_{w/2}d\theta$$

$=0.1998\,Ua\eta$, from (12), by Simpson's rule for 12 equal intervals.

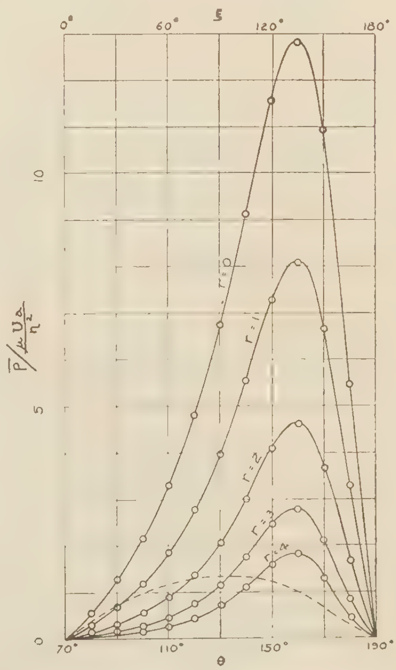

Fig. 8 Mean Pressure Distribution in a Typical Bearing

From (11), $\frac{d\bar{p}}{dx}\Big]_{\theta=A}=0.02667(\eta/h_A)^{3/2}(6\mu Ua/\eta_1^2)\left(\frac{d\xi}{dx}\right)$

$\frac{d\bar{p}}{dx}\Big]_{\theta=B}=-0.01876(\eta/h_B)^{3/2}(6\mu Ua/\eta_1^2)\left(\frac{d\xi}{dx}\right)$

$$Q_A=w\left[\frac{Uh}{2}-\frac{h^3}{12\mu}\frac{d\bar{p}}{dx}\right]_{\theta=A}=\left(\frac{\beta a}{2}\right)\left(\frac{U\eta}{2}\right)(1+0.8\cos 70°)-\left(\frac{\beta a}{2}\right)\frac{(1+0.8\cos 70°)^{3/2}}{12\mu(1-c^2)^{3/2}}(0.02667\times 6\mu Ua\eta)\frac{\pi}{a\beta}$$

$=0.5275\,Ua\eta$

Substituting -0.01876 for 0.02667, and $190°$ for $70°$, in the foregoing, gives

$$Q_B=0.1177\,Ua\eta$$

FIG. 1 PANORAMIC VIEW OF BONNEVILLE PROJECT

(This view shows the unfinished north half of the spillway. Some of the gates are in place, and one gantry on the south half. The Columbia Construction Company's gigantic high line can be seen with the fixed tower dominating North Bonneville. Fish ladders are at each end of the dam, with the south fishway meeting the one from the powerhouse in the form of a Y, leading to the pool between Bradford Island and the Oregon shore.)

Structural-Steel Tolerances at Bonneville

BY T. M. OBER,[1] BREMERTON, WASH.

This paper describes features of the Bonneville Project, which have attracted widespread interest. Noteworthy among these are the eighteen 225-ton vertical-lift spillway-dam gates, each of two sections, operated by two 350-ton gantry cranes; and the variety and number of fishways requiring numerous gates and lifts. The great size of steel units involved in the construction required unusual care in erection. Close tolerances were maintained in the setting of embedded steel. The methods of erection employed and the limits within which the work was carried out are dealt with at some length. The author deals quite extensively with the matter of selecting personnel for the structural-steel inspection staff for a project of this magnitude. Also, in the text, he refers quite extensively to drawing numbers, and specification page numbers, in order that those who so desire may be enabled to refer directly to the original plans and specifications of the project.

ON September 30, 1933, the Federal Administrator of Public Works authorized the construction of the Bonneville Power-Navigation Project as Federal Project No. 28, under the provisions of the National Industrial Recovery Act. The sum of $32,200,000 was allocated for this purpose. The dam was to be constructed under the supervision of the Corps of Engineers, U. S. Army.

The Bonneville Power-Navigation Project is located at tidewater on the Columbia River approximately 140 miles from its mouth and 42 miles east of Portland, Ore. At this point, the river flows in a general westerly direction in two channels which are separated by Bradford Island. The center of the north channel is the boundary line between the states of Oregon and Washington. The spillway dam, approximately 1250 ft in length, was constructed across the north or main channel and the powerhouse and navigation lock were located in the south channel with the lock on the Oregon shore. A levee on Bradford Island connects the dam and the powerhouse.

The lock chamber is 76 ft wide, 500 ft long, and has a depth of 26 ft over the lower sill at low water. The vertical lift at extreme low water is 66 ft, the greatest of any lock yet built. At normal river stage the lift is 59 ft; at extreme high water about 30 ft.

The existing project for the improvement of the Columbia River between Vancouver and Bonneville was adopted by Congress on August 26, 1937, with an estimated cost of $2,649,000 for new work and $200,000 annually for maintenance. This project provides for a channel 300 ft wide and 27 ft deep at low water, which depth conforms with the minimum clearwater of 26 ft over the lower sill of the Bonneville locks, and the depth of 30 ft in the river stretch above Bonneville.[2]

The spillway design was based on the record flow of 1,170,000 sec-ft which occurred in 1894. The design provides for a maxi-

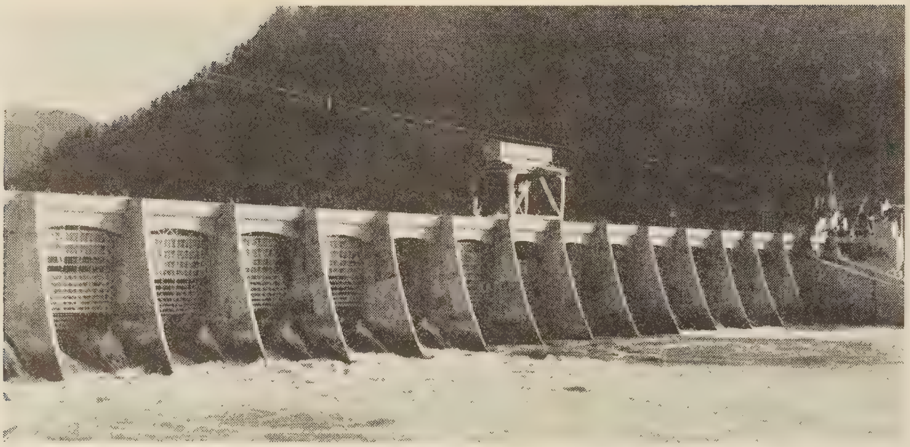

Fig. 2 View of Spillway, Showing Gates and Crane in Operation

mum flow of 1,600,000 sec-ft (an estimated 1 in 10,000 year flood) and a minimum of 40,000 sec-ft. Although both navigation and power are provided by the Bonneville Dam, navigation requirements at the dam or in the river will not affect operation of the power plant. There is no seasonal storage available in the Bonneville pool, but daily load fluctuations can readily be accommodated with 3 ft or less of drawdown.

The size of the turbines was given careful consideration. The units are about as large as is practicable under existing shop conditions. As finally designed, the turbines have a rating of 66,000 hp under 50 ft head. They are the largest Kaplans in this country, the highest Kaplans ever built, and the generators they drive are the largest in physical dimensions so far constructed. Normal headwater elevation at minimum flow was provided to be at elevation +72 with tailwater at +14. With normal maximum flow of 600,000 sec-ft, the headwater is raised to +82.5 to develop the full power of the turbines.[3]

The magnitude of the Corps of Engineers' project at Bonneville prevents discussion here of any save spillway and fishway features.

Spillway-Gate Design

The fish industry in Oregon and Washington, valued at $10,000,000 annually, influenced the gate and dam design. The fish ladders and collecting systems at each end of the dam required the complete closure of the three end gates. The straight-lift-type gate, made in two sections because of the height and the necessity for raising them clear of the water during high flows, was required for a depth of flow of 50 to 60 ft and a width of 50 ft. Accordingly six gates were built with a height of 60 ft for the end bays and twelve with a height of 50 ft 9 in. The twelve center gates were provided with a skimmer section 8 ft high and 42 ft long. The headwater elevation above the dam is regulated by the operation of the spillway-dam gates by means of two 350-ton gantry cranes. An allowable pool-operating range of $^1/_2$ ft above or below the desired level was assumed as reasonable.

Therefore, it was concluded that, because of the large reservoir capacity above the dam amounting to 20,000 acre-ft per ft of depth at elevation 72, neither rapid nor refined gate operation would be required. Provision of a rack bar, enabling each gate to be raised in 2-ft steps, was considered adequate from the standpoint of regulation.

Twenty gates and two gantry cranes were contracted to the Columbia Steel Corporation for approximately $1,200,000. The gantry cranes were built by the Morgan Engineering Company, Alliance, Ohio, and the gates by the American Bridge Company. The general contractor, Columbia Construction Company, placed the embedded steel, which cost approximately $1,000,000 in addition, for both fishways and dam. Gantry cranes were selected for handling the gates on account of the necessity for transferring the upper gate sections from the downstream to the upstream slots; the ease of handling spare gates in case repairs are required; and their considerably lower first cost over fixed hoists. Each crane is supplied with a Climax driven generator for emergency use.

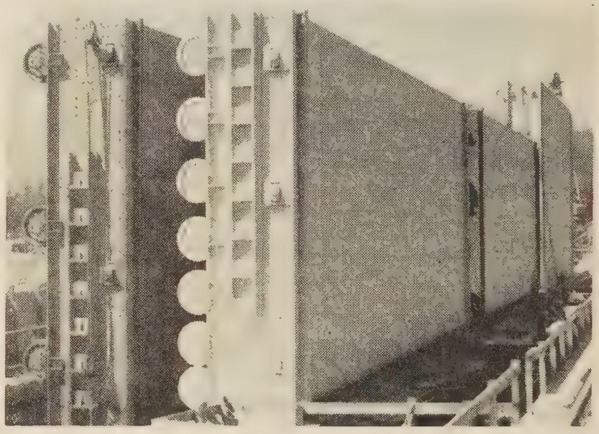

Fig. 3 Spillway Gates Being Painted
(The near gate section with the seven wheels showing is a bottom section, the other near gate at the left is a top section.)

This paper is principally concerned with steel tolerances, but some details of the gate construction and accessories will be related for clarity.

Specifications for Reinforced-Rubber Sealing Strips

The side and intermediate seals for the gates are similar to a J-type used on previous work, but, it is believed, the bottom seal is an innovation. The side seals were specified as follows:

Tread Stock. The tread stock shall consist of high-grade stock containing 60 per cent by weight of new plantation rubber free from reclaim, silica, and other coarse material, balanced to permit thorough cure. Tensile strength shall be not less than 3000 psi, and elasticity not less than 600 per cent.

Cushion Stock. The cushion stock shall consist of high-grade stock, containing not less than 80 per cent by weight of new plantation rubber, free from reclaim, silica, and other coarse material, balanced in compound to permit thorough cure. Tensile strength shall be not less than 2500 psi; elasticity not less than 700 per cent.

Reinforcement. Two-ply 13-oz Karded Peeler tire cord, frictioned both sides and skimmed one side to a gage of 0.047 in., shall be used for reinforcement.

General Notes. The different elements shall be well cured and well bonded together, so as to withstand a friction pull, between the plies of fabric, of 26 lb per in. of width, and shall be cured in a mold. The provisions of Federal Specifications ZZ-R-601 and CCC-T-191 shall apply.

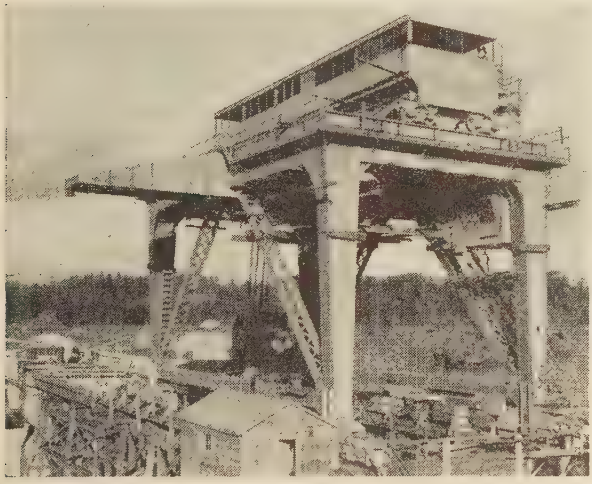

Fig. 4 The First of Two 350-Ton Gantry Cranes Nearing Completion

Length. The rubber seal of above cross section shall be fabricated in unbroken lengths as required.

Aging Test. After samples cut from the various stocks have been subjected to an accelerated aging test in air for 7 days at 158 F, the tensile strength shall be not less than 75 per cent of the original value.

The bottom seal shall consist of tread stock, reinforced by two layers of six-ply 28- or 32-oz cotton canvas duck.

Gate Mechanism

Gates were provided with 27-in-diam wheels and with SKF self-aligning roller-bearing mountings, similar to a number of previous installations. The wheels are mounted on finished flange plates on the gates, and are assembled with corrugated-steel springs and shims to secure an accuracy of alignment on each row of wheels equaling 0.001 in. per ft of distance, when the springs are compressed with a load of 20,000 to 30,000 lb. Gate wheels and mountings were designed to be suitable for carrying the load, due to the pressure of the water against the gates, under the maximum head, and to allow vertical travel of the gates without excessive friction. To assure even bearing of the wheel treads against the gate guide track plates, under varying deflections of the gates, spherical roller bearings were provided. By means of oval shaft bushings contacting cylindrically bored bearing covers, a maximum movement of 1 deg was allowed the wheels from a vertical plane normal to the track, to compensate for gate deflection, and a maximum movement of only 0.1 deg from a horizontal plane, normal to the track, so that the wheels could not "wander" from the track.

To avoid overloading of individual gate-wheel units, caused by unavoidable track irregularities, both pedestals of each unit were mounted upon a pair of transversely corrugated spring plates to permit an elastic displacement of each of the units. Springs were formed as shown in Fig. 6. Twist or warp in any one spring was not to exceed an amount which would prevent full transverse bearing at all bearing planes, when the spring was subjected to a total load of 10,000 lb.

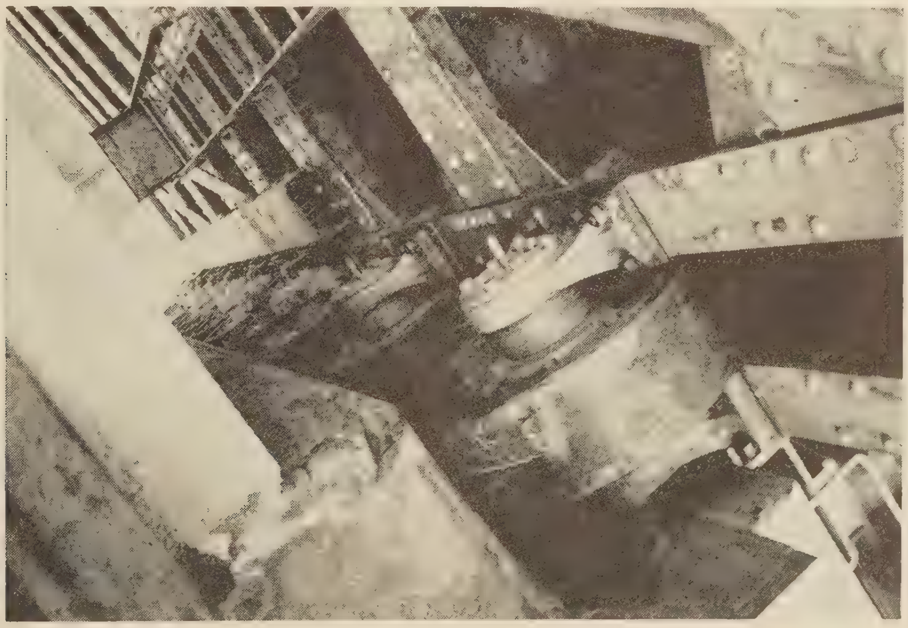

Fig. 5 View Looking Down Gate Slot

(This view shows large size of wheels with pedestal mountings; the water can be seen rushing by underneath.)

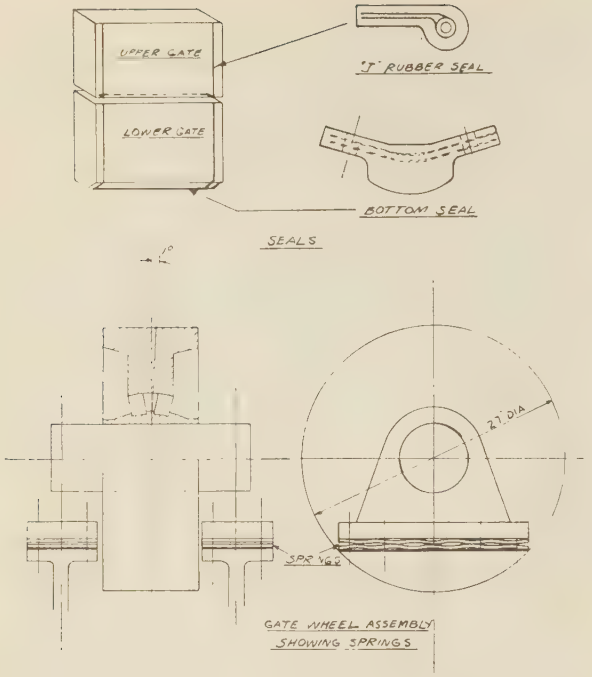

Fig. 6 Arrangement and Sections of Rubber Seals at Top; Below Are Main Wheel Assemblies and Corrugated Springs

To permit the bearing surfaces of the wheels to be brought into a common plane, suitable shims, fabricated from corrosion-resistant steel, were placed between the spring plates and the gates. Shims had a minimum thickness of 18 gage. They were supplied in such total thickness that unit stresses in spring plates in no case varied from that resulting from a minimum load of 5000 lb and a maximum load of 10,000 lb, applied at each pedestal mounting at the time specified tolerance conditions of wheel alignment were met.

The wheels are spaced along the gate end girders so that each wheel carries a radial load of approximately 210,000 lb with perfect alignment of track and wheels. The permitted tolerances would cause a maximum load on any wheel not exceeding 265,000 lb. Errors in track and wheel alignment, the deflection and flexibility of the gate, and wheel assembly and loading on the track beams and concrete piers were factors requiring careful study. The tolerances controlling the placing of the various embedded structural members were maintained at considerable expense both to the contractor and to the government.

Field Personnel

It was concluded, after 6 months of trial, that the construction-survey crews were best qualified to check steel alignments of embedded gates, guides, and structural members. A few of the better-class machinists, who were capable of making sketches and reading construction blueprints, were successful on this work, but their services were obtained only after many difficulties. It is believed the reason for this is that the construction-survey crews are more accustomed to climbing forms at various elevations. Also, they are familiar with making close measurements with tapes, and are experienced in the use of micrometer adjustments on instruments and leveling rods, thus being able to use the machinist's inside micrometer. Mechanical inspectors usually advance from the grade of machinist. It is not only difficult to obtain them for this work, but, as a general rule, they are not as adaptable, since construction is an entirely new world to them. This faculty of adaptability is generally lacking in the case of structural inspectors, who advance from the grade of ironworker. These men are unable to make close measurements requiring micrometers. Of course, some notable exceptions were found in all groups. However the survey crews are recommended as being most readily available and most generally useful.

The dam was built in three steps. The south half was first constructed, with the crest and gate guides at elevation —10. The north half was built inside its cofferdam, as the second step, with crests at elevation +24; later the south-half crests were raised to elevation +24. The completion of the top of the first half and start of the second half were carried on simultaneously.

The maximum number of inspectors and machinists were employed checking steel at this time, the total being thirty-seven men in the section. In addition to the section head, this number included one junior engineer, replaced later by a surveyman (chief of party), as assistant, nine inspectors, twenty-one machinists and helpers, one master mechanic, and four crane operators. The machinists were gradually transferred to the shop, as the work decreased, and two survey crews were used to check spillway-gate steel, with other crews available to give points as needed. The inspectors continued to do individual checking before and after concrete pours. This large staff was required because of the extent of operations, which included fishways on both sides of the river. A great variety of embedded steel, gate guides, anchor bolts, and machinery supports were installed on the fishways, which included two fish ladders, four fish lifts, and

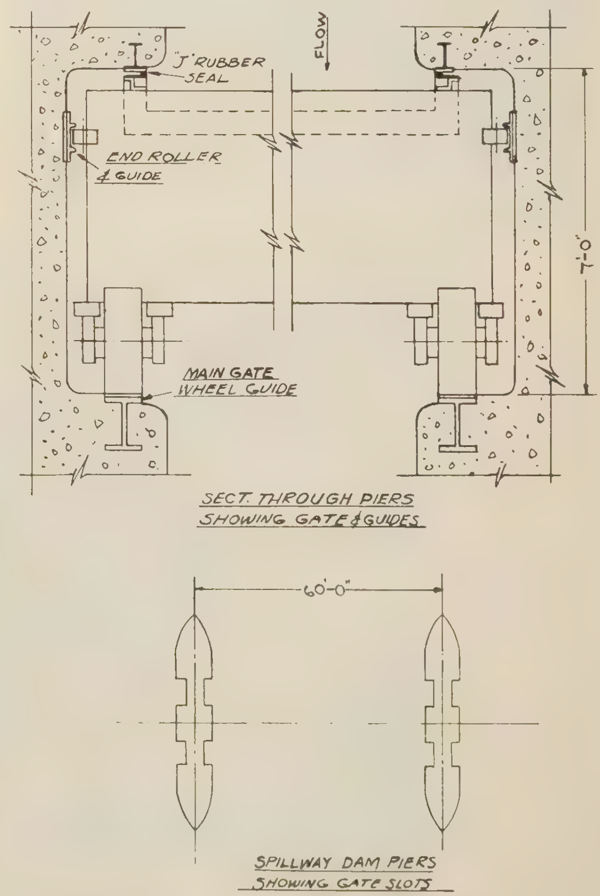

Fig. 7 Sections Through Piers, Showing General Arrangement of Concrete Piers, Gate, and Gate Guides

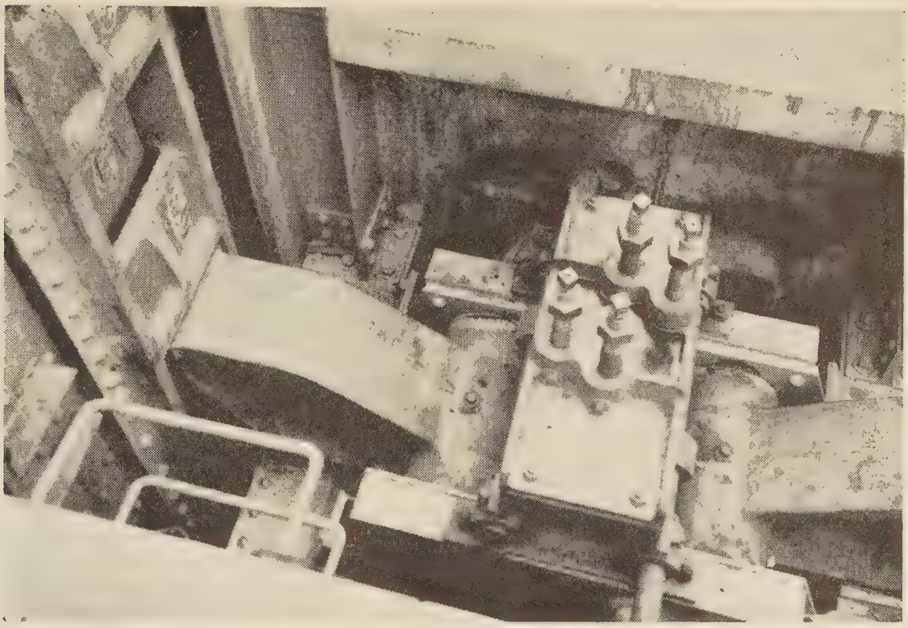

Fig. 8 View of Upper Latch-Operating Mechanism

collection bays at the spillway dam. Other fishways were provided at the powerhouse and ship lock.

Field Inspection at Spillway Dam

Eighteen bays are included in the dam construction, with concrete piers 10 ft wide. Two sets of gate slots are provided—operating slots (downstream) and emergency slots (upstream). During extreme floods, when it is necessary to raise the gates clear of the water, the top sections are transferred to the upstream slots and latched in position above the water level by means of latches provided in the piers. The lower sections are then raised and similarly latched in the downstream slots. In emergency or for repairs to the operating slots, a spare gate is provided for regulating flow in the upstream slot, or to stop off the headwater as required. When this gate is in place, a small slide gate is dropped in front of the latch opening on the opposite side of the pier. Repair and storage pits are provided in two bays located in the northern approach to the dam.

The gate guides and latch-rack frames are attached to steel towers embedded in the piers. As the gates are in two sections, an upper and a lower latch frame are required to support either or both gate sections, if it is desired to do so during operation. It was a fairly easy matter to control placement of the towers which were set on bedplates and embedded anchor bolts. This placement was checked by transits and heavy weights suspended from piano wires. Control points were first established by the government survey parties at the base of each pier on welded steel frames. These points were carried up as the concrete was poured, by using 100-lb weights suspended from piano wires. Three guide beams are located in each slot to guide the gates and transfer the water-pressure loads from gate to piers. These guides are shown in Figs. 7 and 10.

The track beam consists of a heavy 10-in-width flange beam, having a finished flange, faced with a finished 1-in. × 12-in. 3.5 per cent nickel steel track plate. The plate is secured to the beam flange with $^3/_4$-in. round-head cap screws, countersunk in the plate. This track beam and plate are shown in Fig. 5. Special steel tapes, only slightly affected by temperature, were

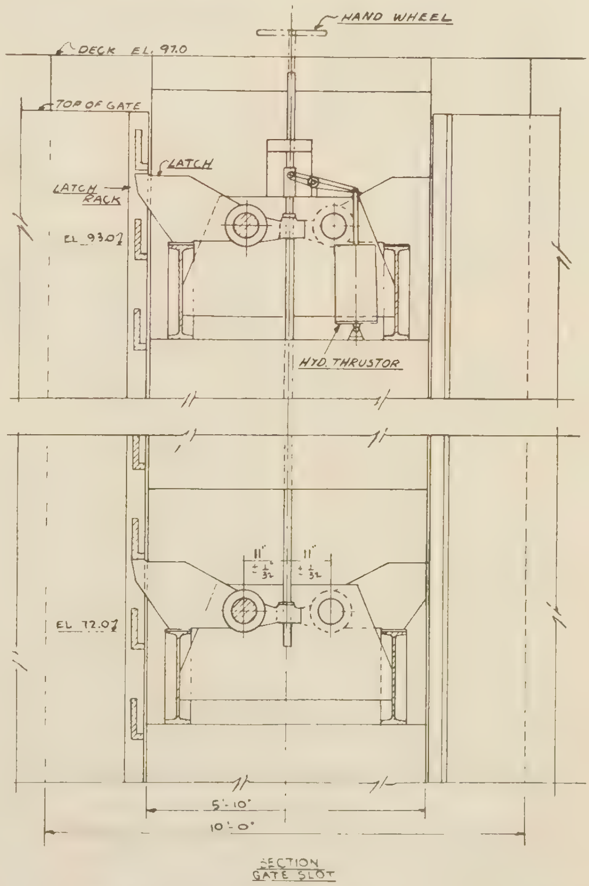

Fig. 9 Section Through Piers, Showing Gate-Latching Mechanism

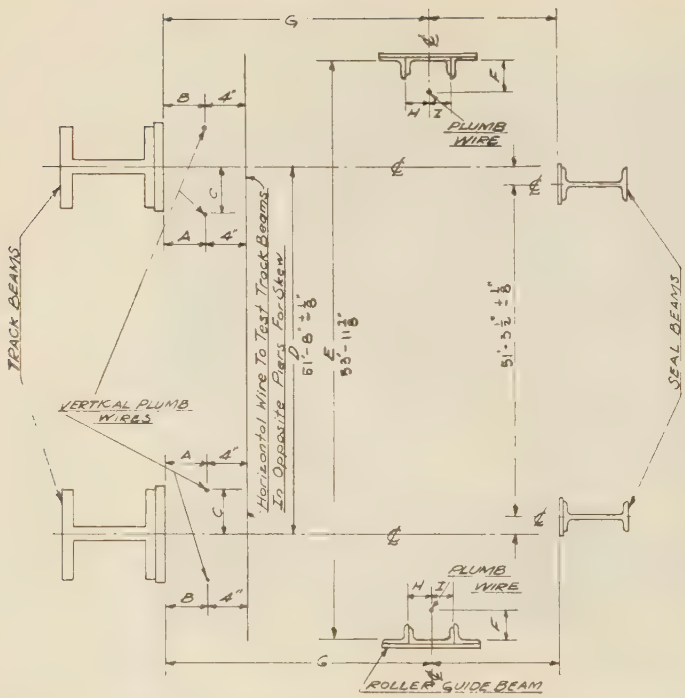

Fig. 10 Sketch of Gate Guides Showing Method of Using Piano Wires for Control of Placement

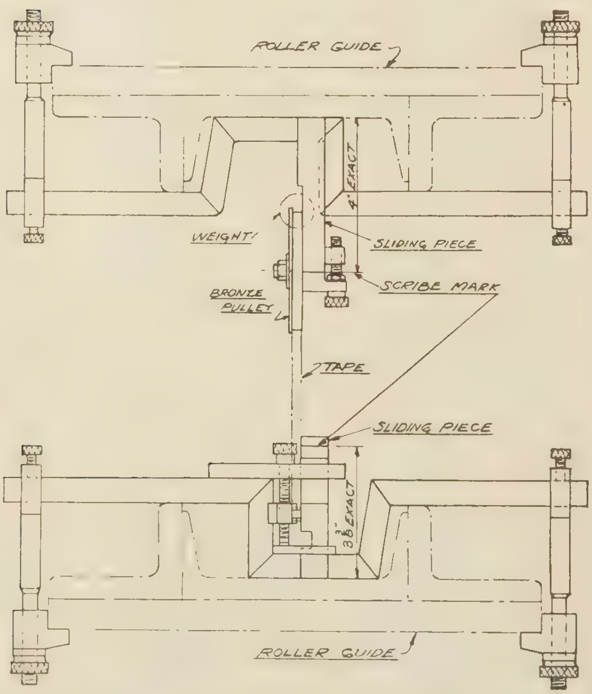

Fig. 11 Measuring Attachments for End Roller Guides

so marked as to give known measurements, when used with measuring attachments, such as those shown in Fig. 11.

These measuring attachments were used to facilitate handling the steel tape across bays on the end roller guides. The sliding pieces were brought into contact with the guides by an operator on each scaffold, then the screw was adjusted bringing the mark on the tape to the $3^3/_8$-in. mark on the lower device. The correction if any was then read on the other device as the distance between the mark on the sliding bar and the mark on the tape. A clamp was arranged to fit over the legs of the angles for the final check after grouting. The clamp was attached to the device shown.

A similar set of attachments was used on the track beams to control the distance between centers, as shown by D in Fig. 10; the tolerance is $\pm 1/8$ in. as given on the diagram. The track roller and seal beams were "boxed out" in the forms of the piers in order to leave them free to be moved and grouted in later, after completion of the piers. To locate these guides, the contractors used piano wires and tapes. Machinists then checked before grouting, and checked a second time after the grouting was completed. The track and roller and seal beams were checked by government employees who were in reality a three-man survey crew. The checking of the guides by the inspectors followed the usual procedure already outlined, except that the seal beam was checked to the track and roller guides by means of an aluminum gage.

The method of using the piano wires is outlined in Fig. 10. The tolerances in thousandths of an inch for track beams were obtained by the use of inside micrometers, measuring between guide and piano wire. Small screw jacks, welded to the backs of beams, were used for adjustments. Guides, found to be out of tolerance after embedding, were ground with portable electric grinders. Due to the severe weather conditions in the Columbia River gorge, which included sleet storms, scaffolding covered with plywood sheets was used. The enclosures were heated during January and February, enabling the contractor to make the same progress in cold weather as in warm weather.

Reasons for Close Tolerance

The design notes to be given indicate the excessive wheel concentrations on the main gate guides of the spillway dam. The author will also analyze the increase of normal concentrations, as affected by the unevenness in gate guides. It is intended to demonstrate the fact that it was imperative to follow specifications in erecting these members. It is thought that this information may be helpful to other structural-steel-erection departments in the future.

As designed, one complete 50-ft gate weighs approximately 450,000 lb, and the horizontal hydraulic pressure against it is 4,190,000 lb. One complete 60-ft gate weighs approximately 560,000 lb, and the horizontal pressure is 5,800,000 lb.

The following wheel loads are figured by elastic analysis, assuming maximum permitted inaccuracy of guide beam by the specifications, which are as follows:

> Gate Guides, Section 710 *a* of specifications: Contract No. W69eng 575, Change Order D, "* * * tolerance of inaccuracy not to exceed $1/100$ of an inch on any 5 feet of length."
>
> The specification of tolerance of inaccuracy of the line of gate wheels from a true line as given on Sheet 12 of M-4-30- is $1/1000$ of an inch per foot.

The combination of these tolerances gives a tolerance of 0.015 in. per 5 ft, or 0.003 in. per ft. Applying 0.002 in. per ft tolerance, conditions for a basis of stress analysis are obtained, Fig. 12.

Considering cases 1 and 2, in Fig. 12, the wheel points are taken as points on a deflection curve for the end girder of the gate,

computing the loads at the several points which would produce a deflection curve passing through these points. The important reactions for these cases are as follows

$$\left.\begin{array}{l}\text{For case 1—}R_a = 472{,}000 \text{ lb}\\ \text{For case 2—}R_e = 395{,}000 \text{ lb}\end{array}\right\} \text{for tolerance of 0.002 in. per ft}$$

These reactions add directly to the normal wheel loads. Case 1 reaction may be neglected because of other effects not considered in this study, tending to relieve some of the stress.

The maximum wheel load, neglecting track yield and deformation of the wheel, bearings, and local deformation of the endgate girder, would be as follows

Normal wheel load	220,000 lb
Increase due to high point on track beam	395,000 lb
Total	615,000 lb

The strain in wheel and track at point of contact is about 0.0015 in. for the normal wheel load. For twice that load, it would be about 0.002 in. The strain in bearings and in the girder around the bearing connection, not considered elsewhere in the analysis, would be approximately 0.0005 in., thus making a total relieving strain of approximately 0.0025 in., which is one half of the assumed track unevenness, Fig. 12.

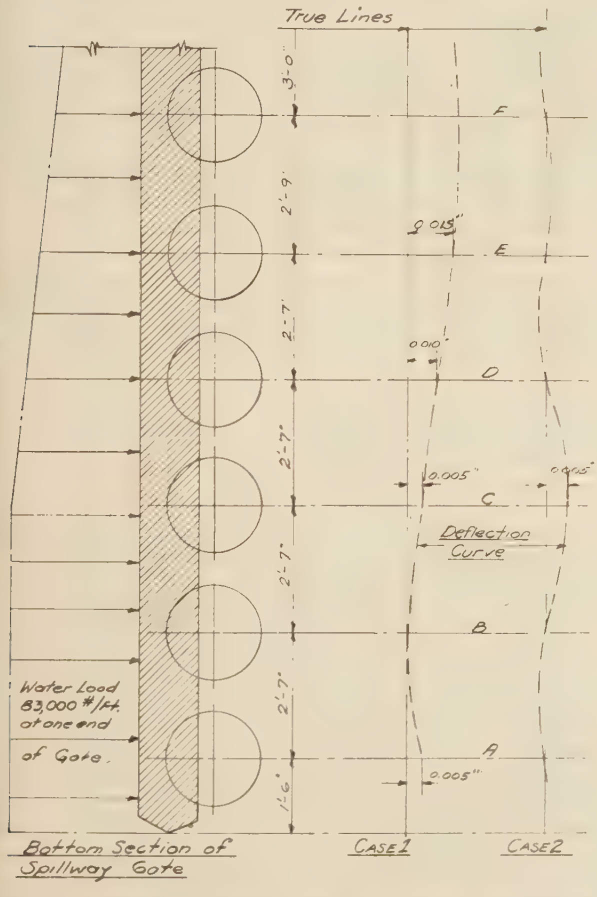

FIG. 12 STRESS ANALYSIS IN MAIN GATE GUIDE OF SPILLWAY DAM

The effect of this yielding is to reduce the increased wheel load, due to the track irregularity. Assume the yielding of adjacent loads to be 0.0005 in. (total), then the net effective yield would be 0.002 in. The resulting wheel-load reduction would be

$$\frac{0.002}{0.005}\,(395{,}000) = 160{,}000 \text{ lb}$$

The net maximum possible wheel load which could be anticipated from conditions as specified could be

$$\begin{array}{r} 615{,}000 \text{ lb}\\ -160{,}000 \text{ lb}\\ \hline 455{,}000 \text{ lb}\end{array}$$

or 207 per cent of normal wheel load. By applying the Timoshenko method of using the Hertz equations, the wheel load of 455,000 lb will produce a stress in the track plate under the wheel of approximately 175,000 psi, which is approaching the elastic limit for this type of stress.

Due to limiting the wheel diameter, the design is limited by the condition of contact stress, even if it were possible to design the wheels themselves for greater loads, which in itself would be wellnigh impossible. Therefore, it becomes necessary to obtain the degree of accuracy, required by the specifications, to insure safe operation of the gates.

To prove the sufficiency of the design of the wheel, bearings, and supports, two full-size experimental wheel assemblies, complete with SKF No. 22336, having two rows of fourteen rollers each, shaft diameter 7.0866 in., outer-race diameter 14.9606 in., rollers 1.772 in. long × 2.165 in. diam, and rated capacity in equivalent radial load 425,000 lb, were tested on a 600,000-lb Southwark-Emery testing machine at Oregon State College.

A special base was provided for the assembly which was to occupy the lower position in the testing machine. Between this base and the assembly was a set of flat springs, also a subject of these tests. The upper assembly, carried by the movable head of the testing machine, was provided with an auxiliary cast-steel block attached without springs.

A section of track plate 12 in. wide, 1 in. thick, and 5 ft long reciprocated under load between the adjacent wheel faces at a speed of 2 fpm. It was the purpose in these tests to simulate as nearly as possible actual conditions of use, except that it was not practicable to arrange for side thrust; instead, equivalent radial loads were computed and applied.

Under section IV in paragraph 416 of the specifications for gate wheels, it was required: "The normal static radial capacity per bearing shall be 210,000 pounds combined with a thrust load of 50,000 pounds and, under a load 75 per cent in excess of this load, the bearings should show no signs of permanent deformation either measurable or microscopically visible." The equivalent radial load for the proposed bearing satisfying this specification is 425,000 lb.

A flat-plate spring with machined loading pads, as well as two types which could be drop-forged or hot-pressed, were tested. Type 1 was a flat-plate spring with machined loading pads. Type 2 was a flat spring with forged loading pads. Type 3 was the corrugated plate spring, shown in Fig. 6. Bakelite models were made of these three types for photoelastic study.

Type 1 showed high stress concentration adjacent to the machined loading pads. Types 2 and 3 proved to be better designed with less stress concentration. They avoid the danger of hardening cracks, due to abrupt changes in section. Type 3 was chosen because of its being slightly more elastic, giving a greater deflection for the same load.

SPECIFICATIONS COVERING ERECTION OF GATE GUIDES AND SEAL BEAMS

Lower sections of towers, gate and roller guides, and seal beams to be set on anchor bolts, truly plumbed, braced and guyed

firmly and held rigidly. Dependence must not be made on anchor bolts or connections to sole plates to resist overturning. Sections to be shimmed and welded or riveted or bolted, as detailed. Plumbing to be observed and to be corrected when necessary.

Gate-guide-beam and seal-beam sections to be plumbed by means of the shims, and welding for guide beams to be performed at the thrust frames just in advance of the pouring of concrete. After each pour, the contracting officer to check plumbness in both directions, and necessary corrections to be made.

Face of gate guides shall not be covered with forms during concreting operations. Tolerance of inaccuracy, shown in Fig. 10, of face of guides shall be maintained during concreting operations without vibration, and access provided for measurement by the contracting officer of this face in two directions. Structural-steel connecting members, composing tower structure, shall be so stayed as to prevent movement of guide members during this period. Face of guide flanges to be milled to a plane surface having a variation not to exceed 0.01 in. in 5 ft of length. This same degree of accuracy to apply when erected. Particular care shall be given to the alignment of gate guides in plane of axis of dam. This alignment shall be based on a true plane surface passing through the milled surfaces of the gate-guide track plates, which in turn shall be parallel to the vertical longitudinal axis of the dam. The method of erection to achieve this result will be submitted to the contracting officer and his approval secured before erection shall be undertaken.

Gate and roller guides and seal beams when erected shall conform with the diagram of tolerances, as given. Axes must be truly at angles of 90 deg, and acceptance or rejection of this work by the contracting officer will be based on obtaining results in accordance with these requirements.

Note: For outside and center girders all construction loads shall be hung at panel points only.

The latch frames must be set to the exact position shown on the plans. The center lines of the pinholes must be in the same horizontal planes. The tops of the 24-in. I-beams must be in the same horizontal planes. The frames must be supported and fastened sufficiently as to prevent displacement during placing of concrete.

Gate-Guide Tolerances. As finally determined the gate-guide tolerances are as shown in Fig. 10, and are as follows:

A tolerance of $\pm 1/8$ in. was allowed across bays between seal beams and also track beams. The end roller guides were held to an exact dimension on print M-4-29, sheet 2, the pertinent data of which are shown in Fig. 10. A variation of $+1/8$ in. was allowed on end roller guides, in the field, but no minus tolerance. The following vertical tolerances were specified for track beams:

From elevation 24 to 56, a tolerance of 0.010 in. in 5 ft of height; from elevation 56 to 72, a tolerance of 0.015 in. in 5 ft of height; and from elevation 72 to top, a tolerance of 0.030 in. was allowed by letter instructions. By M-4-29, sheet 2, seal beams in any 60 ft of height were required to be within a tolerance of $1/4$ in. away from gate, of $1/8$ in. toward gate, and, in any 5 ft of height, not over $1/16$ in. The face sides of seal beams were required to have a mill tolerance of $1/16$ in. This meant that the plane of the flange of the seal beam in its width could not be more than $1/16$ in. out of parallel with the axis of the dam. On the south half of the dam, where crests were poured in two steps for elevations below 21, a tolerance of 0.020 in. in 5 ft of height was allowed. In storage pits, the end roller guides had the following tolerances: "They must not have sweep over $1/8$ in. in 16 ft, straight to tolerance of $1/16$ in. to 5 ft, with camber not more than $3/16$ in. for individual pieces," as specified on sheet 41 of M-4-29.

Latch-Frame Tolerances. The embedded latch frames to support the latch dogs and mechanism, as shown in Figs. 8 and 9, were first designed to be held to an exact dimension. This was found to be too exacting before embedding and impossible to hold while the piers were being poured. Therefore, as in the case of the track beams, a method was devised whereby adjustments might be made after the main part of the steel was embedded. Rivets on part of the steel frame were cut loose and bolted later after the "boxing out" and grouting operation, as in the case of the gate guides. A tolerance of $\pm 1/8$ across bays was allowed between latch pins, and a tolerance of $\pm 1/4$ from the axis of the dam to the latch frame. Due to the clearance of the latch and rack, the $\pm 1/8$ tolerance could have been $\pm 1/4$ in. An elevation tolerance of $\pm 1/8$ in. was also allowed.

Steel tubing of the size of the latch shaft was placed in the holes provided. These holes were bored to a close tolerance, which facilitated the method used to obtain close erection measurements. A piano wire was drawn through a small hole, drilled through the exact center of the tube. The wire was strung across bays, allowing a measurement to be taken to the track beam. This method of control was followed on the gate erection in that measurements were taken from the face of the rollers to the center line of the latch racks on the ends of the gates. The distance from the face of the end roller guide to the latch shaft gave a control or check on the distance between shafts across the bays, as the roller guides were held to a tolerance of $+1/8$ in. across bays.

Roadway-Girder Tolerances. The spillway-dam main truss girders, designed to support the gantry cranes and the roadway which is 30 ft wide, were held to the following:

Steel was required to be free from kinks, bends, and winds, which produce excessive stresses. The tolerance was 1 in 1000, which amounted to 0.6 in. End posts were required to be plumb before grouting; base plates and girder shoes and sole plates were machined for bearing fit. The over-all length tolerance was $\pm 1/4$ in.

There were two side trusses and one center steel truss, embedded in concrete. Concrete deck panels were placed across these to make the roadway.

Fishways

As previously mentioned, two fish lifts are provided at each end of the spillway dam and two at the powerhouse. As the name implies, these are merely elevators. A gate is closed when the chamber is filled with fish, and a platform is raised by means of hoists. The water in the chambers is controlled through exit and entrance passage leading to the bottom of the lifts by the use of radial gates. Four fish ladders are provided, namely, one on each end of the dam, one from in front of the powerhouse, connecting with the one from the south end of the dam, and the last starting from Tanner Creek below the site. This last fishway passes behind the white houses, shown in Fig. 1, then up through the south side of the ship-lock cut. The ladders are simply a series of pools regulated with weirs made of stop logs on top of a concrete wall. The lower pools are referred to here as diffusion chambers. They are provided with additional water, regulated by radial gates and sluice gates coming into the bottom of the pools through a grid of concrete and wood.

The fish-ladder and fish-lock steel caused considerable trouble principally because it was embedded at the time of the pour and not boxed out and grouted later. Where a steel frame for support could be welded across the gate openings, the guides were held to close tolerances but this could not be done in the larger openings of the elevators. These guides were out of plumb as much as $5/8$ in. and the concrete 2 in. in 70 ft, due to the poor placing of forms. The fishway-steel tolerances in general were as follows:

Diffusion-Chamber Gates. These are rectangular, similar to a number of sluice gates on the market. The sealing surface between the gate and the frame was held to a total leakage-orifice area of not more than $^1/_2$ sq in. and an orifice not wider than $^1/_{64}$ in.

Weir Stop Logs and Gate Guides. Maximum crack between log and concrete $^1/_4$ in. Minimum horizontal end play in guides $^1/_4$ in. Minimum side play in guides $^1/_4$ in. Minimum clearance between bottom of latching pin and top of notched end of timber log $^1/_4$ in.

A tolerance of $\pm^1/_4$ in. was specified for the length and width of openings for steel guides for the stop logs: Emergency, regulating, and segmental gates for all fishway gates, including fish-lock stop logs. Fish-lock roller-guide openings had a tolerance of $\pm^1/_2$ in., and segmental gates $\pm^1/_8$ in. A tolerance of not under 90 deg was required for corner end plates for the last two gates mentioned. A tolerance of $^1/_8$ in. at the outside end of these plates over 90 deg was allowed. All guides, except those for fish-lock entrance and exit gates were required to be held to not more than $^3/_8$ in. out of plumb for the entire vertical height, or more than $^1/_8$ in. out of plumb for any 10 ft of height. Fish-lock exit- and entrance-gate guides were required to be not more than $^1/_8$ in. out of plumb for the entire vertical height, or $^1/_{16}$ in. out of plumb for any 5 ft of height. Tolerances for horizontal dimensions were as discussed and were taken from T-3-117 sheets 1 and 2.

Tainter Valve (Radial Gate). Finished seals were specified to have an opening tolerance of $\pm^1/_{32}$ in. top to bottom and $+^1/_{32}$ in. from side to center line of the valve on the sides. The embedded-steel tolerance was generally $+^3/_{16}$ in. The bottom finished seal was required to be level. The top finished seal was required to be plumb and not more than $^3/_{16}$ in. from parallel for the entire width to the center line of the trunnion pin. It was difficult to hold these dimensions, and the finished seals were placed to valve after installation.

Conclusions

1 Where close tolerances on embedded structural steel are required, the best method to employ is that of the so-called "grouting system." This method requires setting the steel after the main body of concrete has been poured. Recesses are made by using box forms with reinforcing bars or ties for the structural steel left exposed. After all forms have been stripped, the structural steel can then be placed, lined up by means of piano wires and other devices, and cement grout placed around it.

2 The construction survey party makes the ideal structural-steel inspection crew for large installations, requiring close measurements, provided the individual members have had some college or engineering training in construction plans and specifications. These men have less difficulty in adapting themselves to making measurements with the special attachments provided than is the case with machinists who ordinarily are not accustomed to working in the field on construction projects. Of course, the regular structural-steel inspector is of value on riveting and welding work.

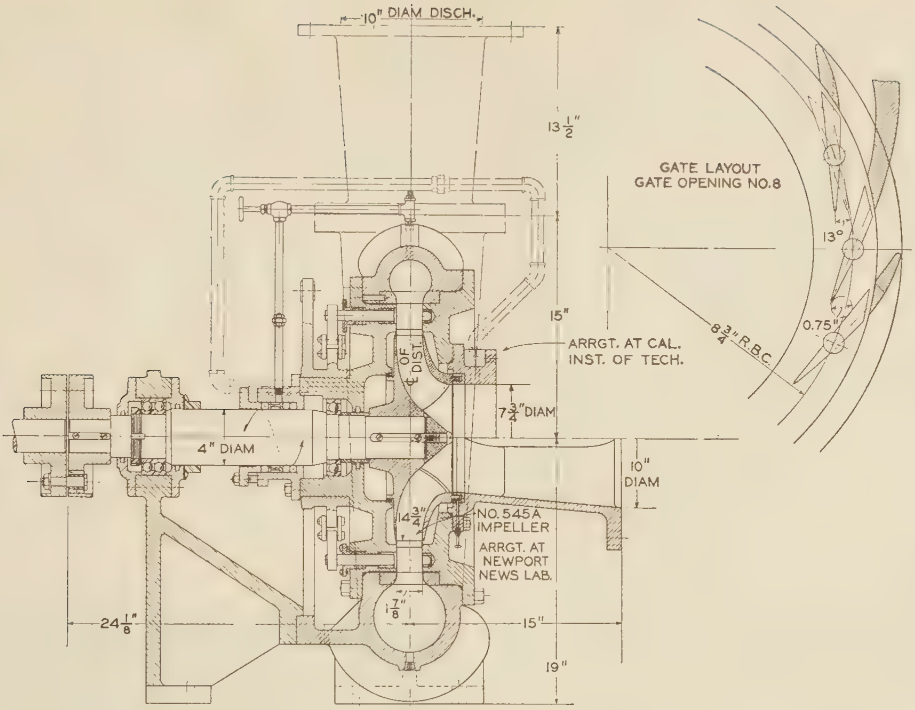

Fig. 1 Sectional Elevation of Pump-Turbine Model

Test Characteristics of a Combined Pump-Turbine Model With Wicket Gates

By R. V. TERRY[1] and F. E. JASKI,[2] NEWPORT NEWS, VA.

Tests of a wicket-gate pump-turbine model at the Newport News hydraulic laboratory and at the California Institute of Technology are described in this paper. The model was one of a series used in a study of pumps suitable for Grand Coulee. Characteristic curves both as a pump and turbine are illustrated, and expected-performance curves for a prototype stepped up to Grand Coulee conditions are developed from the tests. In conclusion, a summary is given of the advantages of the wicket-gate pump-turbine.

DURING recent years considerable study and experimental work have been devoted to the development of combination hydraulic machines with wicket gates which would be suitable for operation either as centrifugal pumps or as hydraulic turbines for peak-load storage development. Certain test characteristics of such a combination machine, and characteristics of wicket-gate pumps have been given in many articles in the technical press (1 to 9).[3]

TABLE 1 MAIN PARTICULARS OF WICKET-GATE PUMP-TURBINE MODEL

Impeller, diameter, in.	14.75 (progressively cut to 12 in.)
Eye diameter, in.	7.75
Number of vanes	8
Entrance angle at band, deg.	20
Entrance angle at hub, deg.	34
Discharge angle, deg.	30
Discharge height, in.	1.875
Number of wicket gates	16
Diameter of gate circle, in.	17.5
Outside diameter of speed-ring vanes, in.	21
Diameter of suction pipe, in.	10 (7⅝ in. diam at California Tech.)
Throat diameter of casing, in.	6⅞ in. (flaring to 10 in. discharge diam; flaring to 8 in. diam at California Tech.)
Offset of casing throat to center line, in.	13.5
Designed gate opening, in.	0.75 (gate 8)
Maximum gate opening, in.	0.95 (gate 10)

However, it does not appear that the complete test characteristics of any one combination machine have been presented to this Society or published elsewhere.

The model described by the authors was one of a series of machines tested at the Newport News hydraulic laboratory in connection with the development of combination machines. It

[3] Numbers in parentheses refer to the Bibliography at the end of the paper.

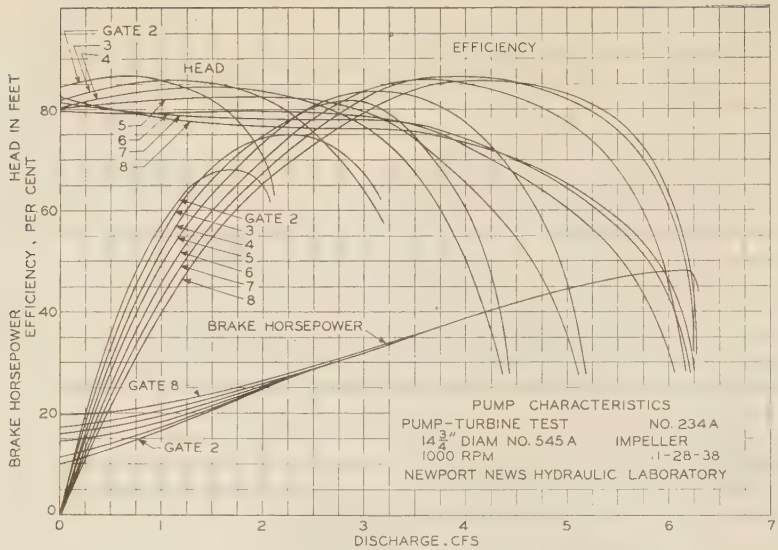

Fig. 2 Pump Characteristics, Newport News Test

was a single-suction machine of a somewhat low-specific-speed type, its specific speed as a pump at best efficiency being about 1750 by the usual formula $N_s = \dfrac{N\sqrt{\text{gpm}}}{H^{3/4}}$ and its specific speed as a turbine at best speed and at 95 per cent of its full-gate power being about 25.

The model was designed to be used in a study of pumps of various types, including volute and double-volute types, which would be suitable for the proposed conditions at the Grand Coulee pumping plant. It is expected that the Grand Coulee pumps will operate under the following range of conditions and at a speed of not less than 150 rpm:

Dynamic head, ft	Discharge, cfs	Inlet head, ft
295 (rated)	1600	+80
367 (maximum)	1000 (approx.)	+ 5

Some of the characteristics of pump models with volute, double-volute, and with fixed diffuser vanes are given in a paper by R. T. Knapp (12).

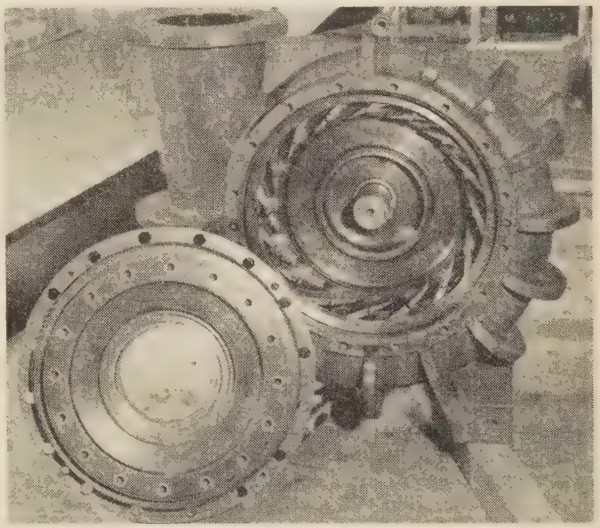

Fig. 3 Casing With Impeller Removed

Description of Model

The model was of the horizontal single-suction type, as shown in Fig. 1. The principal particulars of the model are given in Table 1.

The wicket gates were in line with the fixed stay vanes or speed-ring vanes at 0.75 in. gate opening. At that opening, the angle of the center line of the gate tips was 9 deg with the tangent.

The impeller diameter of 14.75 in. selected was intermediate between that for a normal design of turbine and for a normal design of volute pump. The diameter was about 22 per cent larger than required for a normal turbine and about 5 per cent smaller than for a volute pump. The eye design was dictated by the pump requirements for high efficiency and was somewhat smaller than for a normal turbine.

Throughout the design, its functions as a pump were favored because of the somewhat critical conditions imposed by deceleration in the water passages, as opposed to acceleration in a turbine which is not as critical. Many previous studies by the author and others had shown that the usual proportions of pumps would result in fairly satisfactory turbine performance but that the usual proportions of turbines would not make satisfactory pumps.

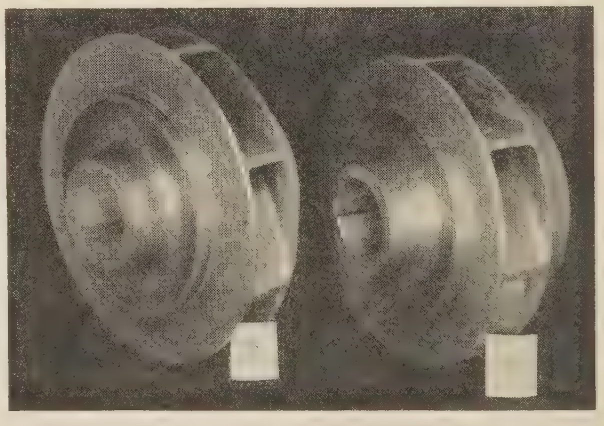

Fig. 4 Impellers (*A*) and (*B*)

Two impellers were built to the same design and are designated in the paper as impellers (A) and (B). The second impeller was necessary in order to make tests under different combinations of proportions, as will be described.

Tests at Newport News

The model was first tested at the Newport News hydraulic laboratory, the following tests being made:

Test no.	Impeller, in.	Type test	Speed, rpm	Head
1	14.75 (A)	Pump	1000	Variable
2	14.75 (B)	Pump	1000	Variable
3	14.00 (B)	Pump	1000	Variable
4	14.75 (A)	Turbine	450 to 1000	Abt. 45 ft

No cavitation tests were made at Newport News on these particular impellers.

Fig. 2 shows the complete pump characteristics for test No. 1 with 14.75-in. impeller (A). The results with impeller (B) were practically identical, except that the discharges were a little higher, the impeller measurements showing about 4 per cent larger suction vent openings than impeller (A). Fig. 3 shows the casing without impellers, and Fig. 4 the impellers.

In the Newport News tests a 65-hp, d-c electric dynamometer was used to measure the torque. A revolution counter, engaged and disengaged by a program machine and a master clock, was used to obtain the speed. The water was measured by a battery of 10-in. and 6-in. Venturi meters, calibrated volumetrically in place in both directions of flow. The inlet and discharge heads were measured by mercury manometers.

The Newport News hydraulic laboratory has been described in a paper previously presented to the Society (13). Tests made in this laboratory are accurate to within about 0.5 per cent.

Tests at California Institute of Technology

By arrangement with the Bureau of Reclamation, the complete model with impellers (A) and (B) was rather extensively tested at the California Institute of Technology. The measurement and control of speed, torque, head, and discharge was made in accordance with the regular practice of that laboratory (14). The pump tests were made principally at 2000 rpm, twice the speed and four times the head for the Newport News tests, corresponding with approximately the full-field-head conditions for the specific speed of the model. The turbine tests were made at constant speeds, principally at 1500 and 1800 rpm, the latter being the practical limit of the laboratory equipment for testing a turbine model of this size. Variation of unit speed was accomplished by variation of head. Turbine-discharge and pump-suction pressures were taken from a single orifice connection at a distance of 1 diam from the model. Turbine-inlet and pump-discharge pressures were taken with a single orifice connection about 6.75 ft from the model. A computed allowance was made for pipe friction.

The gate mechanism was calibrated at ten gate-opening positions, as follows:

Gate position no.	Gate opening, average, in.
1	0.092
2	0.181
3	0.275
4	0.370
5	0.465
6	0.560
7	0.655
8	0.750
9	0.850
10	0.950

Sixty test runs were made and plotted, fifteen as a turbine and forty-five as a pump. Nineteen of the pump runs were made for cavitation studies. It was not possible to test the model for cavitation as a turbine, because of its specific speed, but this was not necessary, since it is well known that, for a combination machine, the cavitation conditions when operating as a pump are critical and controlling. All of the turbine tests were made with impeller (A); while 37 of the pump runs were made with impeller (A) and 7 with impeller (B).

The regular tests for pump characteristics were run with a positive inlet head of 80 ft, measured from the center line of the model.

The diameter of the impeller (A) was progressively cut from $14^3/_4$ to 14, 13.5, 13, 12.5, and 12 in. In some cases, only the tips of the vanes were cut, leaving the shrouds extended, while in others the shrouds were cut back with the vanes. Impeller (B) was first tested at 14 in. diam, and progressively cut to 13.5 and 13 in., vanes and shrouds being cut at the same time.

For operation under 2000 rpm, it was found that the design of the bearings and seals was not adequate. Some trouble was experienced with heating and failure of bearings. The impeller seals were rather narrow axially and the average clearance on diam of 0.019 in. was exceptionally large for this size of model. Leakage past the crown seal ring was measured frequently and found to be 0.075 cfs at 295 ft head, corresponding to a leakage loss of about 2 per cent of the rated discharge for the two seals. This loss could readily be reduced to 1 per cent with a better seal design. However, the test results given in this paper are for the seals as tested, no allowance being made for the excess leakage in either the Newport News or California tests.

Figs. 5 and 6 show the model as installed in the laboratory of the California Institute of Technology.

Results of California Tests

Fig. 7 shows the complete characteristics of the model as a pump with 14.75-in. (designed diameter) impeller (A), and Fig. 8 shows its corresponding characteristics as a turbine.

The following will be noted from the pump characteristics, Fig. 7: (a) The curves at each gate opening above gate No. 3 show a discontinuity at about 4.8 cfs similar to that reported by Gongwer and Knapp (11, 12). Discontinuity at the same speed and discharge was also found from tests at the reduced impeller diameters. The discontinuity point occurred at a slightly higher discharge with impeller (B), corresponding with its increased vent openings previously mentioned. (b) At each gate position, the head at zero discharge is slightly lower than at an intermediate discharge; but, for the enveloping head curve, the highest head occurs at zero discharge. (c) Above a discharge of about 7 cfs, the power input at a given discharge is constant over a wide range of gate opening and head. (d) The shutoff power, required to drive the pump up to speed with the gates closed or nearly closed, is a small fraction of the shutoff power at the most efficient opening (gate No. 7), and is equal to about 16 per cent of the maximum power. (e) The best unit speed as a pump for the best gate openings is as follows:

Gate	Best N_1
6	$2000 \div \sqrt{307} = 114.0$
7	$2000 \div \sqrt{295} = 116.5$ (maximum efficiency)
8	$2000 \div \sqrt{285} = 118.5$

From Fig. 8, the following will be noted: (a) The full gate as a turbine is larger than the full gate as a pump, gate No. 10 versus gate No. 8. (b) The unit power P_1 and unit discharge Q_1 reduce rather rapidly as the unit speed is increased. This corresponds with the usual characteristics of low-specific-speed turbines and is

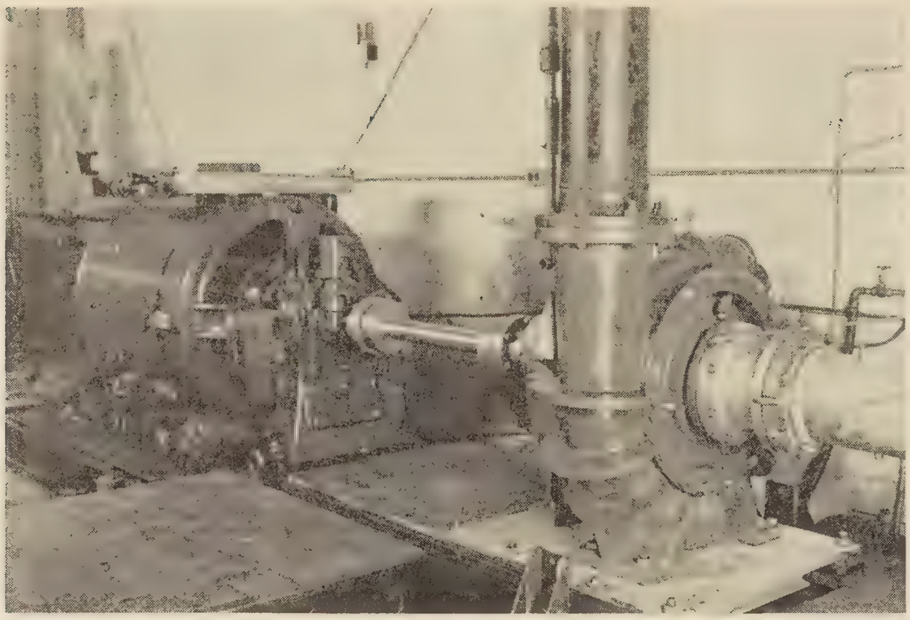

Fig. 5 Pump Setup for Test at California Institute of Technology Laboratory

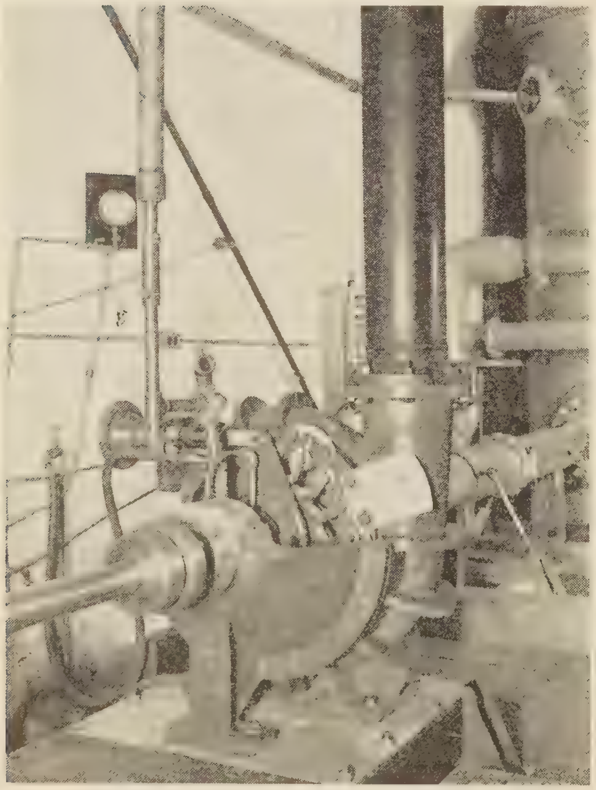

Fig. 6 View of Operating Side of Pump at California Institute of Technology Laboratory

attributable to the bucking effect on the head created by centrifugal force at the higher speed. In the case of the combination machine, since the impeller diameter is considerably larger than for the usual turbine, the centrifugal effect is more pronounced. (*c*) The best unit speed N_1 as a turbine is about 105. Since this is lower than the best unit speed as a pump, the use of a combination machine at constant speed and head would involve some sacrifice in efficiency. However, in a case like that at Grand Coulee where most of the pumped water would be used for irrigation, the unit would be operated as a turbine only at the higher heads which would reduce the unit speed as a turbine to a high efficiency value.

The several cavitation tests made as a pump brought out the following facts:

1 For a given discharge and speed, the limiting and critical inlet heads are the same for different gate openings, and are also the same for the different impeller diameters. This shows that the conditions surrounding the periphery of the impeller have no effect on the cavitation characteristics, which are determined solely by the proportions of the eye and suction edge of the vanes. This was found to be true over the entire cavitation-test range from 3 to 8.5 cfs at 2000 rpm, rather complete tests being made at 3.0, 6.0, and 8.5 cfs.

2 The efficiency as either a pump or turbine was not affected until the runner was cut to below 13 in. diam.

3 Cutting the discharge tips of the impeller vanes, while leaving the shrouds extended, lowered the efficiency both as a turbine and as a pump. However, the extended shrouds had an effect in increasing the head as a pump as would be expected. The head at 13 in. diam, with shrouds at 14.75 in. diam, was about 2 per cent greater than with the shrouds cut back to 13 in.

The cavitation characteristics of impellers (A) and (B) were at first found to be somewhat different. The inlet edges of the (A) impeller were found to be somewhat more irregular and more blunt than in impeller (B). After this was corrected, the results agreed very closely with those of impeller (B).

Comparison of Newport News and California Tests

In Fig. 9, the envelopes of the head and efficiency curves for the California tests at various gate openings at 2000 rpm, are reproduced from Fig. 7. The corresponding curves, stepped up from the Newport News tests of Fig. 2, are also shown. There is a slight increase in efficiency for the California tests under the higher head.

The break in the head curve in the California test occurs at a smaller discharge than in the Newport News test. This was

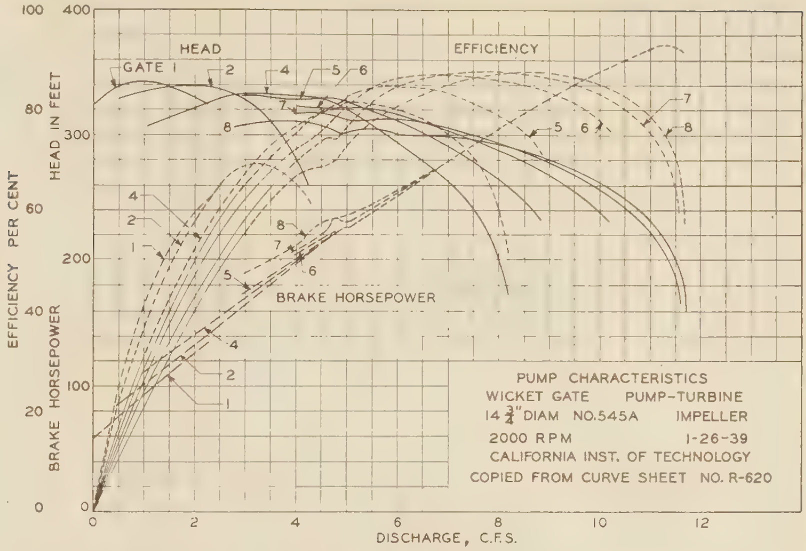

Fig. 7 Pump Characteristics, California Tests

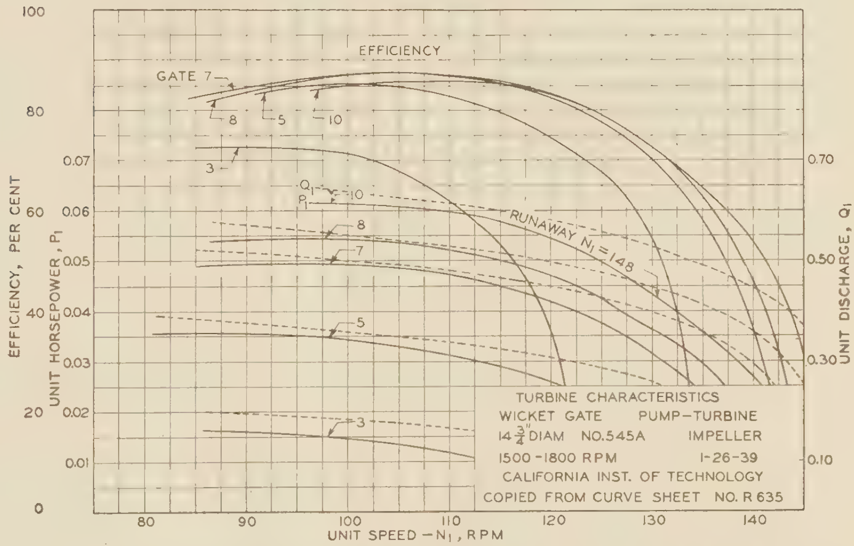

Fig. 8 Turbine Characteristics, California Tests

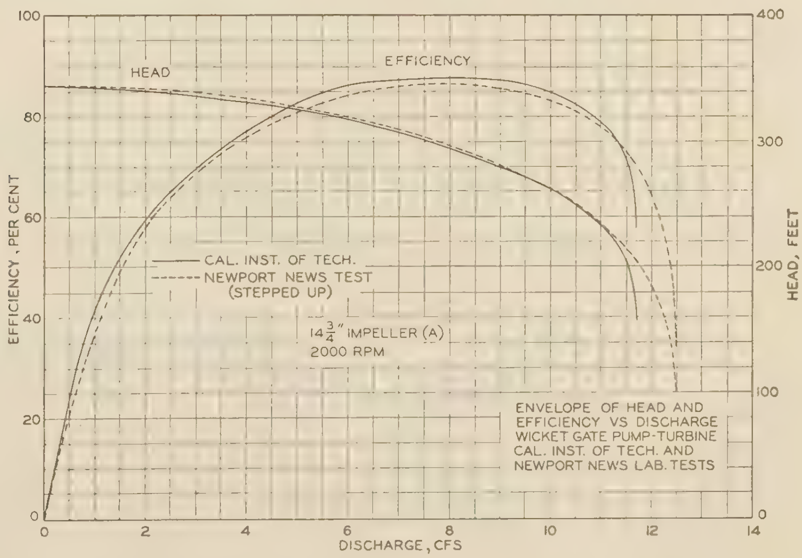

Fig. 9 Comparison of California and Newport News Pump-Test Curves

apparently due to the size of the suction pipe ($7^5/_8$ in. diam) used in the California tests. The entrance loss and friction loss in this pipe were the controlling factors which determined the cutoff point in the California test.

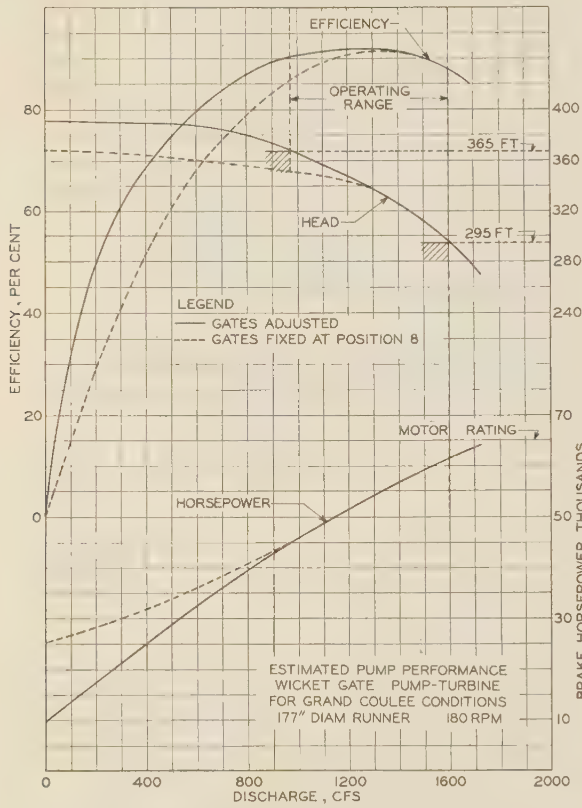

Fig. 11 Expected-Performance Curves for Prototype, Under Grand Coulee Conditions, as a Pump

Comparison of Speed Characteristics, Pump Versus Turbine Operation

Fig. 10 shows curves of efficiency versus unit speed, for turbine and pump operation, deduced from the tests at the California Institute of Technology. It will be noted that the best unit speed for pump operation is 11 per cent higher than for turbine operation. Thus, if the unit were operated as a turbine at a speed corresponding to an N_1 of 105, which is the best N_1 for turbine operation, it would have to run at 11 per cent higher speed when operated as a pump to obtain optimum performance under the same head.

Fig. 10 also shows the corresponding model unit speeds for a unit suitable for the proposed Grand Coulee pumping-plant conditions with a 14.75-ft-diam runner, operating at a constant speed

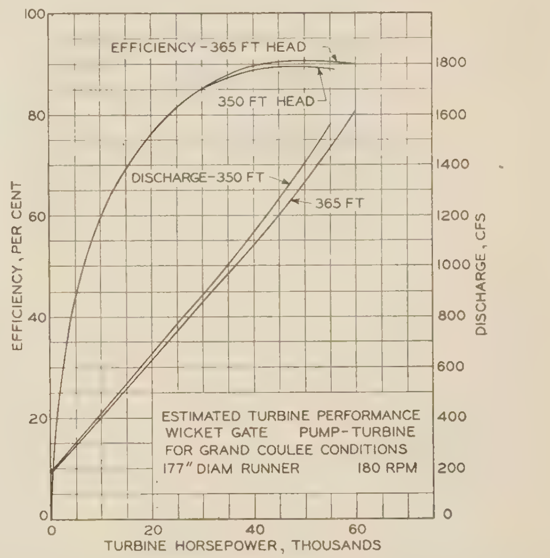

Fig. 12 Expected-Performance Curves for Prototype, Under Grand Coulee Conditions, as a Turbine

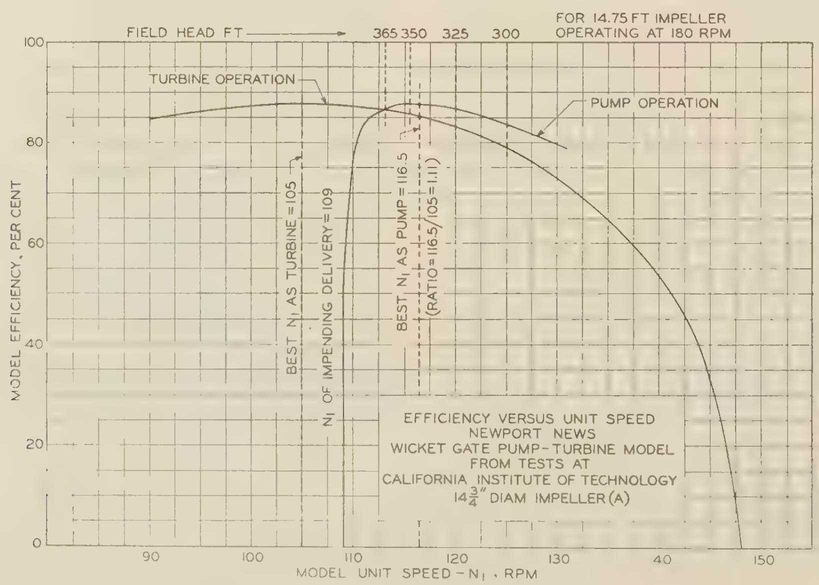

Fig. 10 Efficiency Versus N_1 for Turbine and Pump Operation

of 180 rpm under heads varying from 300 to 365 ft. If the unit were to be operated at the same speed of 180 rpm both as a turbine and as a pump, there would only be a small sacrifice in efficiency as a turbine over the range of heads from 350 to 365 ft, which would be the approximate head range prevailing when it is desired to generate power.

Estimated Performance of Unit for Grand Coulee Conditions

Fig. 11 shows the estimated pump-performance curves for Grand Coulee conditions deduced from the model tests at the California Institute of Technology. The head curve with adjustable wicket gates is much steeper than with gates fixed at best gate position. The brake-horsepower input to the pump is much lower for the adjusted gates at the lower discharges, and the horsepower at shutoff is less than one half of that required with fixed guide vanes. The gain in efficiency over the lower discharges is as much as 20 per cent with adjusted gates. Over the operating range, the gain in efficiency is mainly due to the higher head obtained with adjustable gates.

Fig. 12 shows the corresponding estimated turbine-performance curves for Grand Coulee conditions, deduced from the California tests. Over the range of heads from 350 to 365 ft, an output of 55,000 to 60,000 hp would be obtained when operating the unit as a turbine.

Advantages of Wicket-Gate-Type Pump-Turbine

The advantages of wicket gates for turbine operation are well known and will not be discussed. Some of the advantages for pumps are as follows:

1 Smaller shutoff power required to bring pump up to speed.

2 Flatter efficiency-discharge curves, resulting in higher efficiency over a wide range of discharge.

3 Steeper head curves, resulting in smaller variations in discharge with head changes.

4 More discharge overload capacity at lower heads, unless affected by cavitation.

5 Wicket gates take the place of a shutoff valve, and their use also forms an excellent means of controlling the discharge at constant speed and head.

6 Smaller impeller diameter, about 95 per cent of the diameter of a volute pump.

7 The use of stay vanes in the casing opposite the wicket gates gives a satisfactory casing construction without excessive deflection.

Discussion

R. W. Angus.[4] This paper presents valuable data on an interesting hydraulic machine. Pumped storage plants have been extensively used in Europe, where there are over fifty in operation, while a few have been installed in the United States and in South America,[5] a list being given by F. A. Annett. In a number of those visited by the writer, the turbine, pump, and electrical machine were installed as a unit, while in other plants the pumps and turbines have separate electrical machines.

Frequently, the electrical machine is placed in the center with the pump on one side of it and the turbine on the other; while the turbine is left permanently coupled, a clutch must be used on the pump so that the latter may remain stationary when the turbine is generating power. A unit so built is expensive and requires special gates for the draft tubes in order that the air in the turbines may be rarified when the pumps are running. Thus, the advantage of the dual-purpose hydraulic unit is obvious.

There are some features of the paper on which the writer would comment. The curves, Figs. 7, 8, and 9, are drawn to a somewhat small scale and in reading them the writer may have fallen into certain errors. From the turbine characteristics, for gate No. 8, given in Fig. 8, we find that the quantities corresponding to unit speed $N_1 = 118.5$ rpm are as follows: Unit discharge Q_1 = slightly in excess of 0.50 cfs; unit power $P_1 = 0.048$ hp, and efficiency 84.5 per cent. Calculating from these, the results at a head of 285 ft are: $N = 2000$ rpm, $Q = 8.50$ cfs, $P = 231$ hp. Presumably the efficiency would be unchanged, since the pump and turbine tests were made at nearly the same speed. Actually, however, the turbine speed was the lower, which should probably give an efficiency below 84.5 per cent at the speed of 2000 rpm.

Referring to Fig. 7, for the pump characteristics, it is seen that at $Q = 8.50$ cfs, an efficiency of 88 per cent is obtained, the head being 285 ft, and the power required being 315 hp, corresponding to the foregoing data. This agrees quite closely with the 231 hp from the turbine, if the efficiencies of 84.5 per cent and 88 per cent are allowed for. Thus, it appears that, for this unit speed at least, the machine has the same discharge of 8.5 cfs under a 285-ft head at 2000 rpm, whether running as a turbine or as a pump.

In order to examine this condition, let E_T and E_P represent the efficiencies of the turbine and pump, respectively, while M_T and M_P represent their corresponding mechanical efficiencies, and E_{HT} and E_{HP} their hydraulic efficiencies. Further, let L_T and L_P represent the losses in feet in the turbine and in the pump, respectively, when working under head H, then obviously

$$E_T = M_T \frac{H - L_T}{H} \quad \text{and} \quad E_P = M_P \frac{H}{H + L_P}$$

But, since the machine is assumed running at the speed of 2000 rpm in each case, it would be fair to take $M_T = M_P = M$. In the

[4] Professor of Mechanical Engineering, University of Toronto, Toronto, Ontario, Canada. Hon. Mem. A.S.M.E.

[5] For a list of plants, refer to "Experience Story of the Safe Harbor Plant, Part 1," by F. A. Annett, *Power*, vol. 78, 1934, p. 338.

case being examined $E_T = 0.845$, $H = 285$ ft, and $E_P = 0.88$. Substituting these values in the foregoing equations

$$0.845 = M\frac{285 - L_T}{285} \quad \text{and} \quad 0.880 = M\frac{285}{285 + L_P}$$

or

$$L_T = 285 - \frac{240.82}{M} \quad \text{and} \quad L_P = 323.90\,M - 285$$

The following table may then be constructed:

M	1	0.98	0.96	0.94	0.92	0.90	0.88
L_T ft	44.2	39.3	34.2	28.8	23.2	17.4	11.4
L_P ft	38.9	32.4	25.9	19.4	12.9	6.5	0
$(L_T - L_P)$ ft	5.3	6.9	8.3	9.4	10.3	10.9	11.4

Evidently M exceeds 88 per cent and in all probability is over 90 per cent. The difference $(L_T - L_P)$ must be due to shock, since the water velocities are the same in both cases; it would appear that the shock losses should also be similar in the two cases. It would tend to confirm the generally accepted view that the water passages in the impeller are not completely filled, so that the distributor setting for maximum efficiency must be changed when the flow is reversed.

At this same unit speed of $N_1 = 118.5$, with $Q = 8.5$ cfs, the velocity in the $7^3/_4$-in. suction pipe is 25.9 fps, with a corresponding velocity head of 10.4 ft, which is high for such a unit. However, the writer checked out the conditions at the rim of the impeller and, taking the distributor-guide angle of 9 deg stated in the paper and the impeller discharge angle as 30 deg also as given in the paper, found that these corresponded to best efficiency, assuming that the metal in the impeller vanes occupies 11.5 per cent of the total area, which seems reasonable.

The question of cavitation in such a unit is of great importance, and serious trouble has been experienced in some of the plants in operation. Hence, a valuable addition to the paper would be the results of further study on this phase of the work. Attention might also be called to the fact that this dual-purpose unit is confined to the case where a single-stage pump suffices, because the multistage turbine has not, so far, proved attractive.

The writer raises a mild protest against the practice of stating specific speeds of pumps in terms of gallons per minute, instead of cubic feet per second. The latter is the logical unit and makes it easier to compare results of machines in general.

R. L. Daugherty.[6] This paper is a clear presentation of the characteristics of a centrifugal pump when equipped with movable diffuser vanes; and it also shows the performance of the same pump when used as a reaction turbine. There are certain cases where such dual operation may be very desirable.

In Fig. 9, the authors show the efficiency curve for this pump as obtained at the California Institute of Technology with the pump being operated at 2000 rpm. They also show an efficiency curve obtained by them in the Newport News laboratory with a pump speed of 1000 rpm, but with the test results stepped up to 2000 rpm. The agreement between the two curves is very close. It is not to be expected that the two curves should coincide.

In general, the efficiency of any centrifugal pump will increase slightly with an increase in speed, until incipient cavitation or some other factor causes it to begin to decline with further increase in speed. This is shown in Fig. 13 of this discussion, in which the writer has plotted maximum efficiencies as a function of speed for four stock centrifugal pumps which were tested at the California Institute of Technology. An inspection of this figure will show that, for an increase in pump speed from 1000 rpm to

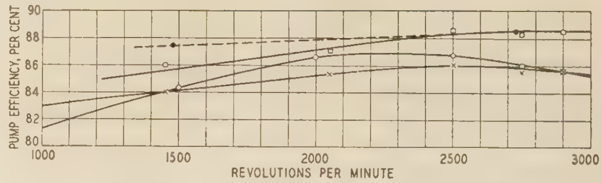

Fig. 13 Variation of Maximum Efficiencies of Four Centrifugal Pumps With Speed

2000 rpm, the difference of about 1 per cent in efficiency, shown by Fig. 9 of the paper, is entirely reasonable.

The authors state that the difference in the point where the break occurs in the head curve is caused by the fact that the intake pipes in the two laboratories were not of the same size. The method of computing the head would seem to make the size of the intake pipe of no importance, but what will influence the break in the head curve is the beginning of cavitation. Cavitation is a function of a factor defined by the equation

$$\sigma = \frac{b - p - h_f - L}{H}$$

where b is the barometric pressure, p is the vapor pressure, h_f is the friction loss in the intake pipe, L is the static suction lift, and H is the total head developed by the pump per stage. If the water is supplied to the pump by gravity then the sign of L would be positive. Cavitation begins at the same value of σ regardless of other external conditions.

A. Hollander.[7] It is only a short time ago since it was realized that efficient pumps may serve also as efficient turbines. The historical review is given in Professor Knapp's paper,[8] which also first presented the circle diagram suggested by Prof. Th. von Kármán. This diagram, with ordinates of speed and flow rate in the positive and negative directions, and constant head and torque lines, covers all possible operating conditions of the machine which the authors call the pump-turbine, including, besides the normal pump and turbine operation, the abnormal pump and turbine operation when the units are running in the direction opposite to the normal, and showing besides these four sectors of energy dissipation. Consideration of this pump-turbine as a machine equally adapted for both purposes, and going over the full circle with all possible ways of its operation, would give a better and more complete picture of its nature. In colleges, the deduction of the energy formulas and the description of velocity diagrams, on this general basis, would constitute an advance compared with present teaching methods.

It was Dr. Knapp's paper, showing for the first time these results with good pumps of about 4-in. size and 80 per cent efficiency which induced the Metropolitan Water District of Southern California to install a modern hydraulic laboratory at the California Institute of Technology,[9] in order to establish specifications and later conduct the model tests for the large pumps of 4000 to 12,000 hp, required for the Metropolitan Aqueduct of Southern California.[10]

[10] "Centrifugal Pumps for the Colorado River Aqueduct," by R. L. Daugherty, *Mechanical Engineering*, vol. 60, 1938, pp. 295–299.

The Reclamation Bureau used the results of this laboratory with 8-in. pumps of 300 to 500 hp and continued the work for the proposed 60,000-hp pumps for Grand Coulee. The results published by Dr. Knapp (12) are further elaborated and extended by the authors. The authors are to be congratulated that they gave not only performances but most of the physical dimensions. The interest of the turbine builders in these pumps is fully justified because of the large size of some of these units, particularly for hydroelectric-storage developments. Such pumps are more in line with the turbine manufacturers' facilities than with those of most pump builders. The developments, based mainly on the California Institute of Technology tests, will certainly permit us to make our hydroelectric storage projects a great deal simpler and less costly than those in Germany, which in a number of cases could have used the same machine as pump and turbine instead of having independent units with a great number of auxiliary connections, clutching and declutching apparatus, etc.

We missed the list of the disadvantages of the wicket-gate pump-turbine, as compared with the simple volute pump-turbine, without a wicket gate, and possibly a valve to regulate flow. Undoubtedly, for some purposes, particularly for widely varying flows, the wicket-gate pump-turbine has some justification. On the other hand, such units and especially their volute cases, due to the increase in diameter by the diffuser, are of very much greater over-all dimensions than plain single or double volutes. Thus, in the end probably they will be a great deal more expensive than volute-case pumps. For applications where the levels do not change very much, it seems that the plain volute will have its place even for hydroelectric storage units and, undoubtedly, in most cases where pumping is the only application.

It seems that, for the discussion of the Grand Coulee units, members of the staff of the California Institute of Technology, which conducted all the tests of the different types and makes of models, are best qualified; having all the test results at their disposal their contribution would complete and round out the very instructive paper of the authors.

R. T. Knapp[11] and J. W. Daily.[12] The following discussion is based primarily upon the results of the test program carried out in the hydraulic-machinery laboratory of the California Institute of Technology to investigate the pumping problems involved in the Grand Coulee installation for the U. S. Bureau of Reclamation. This program was conducted under the immediate direction of Profs. T. H. von Kármán, R. L. Daugherty, and R. T. Knapp, with J. W. Daily in charge of the technical staff.

The information contained in this paper makes it possible to complete the set of comparative studies previously presented by R. T. Knapp (12) in which the performance characteristics of single-volute, double-volute, and fixed-vane diffuser pumps were compared and discussed. The pumps involved were units purchased by the hydraulic-machinery laboratory for the study referred to. The performance of the wicket-gate pump, described by the authors, was not included in this comparison because, although it was designed to meet the same specifications, it was not a part of the test program. However, during the program it was tested for the Newport News Shipbuilding and Dry Dock Company, under special arrangements made with the Bureau of Reclamation. Therefore, the writers did not feel free to use the performance of this pump at the time the former paper was prepared.

This group of pumps presents a unique opportunity for a comparison of the performance characteristics of these different types of casings, since all of the units were designed for the same head and capacity and the same range of inlet heads. Two series of units were procured, one having a specific speed corresponding to 150-rpm operation of the Grand Coulee units, and the other having a specific speed corresponding to 180-rpm operation. The wicket-gate pump described in the present paper belongs to the first series. These test units represent the most modern design practice of some of the leading hydraulic-machinery manufacturers in the country. They are comparatively large machines, having discharge nozzles of 8 in. diam and requiring over 300 hp to drive them at normal capacity. It is seen that these units are considerably larger than the average commercial pump. Therefore, it is felt that the conclusions which can be drawn from the comparison of the performance of the different units must carry considerable weight.

Before the specific comparisons of the performance of the wicket-gate pump with the other test units are presented, the writers have a few miscellaneous comments on points brought out in the paper.

1 In describing the range of conditions under which it is expected that the Grand Coulee pumps will operate, the authors state that, at the maximum dynamic head of 367 ft, the discharge will be approximately 1000 cfs. Actually, this figure is best considered to be a minimum acceptable value. In the Grand Coulee operation the more water that can be pumped at maximum head the better, since this condition occurs at the beginning of the irrigation season. Thus, the capacity at the maximum head is limited only by the obtainable steepness of the pump characteristic.

2 In the description of the tests at the California Institute of Technology, the statement was made that turbine tests were limited to a maximum of 1800 rpm for units of this size by the laboratory equipment. Actually, the limitation is one of capacity and not of speed, since speeds of better than 4000 rpm are well within the range of the test equipment.

3 In discussing Fig. 7, the authors state that for an envelope head curve the highest head occurs at zero discharge. This must be thought of as a statement of idealized conditions, because in the actual test some droop of the head curve was always encountered as zero discharge was approached due to the impracticability of obtaining complete closure of the gates.

4 In discussing Fig. 8, as compared to Fig. 7, it is concluded that a full gate as a turbine is larger than a full gate as a pump, i.e., gate No. 10 versus gate No. 8. As the writers remember the situation, preliminary tests of the pump show that, for gates Nos. 9 and 10, the maximum efficiency was lower than for gates Nos. 7 and 8, and therefore the final test gates Nos. 9 and 10 were not run. In the turbine test a run was taken at gate No. 10, but as will be noted the maximum efficiency is again lower than for gates Nos. 7 and 8. Therefore, the writers have difficulty in understanding the conclusions of the authors.

5 In discussing these same two figures, it is pointed out that the best unit speed for the machine operating as a turbine is lower than the best unit speed as a pump. It is concluded from this that "the use of a combination machine at constant speed and head would involve some sacrifice in efficiency." It is felt by the writers that this generalization is not justified. The statement is certainly true as applied to the specific unit. However, if a different design point were used it would be possible to obtain equal efficiencies for both modes of operation. For example, this point is excellently illustrated by use of Fig. 14 of this discussion, which is a reproduction of Fig. 15 of the paper (12) previously mentioned. It will be seen from this diagram that a turbine operating at 100 per cent speed and normal head would have an efficiency about 3 per cent lower than the same unit operating as a pump at the same head and speed. However, if operating conditions are chosen with normal head and 96 per cent normal speed

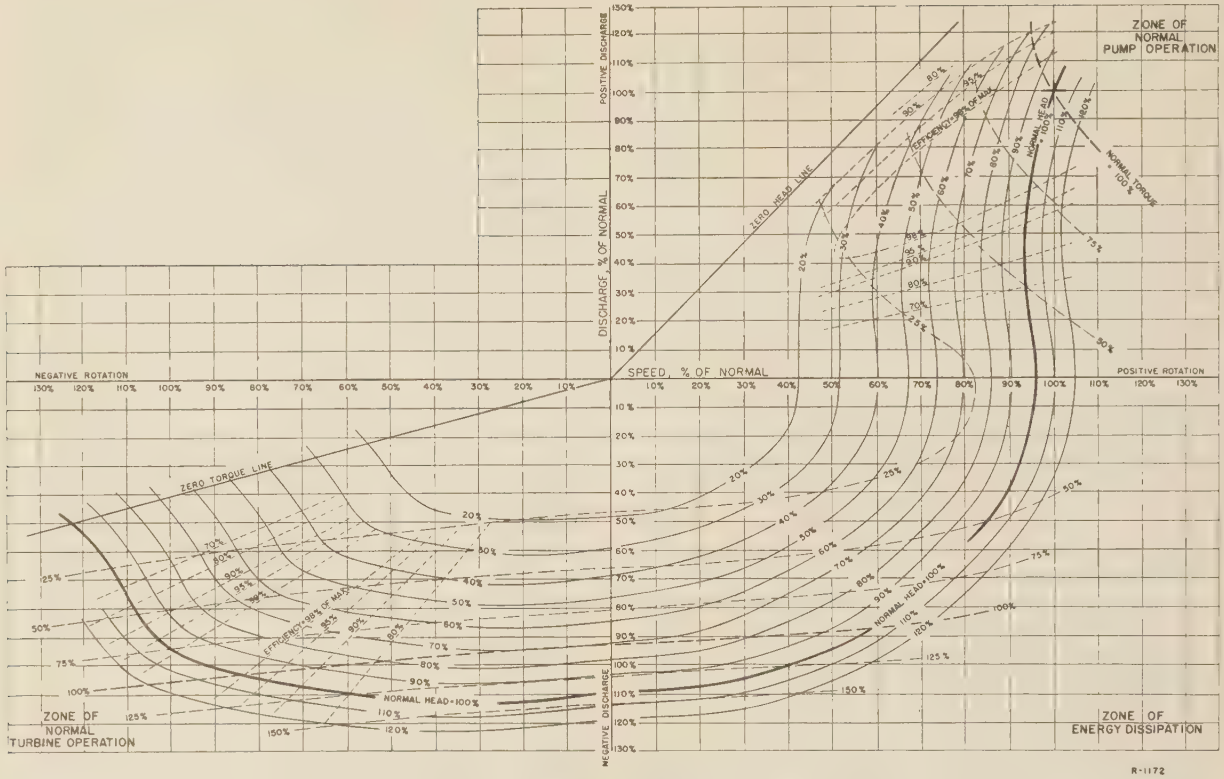

FIG. 14 COMPLETE CHARACTERISTIC DIAGRAM, DOUBLE-VOLUTE PUMP
(Reproduced from R. T. Knapp paper, authors' Bibliography 12, Fig. 15.)

both as a pump and a turbine, it will be seen that the maximum possible efficiency is obtained from both units. On the other hand, if operating conditions as pump and turbine had been chosen as normal head and 110 per cent normal speed, the diagram shows that the pump would still be operating within 3 per cent of its maximum efficiency, whereas the turbines would have dropped off about 25 per cent.

6 In presenting some of the general results of the California tests, the authors called attention to the fact that the efficiency as either a pump or a turbine was not affected until the impeller was cut below 13 in. in diameter, whereas cutting the discharge tips of the impeller vanes while leaving the shrouds extended lowered the efficiency. The writers feel that this test result has interesting implications, i.e., that the close clearance between the runner and the gate vanes generally incorporated in turbine design may not be necessary, and that there might be advantage in the pump practice of using large axial and radial clearances at the periphery of the wheel.

7 In comparing the Newport News and California tests, as illustrated in Fig. 9, the authors explain the smaller discharge at which the break in the head curve occurs in the California test by the small size of the suction pipe used. They say "the entrance loss and friction loss in this pipe were the factors which determined the cutoff point in the California test." However, in the California tests, the total dynamic inlet head was measured at a point only one diameter upstream from the impeller eye, so that the effect of any inlet-piping loss on the calculated inlet or net head produced was eliminated. It is probable that the discrepancy observed in the shutoff point is due to cavitation caused by a difference in the relative submergence at which the two tests were run. The California tests were made with an 80-ft submergence. This corresponds to a lift of 4.7 ft under the conditions of the test at Newport News. If the Newport News tests were run with an inlet pressure greater than this, the cutoff point would be expected to occur at a correspondingly higher capacity.

8 In preparing Fig. 11, the authors apparently stepped up the model efficiency to the expected prototype values by the use of the normal turbine step-up formulas. Thus the maximum model efficiency of 87.6 per cent has been increased to an expected prototype efficiency of 92 per cent. At this point it should be noted that it is the practice of the hydraulic-machinery laboratory of the California Institute of Technology to test the units at full prototype heads and velocities. In the case of the present units, this means that the Reynolds number of the flow in the suction and discharge nozzles is in the neighborhood of 2,000,000. Thus, comparatively little change in relative losses can be expected for any possible increase in the size of the units. This conclusion is borne out by the few comparisons between model and prototype test efficiencies in which models were tested at full prototype heads and velocities. Of the $4^1/_2$ per cent step-up assumed, 1 per cent is justified, as the authors point out, by the excessive leakage found in the model tests. The writers feel that the remaining $3^1/_2$ per cent is much too great a step-up to be warranted with the present knowledge.

Figs. 15 and 16 of this discussion show the comparative performances of the double-volute pump, the fixed-vane diffuser pump, and the adjustable wicket-gate pump. Fig. 15 is plotted on the basis of 150 rpm prototype operation, while Fig. 16 is calculated for the same machines but operating at a speed corresponding to 180 rpm prototype operation. Capacities and heads are represented in percentage of normal in accordance with the convention used in the previous paper (12). However, actual efficiencies of the test pumps are plotted in the place of relative efficiencies formerly used. The first point that is observed

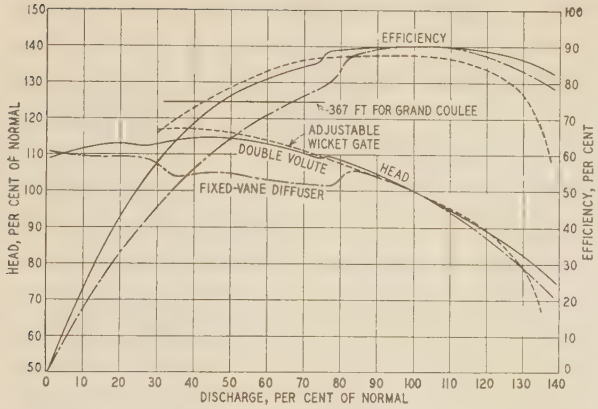

Fig. 15 Comparison of Casing Effects on Characteristics; Double-Volute, Fixed-Vane Diffuser, and Adjustable Wicket-Gate Pumps

(Prototype speed, 150 rpm.)

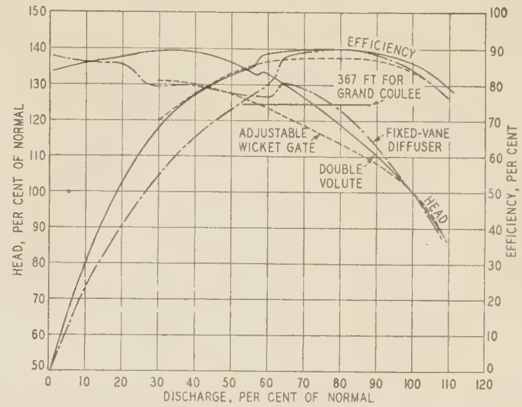

Fig. 16 Comparison of Casing Effects on Characteristics; Double-Volute, Fixed-Vane Diffuser, and Adjustable Wicket-Gate Pumps

(Prototype speed, 180 rpm.)

in Fig. 15 is that none of the pumps when operated at the design speed would develop sufficient head to deliver against the maximum head encountered in the Grand Coulee installation. The second point of interest is that, over a surprisingly wide range, the double-volute and the wicket-gate pumps have nearly identical capacity-head curves. A comparison of the efficiency curves shows that both the double-volute and the fixed-vane diffuser pumps have maximum efficiencies about 3 per cent higher than the wicket-gate machine. Of this difference, 1 per cent is undoubtedly due to the excessive leakage loss previously mentioned, but the remaining 2 per cent is probably chargeable to the additional amount of friction surface in the high velocity flow.

The broad range of high-efficiency operation of both the wicket-gate and double-volute pumps is very apparent. Calculation shows that a range of capacity of approximately 61 per cent of the normal is covered with an efficiency within 5 per cent of the maximum by the wicket-gate machine, whereas, the corresponding value for the double-volute is about 58 per cent and for the fixed-vane diffuser about 43 per cent. The adjustable wicket-gate pump has a noticeably higher efficiency for all discharges below 60 per cent of the normal.

If Fig. 16 is now examined, it will be seen that the situation is changed. In the first place, all three pumps now are able to meet the required range of head when operated at 180 rpm. However, the relative steepness of the head curves is no longer the same. The fixed-vane diffuser case shows the best performance, giving a delivery of 78 per cent of normal capacity at the maximum head. The double-volute pump is next with 73 per cent, whereas, the adjustable wicket-gate pump delivers only 58 per cent. At this higher operating speed, the double-volute case shows a considerably wider range of high-efficiency operation than does either of the other two. The adjustable wicket-gate unit still shows a 3 per cent lower maximum efficiency and, in addition, no longer shows a better efficiency for the lower capacities. These conclusions are somewhat surprising when it is remembered that the curve shown here for the wicket-gate pump is the envelope for the different gate positions.

In the concluding paragraph of the paper, the authors give seven advantages of the wicket-gate construction over the non-adjustable cases. Figs. 15 and 16, of this discussion, offer a concrete means of evaluating these items as follows:

1 While the power curves for the three cases are not shown in either of these figures, it is recognized that the shutoff power for the wicket-gate pump is definitely lower, provided, of course, that the flow is controlled by closing the wicket gates themselves.

2, 3 These depend upon the speed selected for making the comparison. As was shown in the discussion of Figs. 15 and 16, the difference is small for the 150-rpm operation, but for the 180-rpm operation the double-volute case shows a flatter efficiency discharge curve, and both it and the fixed-vane diffuser case show steeper head curves.

4 Neither Fig. 15 nor Fig. 16 shows an appreciable increase in discharge-overload capacity in the lower heads. This is surprising for the 180-rpm operation, because of the flatter head curve of the wicket-gate pump. Here the lack of overload capacity is probably due, as the authors suggest, to cavitation.

5 It is certainly true that wicket gates form an excellent means of controlling discharge at constant speed and head.

6 The adjustable wicket-gate pump had a smaller impeller diameter when compared on a prototype basis. For the three pumps shown in Figs. 15 and 16, the adjustable wicket-gate pump would have an impeller diameter of 16.7 ft, the double-volute pump 16.95 ft, and the fixed-vane diffuser 17.1 ft. For this particular group, this represents a range of 2.4 per cent. However, this is not the entire story. The figure which best characterizes the casing sizes is the one given by the authors in Table 1, as "offset of casing throat to center line." Again, on the basis of 150 rpm prototype speed, this distance would be $15^1/_4$ ft for the adjustable wicket-gate pump, $13^1/_2$ ft for the double-volute pump, and $14^1/_2$ ft for the fixed-vane diffuser. Thus it is seen that, while the adjustable wicket-gate machine has the smallest impeller diameter, it has the greatest over-all case diameter. The cross-sectional areas of the spiral case surrounding the wicket gates and stay vanes will be larger also since the effect of the adjustable wicket gates is to reduce case velocities.

7 In units of this size, the structural design of a single-volute case is quite difficult. The introduction of a second volute overcomes a large part of this disadvantage. On the other hand, the stay vanes used in both the fixed-vane-diffuser and the adjustable wicket-gate pumps make possible a very satisfactory structural design.

In conclusion, the writers would like to make a few comments regarding the operation of these units as turbines. In the light of the comparison of the pump characteristics, it would appear that the chief advantage to be gained by the use of the adjustable wicket-gate case lies in the region of turbine operation and that, therefore, the whole discussion must be on a basis of the combined operation both as pump and as turbine. If, when the unit is operated as a turbine, the system conditions are such that

it must be governor-controlled, then the wicket-gate construction offers advantages which cannot be obtained with the other cases. However, if the system conditions permit the utilization of the unit to supply a block load, then governor-controlled operation is not necessary. For this condition, any of the case types gives satisfactory operation. For the three units under comparison, both the fixed-vane diffuser and the double-volute type show higher efficiencies as turbines than does the adjustable wicket gate. The wicket gate, however, does have the one advantage in that a wider range of power output can be obtained for a given head for the same relative variation of efficiency. For the non-adjustable type case, unless a throttle valve is incorporated in the system, there is only one output. For a multiple-unit installation this seems to offer no disadvantage.

It should be emphasized that the writers have been as objective as possible in making comparisons, limiting statements to the results which were substantiated by the tests. The laboratory staff feels that each of the different casing types has its own field of application and, therefore, few generalizations are justified. The present comparisons have as a background the Grand Coulee requirements. Other installations, which have entirely different operating conditions, would result in a completely different order of desirability of casing requirements.

R. E. B. Sharp.[13] Discussions of the performance of pump-turbines are in order, in view of the fact that the present capacity demand has recently awakened decided interest in pumped-storage projects.

For comparison with the authors' tests, Baldwin-Southwark Model Runner 115, tested during July, 1931, and Model Runner 117, tested during July, 1933, may be of interest.[14] Model 115 was designed for peak-load storage plants with relatively high heads, and Model 117 for medium heads. The specific speed of Model 115, when pumping, at best efficiency, is 1970, as compared to the authors' 1750; and when generating is 26, as compared to the authors' 25. Runner 117 has a specific speed of 2700 when pumping and 41 when generating. These tests were made under low-head conditions (3 to 4 ft).

While the resulting Reynolds number is low, it has been demonstrated as being sufficiently high to be well within the turbulent region of flow and to form a reliable comparison with prototype performance and with model tests under higher heads. The discharge was measured by a calibrated weir, and the power by electric dynamometer. The head, acting both for pumping and generating, was considered as the vertical difference between headwater and tailwater levels. The tests were made with vertical shafts, with the volute casing submerged, and with draft elbows of usual turbine design. The draft-tube losses are charged against the pump-turbine for both cycles of operation.

Figs. 17 and 18 of this discussion show characteristics, in general, similar to the authors'. The same tendency for irregularity in the curves to the left of the maximum-efficiency point was encountered.

The practical utilization of pump-turbines, in virtually all cases, requires that the head when pumping be somewhat greater than when generating, due to the friction losses both ways in the penstock. The pumping operation, although occurring at times of low system load, requires for its justification the minimum expenditure of energy. Therefore, both the pumping and generating cycle should be at the most efficient condition.

In Fig. 17, the performance of model 115 as a pump has been stepped up to 1000 rpm, the head at best efficiency being 111 ft. In Fig. 19, the performance of this model as a turbine has been plotted when operating at the same head of 111 ft. The curves for two speeds are shown, the lower efficiency curve being for 1000 rpm, and the higher efficiency and output for a speed of 868 rpm. It will be noted that the loss in efficiency for uniform speed of operation during both cycles is about 5 per cent. Therefore, in practice, two speeds are necessary, the indicated loss with uniform speeds being aggravated by the pumping head being in excess of the generating head. As an alternative, a booster pump in series with the pump-turbine can be utilized to reduce the pumping head on the pump-turbine so that maximum efficiency will be attained at a uniform speed.

In Fig. 18 of this discussion, the performance of model 117, as a pump, has been stepped to 1000 rpm, the head at best efficiency being 86.75 ft. In Fig. 20, the performance of this model as a turbine has been plotted, when operating at the same head (86.75 ft). In this case also, the curves for two speeds are shown, the lower one being for 1000 rpm; the higher curve is for 900 rpm. It is interesting to note that, for this higher-specific-speed

[13] Chief Engineer, I. P. Morris Department, Baldwin-Southwark Division, Baldwin Locomotive Works, Philadelphia, Pa. Mem. A.S.M.E.

[14] Note the following pertinent patents: No. 1,494,008, issued May 13, 1924, Method and Means for Converting Energy, by Forrest Nagler, assigned to Allis-Chalmers Manufacturing Company; No. 1,919,376, Reversible Pump-Turbine, by L. F. Moody; No. 1,941,-361, Air Inlet Control and Method of Operating a Pump-Turbine, by L. F. Moody; No. 2,010,555, Hydraulically Reversible Pump-Turbine, by L. F. Moody; No. 2,246,472, Hydraulic Power Accumulation System, by R. E. B. Sharp, assigned to Baldwin Locomotive Works.

model, the loss in efficiency at uniform speed is distinctly less than for runner No. 115, of lower specific speed; that is, a two-speed unit, or the provision of a booster pump, is more essential for high-head units (400 to 600 ft) than for lower heads. The pumping efficiency of the pump-turbine models tested to date does not compare well with the best pumping efficiency obtainable without movable guide vanes surrounding the runner. Also the efficiency when operating as turbines of some conventional pumps has been found to be excellent. However, movable guide vanes on pump-turbines appear to be essential for operation as turbines, to obtain the best efficiency and maximum power possible under this cycle of operation. Pump-turbine research is still in its early stages and improvement in performance, particularly when pumping, can be effected.

A. J. Stepanoff.[15] The authors should be commended for publishing the design data as well as the tests and description of the pump. This permitted a critical examination of the test data. In the writer's opinion, some of the advantages claimed by the authors for the pump with adjustable diffusion-casing vanes are not sufficiently corroborated by their test data.

Considering that the double-volute pump, previously described by R. T. Knapp (12), had a maximum efficiency of 90 per cent, the authors envelope of efficiency curves lies below the double-volute-pump efficiency curve for capacities between 50 to 125 per cent of the rated capacity. It is only at capacities lower than 50 per cent that the authors' efficiency envelope passes above the double-volute-pump efficiency curve.

[15] Ingersoll Rand Company, Phillipsburg, N. J. Mem. A.S.M.E.

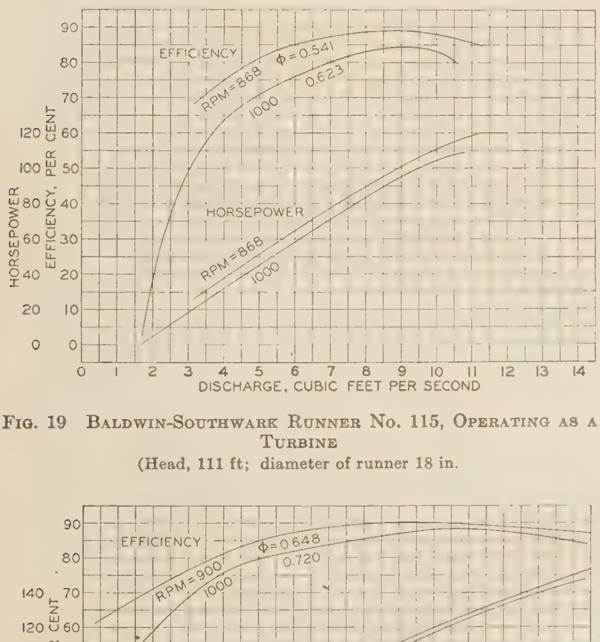

Fig. 19 Baldwin-Southwark Runner No. 115, Operating as a Turbine
(Head, 111 ft; diameter of runner 18 in.

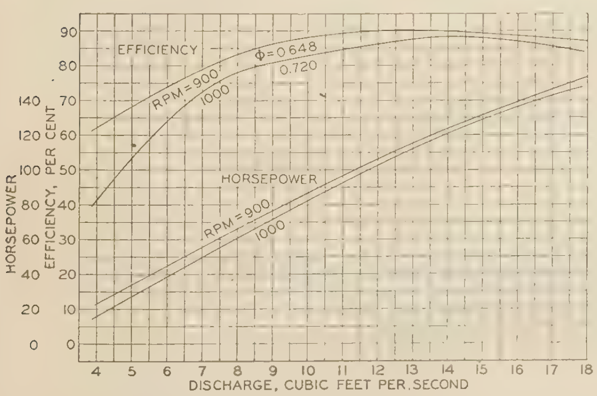

Fig. 20 Baldwin-Southwark Runner No. 117, Operating as a Turbine
(Head, 86.75 ft; diameter of runner 16⁵/₁₆ in.)

The double-volute pump has actually shown a steeper head-capacity curve for capacities from 50 to 125 per cent of rated capacity than the authors' envelope head-capacity curve, shown in their Fig. 9. With a special design, it is possible to reproduce the authors' envelope head-capacity curve with a double-volute pump, without sacrificing any efficiency; in other words, it is possible to eliminate the drop of head toward the zero capacity now appearing on the double-volute pump head-capacity curve given by Knapp (12).

Since the double-volute-pump head at overload capacity is the same as that of the authors' pump, and the efficiency is probably better, the overload capacity of the double-volute pump at lower heads is essentially the same as that of the authors' pump.

A smaller impeller diameter of the authors' pump resulted from the use of a high discharge vane angle of 30 deg rather than any special feature of the adjustable-vane casing. The over-all dimensions of the authors' pump casing will be greater than those of the volute pumps by the space occupied by adjustable vanes.

It is believed that the double-volute design will result in a casing which will be rigid enough even when built in the size proposed for the Grand Coulee project.

The authors' mechanical design deviates from the orthodox construction in that they have placed the inboard ball bearing inside the pump casing between the stuffing box and the impeller. The writer wonders whether this was the bearing which caused trouble during testing mentioned in the paper. The casing is heavily ribbed, which is hardly necessary for this size of pump and pressures involved.

The writer is grateful to the authors for the published information, which enabled him to study the test results and be benefited by the authors' experience.

G. F. Wislicenus.[16] The paper presents an unusually complete account of the test results as well as the design characteristics of a pump-turbine model with wicket gates, and so represents a most valuable contribution to the literature on pumping machinery.

The comparison between pumps with adjustable wicket gates and pumps with a fixed-casing design might be slightly misleading, in so far as the characteristics of a fixed-casing machine may be somewhat more favorable than the characteristics of an adjustable-gate machine at a fixed-gate setting. For this comparison, the material presented by R. T. Knapp (12) will be found helpful and instructive.

The value of adjustable wicket gates for controlling the unit during turbine operation is so well established that the use of adjustable gates for pump-turbine units is almost a necessity wherever a close control of the power output during turbine operation is required. In designing such units, it is necessary to take into account the fact that the flow conditions at the gates during pump operation are such that increased and possibly pulsating forces on the gates can be expected which would not exist during turbine operation. This expectation is based on the fact that the accelerated flow through the gates during turbine operation is probably smoother and more stable than the outward flow during pump operation. Some experience gained with pump-turbine operation seems to bear out this reasoning.

In hydroelectric power plants where the units will be operated as pumps and as turbines, it may be possible to eliminate the necessity of using adjustable gates on the pump-turbine units if the plant contains, besides the pump-turbine units, at least one

[16] Engineer, Design, Worthington Pump and Machinery Corporation, Harrison, N. J. Mem. A.S.M.E.

water-turbine of standard design which would not be operated as a pump. In this case, the pump-turbine units could be used to carry the base load, while the load fluctuations are taken up by the standard control mechanism of the turbine. This arrangement is the more likely to be acceptable, since, for most hydroelectric storage plants, the turbine capacity has to be greater than the pump capacity in order to take care of peak loads.

Authors' Closure

The authors obtained both benefit and satisfaction from the large number and extensive discussions presented on this paper. In view of the great amount of material presented and the thorough analysis of the subject brought out in these discussions, the authors feel that they can hardly contribute much more in reply.

To Professor Angus we might add, that when the model was operated under a head of 365 ft, cavitation was not apparent until there was a suction lift of about 7 or 8 ft. On the prototype when operating under this head there would be a positive suction head of about 5 ft. When the model was operated at 295 ft head, cavitation set in at a suction head (positive) of about 13 to 14 ft. On the prototype there would be a positive suction head of 80 ft when operating under this condition. The sigma for the first condition is about 0.07, and for the latter condition about 0.15.

Professor Daugherty suggests that the cutoff point on the *H-Q* curve would not be influenced by the size of the suction pipe. The authors feel that not only the size of the suction pipe but also the kind of entrance piece used on the suction pipe would effect the cutoff point. These would determine the friction head loss h_f in the intake pipe and would thus be reflected in the sigma as illustrated in his discussion.

Professor Knapp and Mr. Daily question the conclusion that for turbine operation, as shown in Fig. 8, gate 10 is accepted as full gate, and for pump operation, shown in Fig. 7, gate 8 is considered as maximum.

In Fig. 7 it will be seen that the *H-Q* curves for gates 7 and 8 rapidly approach each other at the larger discharges. If gates 9 and 10 had been plotted it would be seen that there would not be much further gain in discharge for a given head at these larger discharges than is obtained with gate 8, and the efficiency would be lower. However, when operating as a turbine, as seen in Fig. 8, there is considerable gain in power at gate 10 over that obtained at gate 8, and the efficiency is still only about 3 per cent lower. Therefore, it may be concluded that for the pump, when operating at gates 9 and 10, it would be overgated, while when operating as a turbine, gate 10 could be used to considerable advantage.

The authors wish to thank all of the discussers for their valuable contributions and hope that the description of the model and its performance characteristics will be accepted only as another step in the development of the combined pump-turbine.

The Foren Mill for Rolling Seamless Tubes Achieves Virtually Continuous Production

By E. W. WRAGE,[1] MILWAUKEE, WIS.

This paper deals with the development of the Foren tube-rolling process, details of the first experimental unit, and the problems which required solution in making it commercially practicable. Operation of the present unit, which is based on straight-line production methods, is described. Automatic controls for practically all operations have been developed, which makes possible the reduction of personnel to a minimum.

THE production of seamless tubes had its inception about 1885, when two German engineers developed a cross-rolling method for manufacturing seamless hollow billets. Subsequently, the process came to be known as the Mannesman piercing method which is in use today with practically no changes other than refinements in machine design. This method is illustrated diagrammatically in Fig. 1.

One of the best known methods developed to improve upon the crude hollow billets, produced by the early machines, is the plug-type tube-rolling unit, which today produces the largest tonnage of seamless tubing in the industry. A typical cross section of this machine is shown in Fig. 2.

In this illustration it will be noted that the hollow pierced billet is forced between two large rolls, each of which is grooved to the correct dimension required to produce a predetermined tube size, in conjunction with a rolling mandrel or plug on the inside of the hollow pierced billet, supported on the end of a mandrel bar. As the tube is passed between the revolving mill rolls and the plug, it is rolled for approximately 60 per cent of two sections of its periphery, directly opposite each other, to a determined diameter and wall thickness. Upon completion of this cycle, the upper roll is raised to permit the return of the rolled billet to its original position by the stripper, or return rolls, which are located directly behind the forming rolls. The hollow billet or tube is then turned 90 deg from its original pass to permit working the roll and mandrel on this new axis. This turning operation is repeated with each pass until the required tube diameter, as well as the wall thickness, has been developed. Thereafter the tube is passed to the next operation for further processing.

Since the roll setting must be changed in accordance with the passes required, a great deal depends upon the skill of the operators in the production of tubes of uniform diameter and wall thickness.

Until recent years, this seamless-tube-rolling method was universally used throughout the industry, and but slight progress had been made toward perfecting a better one. Then several improved methods were devised, including the Pilger mill, the Assel mill, and the Diescher mill, all of which have a definite place in their several fields, and are being used to advantage for tube production.

Development of the Foren Mill

During the same period as these developments were taking place, P. A. Foren, a Swedish engineer in the employ of the author's company, conceived the idea that rolling a pierced billet over a solid bar on the inside, and through a series of successive passes, should produce a tube of better inside and outside finish, with a closer wall tolerance than is practicable on the conventional plug-type mill. He began his experiments about 1927, using

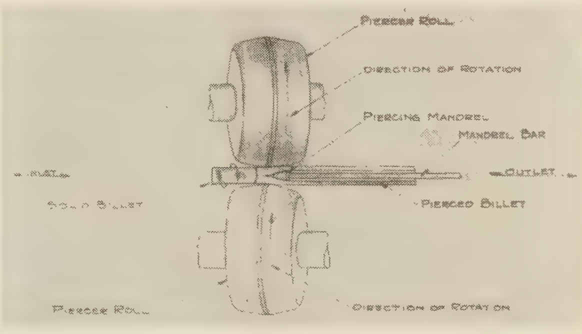

Fig. 1 Cross-Rolling Method for Manufacturing Seamless Hollow Billets
(Diagram shows billet passing through piercing machine.)

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

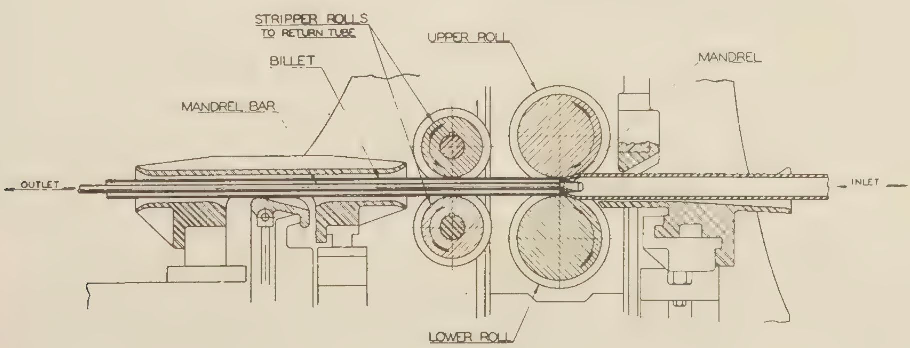

Fig. 2 Billet Passing Through Rolling Mill of Standard Single-Stand Type

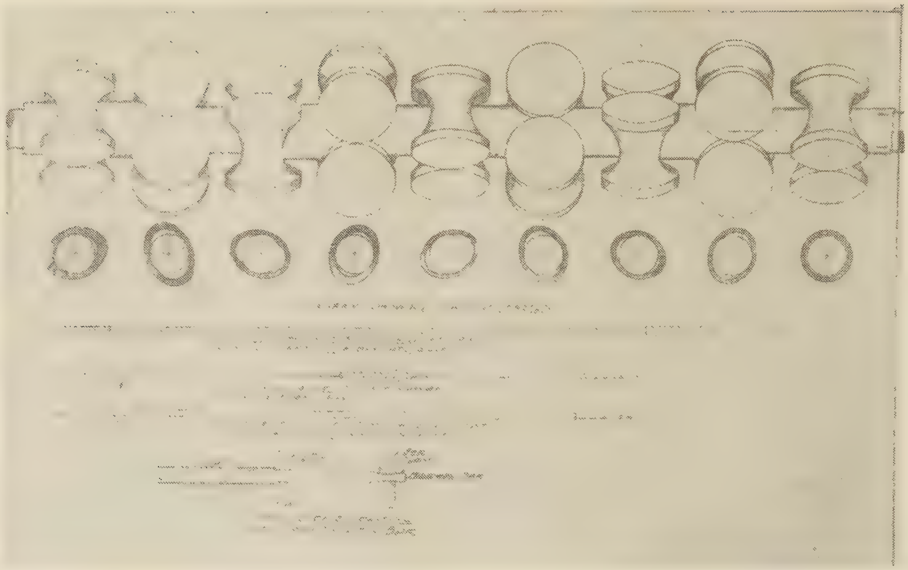

Fig. 3 Diagram Showing Various Passes and Details of Relation Between Mandrel Bar and Billet at Different Stages of Process

mandrel bars in tubes produced on the plug mill and passing them through what is known as reducing or sizing mills. His experiments resulted in obtaining records of elongation, reduction per pass, and power consumption. Crude as it was, this procedure furnished sufficient information upon which to base the detailed development of the present-day Foren tube-rolling unit. In 1928 his ideas had advanced to a point where a patent covering this method of tube rolling was applied for and subsequently granted.[2]

However, there were still many unknown factors which required determination before a commercial unit could be designed and built, i.e., permissible speeds, roll pressures, impact angles, groove clearances, power consumption, and proper rolling temperatures. The development of motors to give a constant predetermined roll speed constituted a new problem for the motor builders.

In designing the mill twenty-one roll stands were selected, based on a certain contemplated reduction per pass. Realizing that in the use of twenty-one successive rolls considerable elongation of the pierced billet as well as reduction in diameter would materialize, and that the roll speed for each set of rolls would have to be of corresponding revolutions for a given tube diameter, a motor speed would naturally have to be developed for each different tube diameter and wall thickness. With this in mind, it was obvious that each roll set, or stand, would have to be independently driven, inasmuch as it was not practicable to design a gear train with such flexible ratios that all speeds could be obtained from a single drive.

The next step in the design of this mill was positioning the roll stands with respect to the pass line of the mill. The advantage of engaging the hollow billet by the rolls at as many angles as possible, in order to cover the entire circumference, was recognized.

To illustrate this point more clearly, let us assume that the first set of two rolls is placed on the horizontal plane with a groove of such design that both the upper roll and the lower roll will engage the billet for 50 deg of its circumference. In the first pass, the billet will be rolled at two sections by this set of rolls for 100 deg of its circumference. The following set of rolls, performing an equal amount of work on the billet, is placed at a 90-deg angle with the first roll set, or in a vertical plane. Hence, the billet, having passed through the first and second set of rolls, each set engaging it for an equal amount of its circumference, has received rolling by two sets of rolls to a total of 200 deg, in four sections of its circumference. In order to perform work on the billet over its entire circumference, the next two sets of rolls are placed in the same relation to each other, except that their axis is placed at a 45-deg angle with that of the first two sets. By this arrangement the billet having passed through four sets of rolls has received work over its entire circumference; a small overlap is also provided for each pass.

It should be noted that the groove design in each roll set is not a true radius. The billet, passing through each roll set with the mandrel bar on the inside, does not emerge from the pass perfectly round but is slightly oval in form, for reasons which will be explained. Obviously, the billet, having gone through four passes, is reduced in diameter as well as in wall thickness and is irregular in cross section, Fig. 3.

The billet then passes into the next set of rolls which have grooves so designed as to restore its circular cross section. The foregoing procedure is descriptive of a complete rolling cycle. In succeeding rolling cycles the operations are repeated, continuing to reduce both billet diameter and wall thickness, which results in elongation of the billet. After the billet has passed through the ninth set of rolls, it is again restored to a circular cross section, thus accounting for ten roll stands.

Passing through an additional eight sets of rolls, placed at alternating angles as previously, the billet is further reduced both in diameter and in wall thickness. The remaining three passes of the original twenty-one sets of roll stands perform the function of freeing the billet from the mandrel bar and, at the same time, of sizing the outside diameter, the wall thickness having been fixed by the previous passes.

Selecting the Motor Drive

Having determined the arrangement of the rolling cycle, as well as the angular location of the rolls, suitable drives had to be provided. In order to simplify the gear drives and their respective locations, the following arrangement was adopted:

[2] U. S. Patent No. 1,858,990, assigned to Globe Steel Tubes Co.

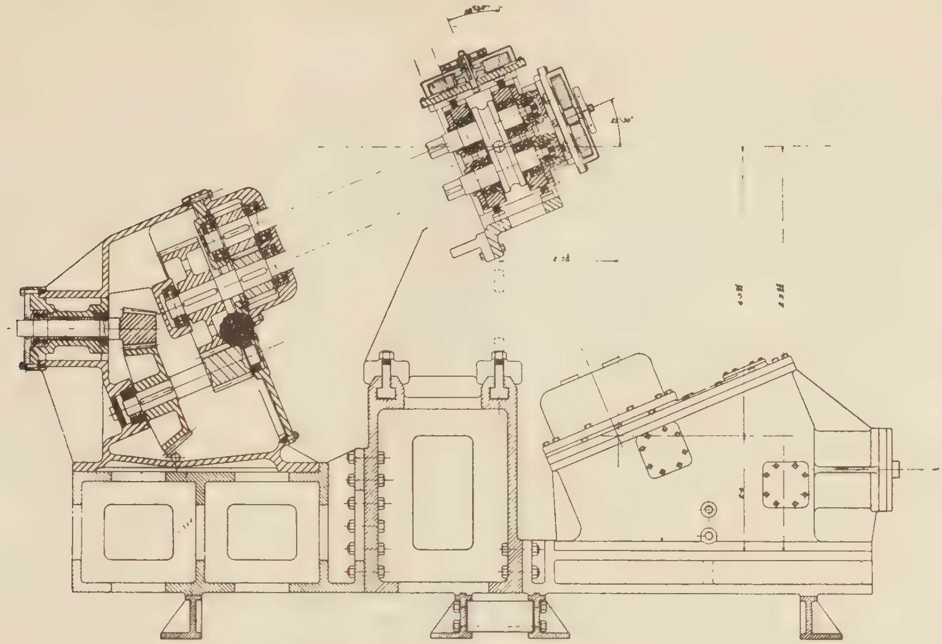

Fig. 4 Typical Roll Stand Giving 45-Deg Angular Contact Between Rolls, Also Showing Cross Section Through Gear Drive Designed for 22-Deg 30-Min Angle

The first set of rolls was set at an angle of 22 deg 30 min with one side of the vertical center line of the mill, followed by the second set of rolls, placed at an angle of 67 deg 30 min with the vertical center line but opposite to the first set, thus giving a total angular distance of 90 deg between roll stands Nos. 1 and 2. The following two sets of rolls were arranged as before, with this difference, that the third set of rolls was placed at 22 deg 30 min with the vertical center line on the side of the second roll stand which was placed at 67 deg 30 min. Pass No. 4 placed at 90 deg from pass No. 3 would then be located 67 deg 30 min on the opposite side from the vertical center line. In studying this arrangement it will be seen that the axes of the several sets of rolls throughout the mill are at an angle of 22 deg 30 min with each other, making it feasible to engage a billet to be rolled with a 45-deg angular contact between rolls. This is better illustrated in Fig. 4 which also shows a typical cross section through one of the gear drives designed for the 22-deg 30-min angle. This arrangement of gear drives with motors for each roll simplifies the design of the subbase as well as the angular drive spindle connection between gear unit and roll necks.

Experimental Period

The first Foren mill, as described, together with its auxiliary equipment and electrical controls, was installed in a separate building and operated on an experimental basis for some time before it was placed in the production line. During the experimental period considerable data concerning its operation were developed and many difficulties were corrected. Some of the problems solved in this way involved such matters as determination of the maximum reduction per roll set; the correct elongation, resulting from each pass; the necessary increase in roll speed from one pass to the next; groove contours to provide for the free flow of metal; rolling tension between passes; power consumption per pass; generator loading for the entire unit; bar requirements; rolling temperatures; coefficient of friction between hot metal on a cold bar surface; and other essential data.

As already mentioned each set of rolls had to have a very flexible speed control. This was accomplished by driving each set of rolls through reduction gears by means of a direct-current motor with variable voltage and speed. All of the motors were in turn connected to a single motor generator set, having a voltage range from 230 to 375. A speed range of 2 to 1 was built into each motor at all voltages. This speed range plus the voltage variation for the motors furnished the flexible speed requirements. Each motor was equipped with an electric tachometer which indicated the correct motor revolutions. The motor speeds in turn were set by means of a coarse and fine rheostat in the motor field circuits. Automatic voltage regulation on the generator eliminated wide fluctuations.

After months of experiment, during which time a number of adjustments and changes were made in the mill drive, the unit was placed in the production line-up. The results were very encouraging, but it became apparent that additional study was required to develop the full potentialities of this rolling unit. Fig. 5 is a plan view of the mill as it was originally installed.

Fig. 6 is a diagrammatic arrangement of the rolls in their respective locations showing the reductions per pass throughout the mill to the final finish of the rolled billet, or tube, prior to the extraction of the mandrel bar.

Fig. 7 is a general layout of the entire Foren tube-rolling process from billet-heating furnace to the cooling table. This arrangement is being used today except for modifications and changes on the mill proper and on some of its auxiliary equipment.

Development of Present Mill and Its Operation

The original mill having been in the production line for several years under constant observation by the engineering department, it became apparent that increased reductions per roll stand would result not only in a better product but also in increased production, chiefly through conservation of the heat in the pierced billet. After thorough study of the situation, the mill was changed from twenty-one sets of rolls to thirteen sets, which

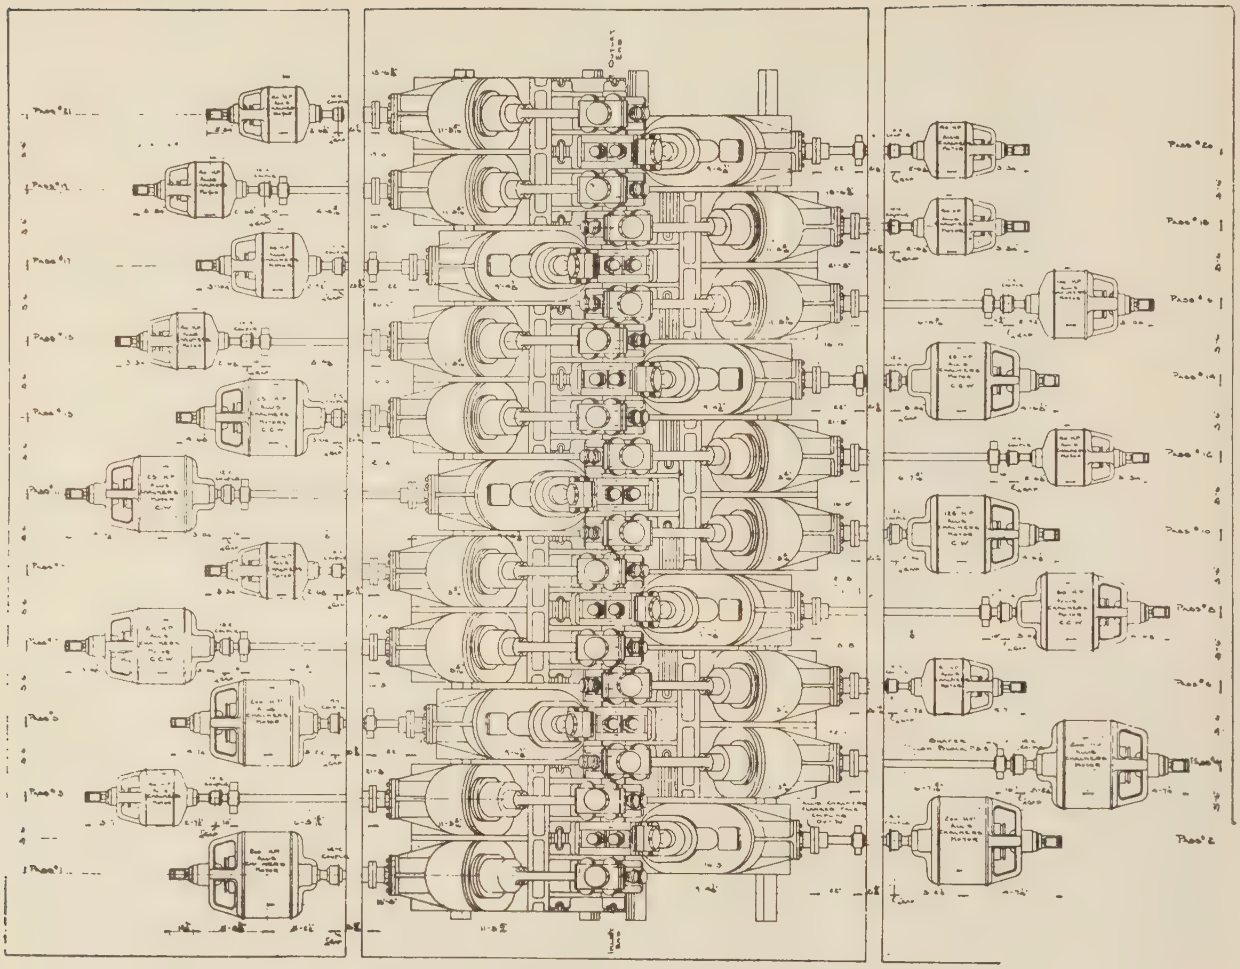

Fig. 5 Plan View of Mill as Originally Installed

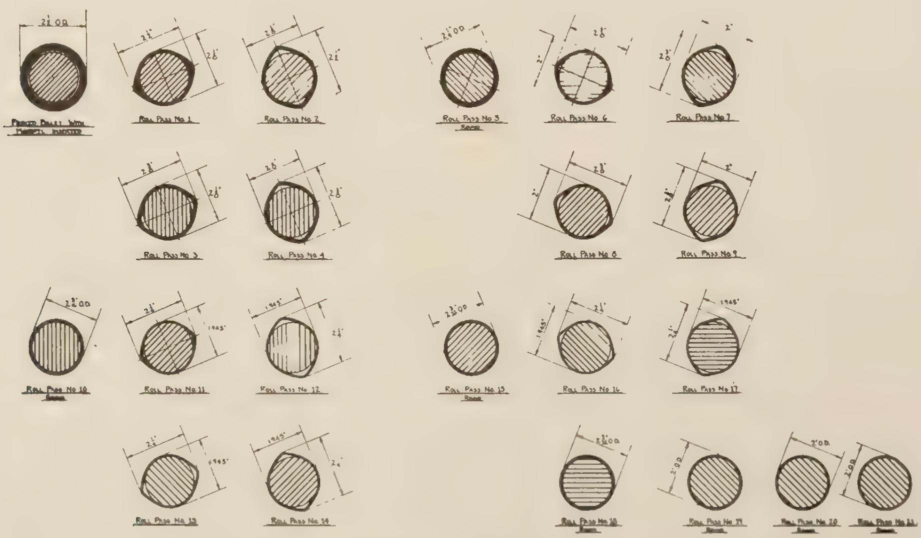

Fig. 6 Schematic Arrangement of Rolls and Respective Locations

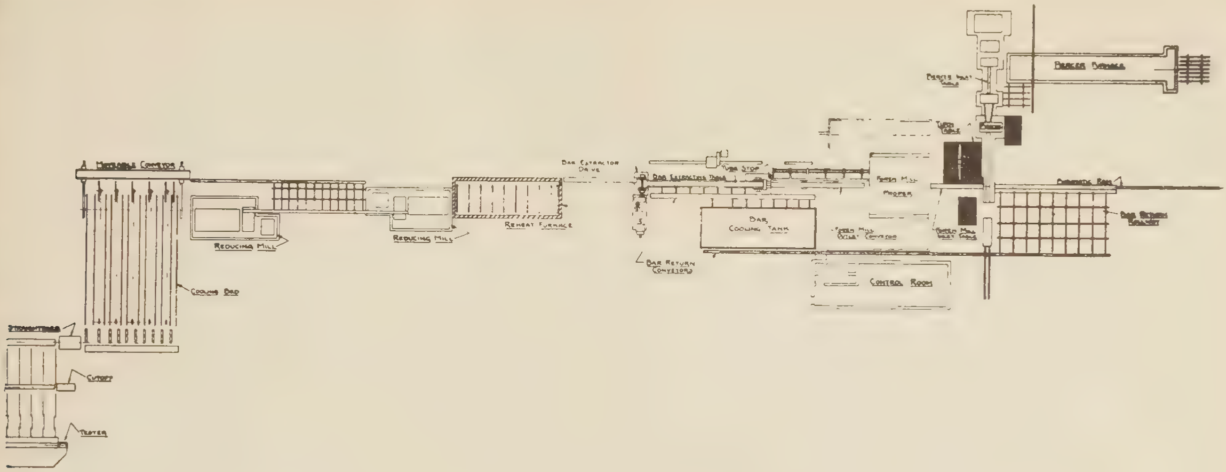

Fig. 7 General Layout of Foren Tube-Rolling Process

would appear to be a rather large reduction in the number of passes. However, it was possible to accomplish this change by installing larger motors in some of the mill stands which were called upon to take heavy reductions on the pierced billet. Motors were equipped with flywheels which provided against a drop in speed due to the impact loading on the rolls. The WR^2 built up in the flywheel, plus the gear reduction, plus constant voltage, resulted in a close regulation of the roll speed. From observation it was further determined that proper lubrication on the rolling mandrel was essential, as this has a direct bearing on the flow of the metal in each pass. The cycle of events on the thirteen mill stands, as they are now being operated with entirely satisfactory results, is as follows:

Upon inserting the mandrel bar into the pierced billet, the first two sets of roll stands reduce it to a diameter with which the inside of the billet is engaging the mandrel bar. The next eight sets of rolls, their angular positions remaining the same as in the original setup, perform the entire operation of reducing the diameter and wall thickness of the pierced billet. This is followed by a rounding-up pass, the remaining two passes then functioning as a means of freeing the billet from the mandrel bar and, at the same time, of acting as a sizing roll for the tube diameter. This arrangement achieves conservation of heat because of increased roll speeds and fewer passes.

To illustrate the results obtained by this mill, Fig. 8 incorporates a table of certain popular sizes which gives the billet size prior to piercing, the pierced-billet dimensions, the pierced-billet length, as well as the billet length leaving the mill. From this table, the elongation of the billet can be determined. It also gives a micrometer reading on the cross section of a certain tube size, illustrating the variations throughout the circumference of the tube at ten different positions of the circumference. This table also shows a graph of reduction in area, per cent of elongation, and roll speeds in feet per minute.

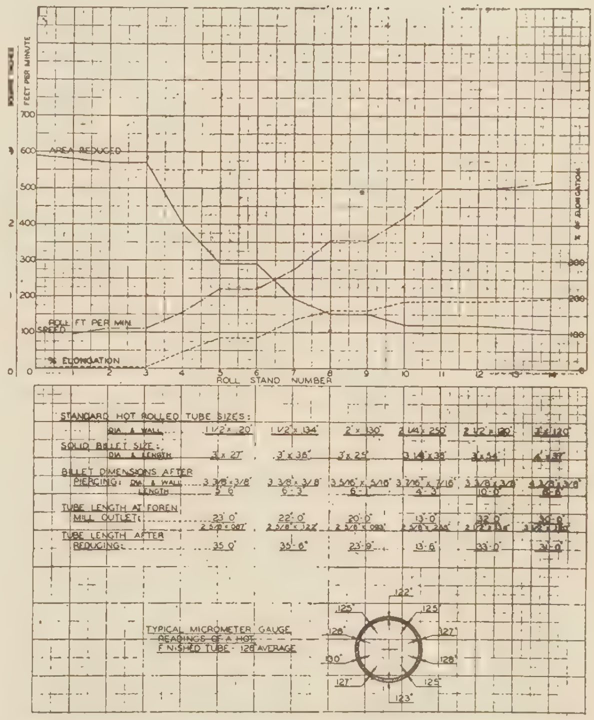

Fig. 8 Working Table of Hot-Rolled Tube Sizes, and Graph of Reduction in Area, Per Cent of Elongation, and Roll Speeds

Results Achieved

The results obtained have been gratifying because seamless tubes have been produced with walls as thin as 16 gage, which has not been accomplished by any other hot-rolling method.

All of the rolls can be completely changed from one groove diameter to another groove diameter in 4 hr, including the checking of all passes. To make a change in the wall gage requires only 15 min, as this involves changing only mandrel bars and speeds.

The capacity of this rolling unit together with its auxiliary equipment, including reducing mills, ranges from $1^1/_2$ in. OD to $4^1/_4$ in. OD in various gages. The process is not confined to rolling low-carbon steels, but will handle all alloys and stainless steels that can be successfully converted into tube stock.

From the standpoint of hot finish, tube-stock tubes produced on this mill are superior to those produced on the conventional plug-type rolling mill. By using a mandrel bar instead of a plug on the inside of the tube, a smooth inside diameter is assured. In general all tubing eventually becomes a container either for liquids or gases; hence a smooth interior finish is important. Another important advantage of smooth inside walls as well as a

smooth exterior is appreciated when this stock is to be used for further processing such as cold drawing. It has been found that reduction in diameter, as well as in wall thickness, can be increased and the die and mandrel life extended which results in better draw-bench capacity.

Tube lengths made on this type of mill are restricted only by the length of the mandrel bar providing all other auxiliary equipment is arranged for long lengths.

Production of Seamless Tubes on Present Foren Mill

In order to obtain a better understanding of this rolling unit and its auxiliary equipment, let us again refer to Fig. 7 showing the entire arrangement of the mill. The predetermined billet lengths of the proper grade of steel are stored in a yard which has been equipped with a chain conveyer to move the billets individually to a loading station. At this point the billet is automatically removed from the conveyer to a chain-driven billet elevator which conveys the steel to the inlet or charging end of the billet-heating furnace. This furnace is designed with an inclined hearth, which permits the billets to pass from the charging end to the discharge end by gravity. This oil-fired billet-heating furnace has a hearth 10 ft wide by 80 ft long, and is so arranged with heating zones that the steel will be heated to its required temperature gradually, thus assuring uniform temperature throughout.

At the discharge end of the furnace an automatic billet extractor, or pusher, is installed which is motor-operated and controlled by automatic timing. This extractor discharges each billet onto an inclined rollway from which it rolls into the inlet guide, or trough, to the Mannesman piercer. The inlet trough to the piercing mill is equipped with a pneumatic billet-inserting ram which forces the billet between the rolls of the piercing mill. The piercing mill engages the heated billet, passing it between the two rolls and the upper and lower guides and over the piercing mandrel, on through to the piercing-mill-outlet table, whereupon the piercing mandrel and its supporting bar are withdrawn pneumatically. No operator is required at the piercing mill, because the piercing mandrel, of patented design, does not require replacement and will pierce from 1000 to 1200 billets in normal operation without changing.

A pneumatically operated kickout conveys the hollow pierced billet to a table upon which is located a gate that turns the pierced billet through an arc of 90 deg. Again the pierced billet rolls onto an inclined table which conveys it to the entering table, or trough, immediately in front of the rolling unit. This entering trough is in line with a table on which the mandrel bar is conveyed. The bar is then moved forward through the pierced billet by a pneumatically operated ram. The movement is automatically controlled by limit switches, so arranged that the bar is inserted into the pierced billet to a predetermined position. In order that the friction of the inserting operation may not force a pierced billet into the entering rolls of the mill, a gate is installed at the mill entrance to restrict the movement of the billet and mandrel until the proper relative positions of billet and bar have been obtained. The gate is thereafter withdrawn by an air cylinder, equipped with automatic control, and both billet and mandrel bar enter the first set of rolls.

Having passed through the mill, the rolled billet, with the mandrel bar still inserted, is conveyed to the bar-extracting table. This table is designed to perform several operations. The tube and mandrel bar come to rest in their longitudinal travel just sufficiently long for a plier to engage the protruding end of the mandrel bar. At the moment this extracting plier engages and firmly grips the mandrel bar, a gate is simultaneously set in motion which holds the tube in place while the extracting plier withdraws the bar. Having withdrawn the bar from the tube the plier is immediately disengaged, whereupon the mandrel bar is automatically ejected from the conveyer rolls in the extracting table onto another conveyer which returns it to a point where it is loaded onto a transverse conveyer, which submerges it in a tank filled with cooling water. The moment that the mandrel bar has cleared the extracting table, the gate holding the tube is automatically released and the tube proceeds to travel longitudinally into a reheating furnace.

In the reheating furnace the temperature of the rolled tube is raised to a point which may be required for further processing. After the tube has acquired its proper temperature, it is extracted from the reheat furnace on conveyer rolls and enters a reducing mill having thirteen sets of roll stands. If the reduction in diameter through the first reducing mill is not sufficient, the tube is then conveyed to a second reducing mill capable of reducing the diameter to a minimum of $1^1/_2$ in. However, if the desired diameter is obtained in the first reducing mill, rollways and conveyers are so arranged that the tube can by-pass the second reducing mill, in which case it is deposited on a cooling table equipped with conveyer chains of such slow travel that it has sufficient time to cool before being conveyed to the inlet table of a straightening machine.

After the tube has passed through the straightening machine it is automatically ejected from the outlet table of the straightener and rolls onto inclined tables which carry it to the cutoff machines where it is cut to length and passed to the next operation which is the hydraulic test. Each tube is tested to a hydrostatic pressure of 1000 psi, carefully drained, and thereafter passed to the inspection tables for the last checkup of surface quality, wall gage, and other requirements for hot-finished tube material.

The rolling unit is not only used for hot-finished material, but a very large percentage of its output is further processed by the cold-drawing method to obtain small diameters and light gages. With the close hot-finish tolerances that are feasible, the advantage is marked when close tolerances and hot finish are required by the cold-drawing method.

After the mandrel bar has passed through the cooling tank with its temperature now reduced to normal, it is returned by a conveyer line to the storage rack parallel with the mandrel-bar-inserting table. In order that no delay may occur in the tube-rolling process, a sufficient number of mandrel bars are employed in order to maintain a supply of at least four at the inserting table.

Control of the Bar-Extracting Table

The numerous operations of the bar-extracting table have been so carefully interlocked by limit switches and pneumatic valves that no manual operations are required. In order to appreciate the complicated control thus involved let us consider the time required for the operations previously outlined. A billet with its mandrel bar, having a length of 40 ft, passes through the mill in 7 sec. Under normal operating conditions, a billet and mandrel bar enter the mill the moment the preceding billet and mandrel bar have cleared the mill. This means that the time is very short indeed in which the extracting plier must engage the bar and extract it from the tube, after which the bar must clear the extracting table, the tube must pass over it to the furnace, and the plier return to its original position ready to engage the next bar. These various operations are timed in fractions of a second and, being fully automatic, no manual labor is required. However, a technician is stationed at an extracting-table control desk on which are mounted all of the automatic controls, as well as independent push-button controls, so that he can perform any operation by individual control should an interruption in the rolling cycle occur.

The various operations of this mill have been carefully studied

and reduced to tabular form for use by the rolling-mill foreman. From these data he can adjust his cycles in accordance with the billet lengths, i.e., if a certain billet length requires the processing of four per minute without any lost time, he has a device at his desk which automatically controls the billet-extracting mechanism in the furnace. If he sets this timing device at four billets per minute, all that is required of the furnace operators is to have the heated billets at the inlet to the extractor, and the balance of the operations are fully automatic.

Operating Personnel

The operating force required for this rolling unit is very nominal. Three men are stationed at the billet-heating furnace. The next operator is on the control platform located at the junction of the piercing-mill-outlet table and the bar-inserting table. This operator manipulates push buttons and pneumatic valves which control the operations mentioned. Next in order is the technician stationed at the stripper table followed by two men at the reheating furnace. The reducing mills are in charge of two men. From the time it is discharged to the cooling table from the rolling mills, until it is conveyed to further processing operations, the tube is in the hands of the inspectors.

Thus the total operating force required on the rolling unit from the billet-heating furnace to delivery on the cooling bed consists of twelve men. In addition there is one man in charge of the lubricating systems on the various units, as well as general maintenance man who looks after details on the rolling unit should an interruption occur.

Controlling the Rolling-Mill Motors

In describing the Foren mill proper it was pointed out that each roll set is operated by an individual direct-current motor, connected to a motor generator set. This set and the controls for the motor and switch gear are located in a separate enclosure, in charge of an electrician. The electrician receives instructions from the rolling-mill foreman as to the size billet and tube to be rolled; from tables which have been computed from experience, he can then set the motor speeds required for the rolling operations. During normal periods after all motor speeds have been set, the operator is able to devote his time to the maintenance of all control equipment and other miscellaneous work on the various automatic controls built into the rolling unit. Thus whenever an interruption occurs because of failure of either electrical or mechanical equipment, skilled technicians are always on hand to correct the difficulties in the shortest possible time.

Conclusion

It will be obvious from the description given of this rolling unit that the entire layout is so designed that all of its operations come within the requirements of straight-line production. There is no movement of material which entails any backtracking. hence the process achieves virtually continuous tube production,

The Analysis of a Continuous Process by a Discontinuous Step Method

By J. A. HRONES,[1] CAMBRIDGE, MASS.

In this paper an attempt is made to predict the dynamic behavior of a simple heat exchanger by means of the hydraulic-thermal analog. The heat exchanger was subjected to a known input-temperature disturbance, and the resulting dynamic response of the output temperature was calculated and also measured. It was assumed that the physical conditions in the actual system could be approximated by considering the heat-exchanger tube to be divided into a number of sections; in the example carried through, three equal sections were considered. For purposes of calculation, the heat exchanger is represented by a hydraulic analog, in which the weight of fluid in a tank corresponds to the quantity of heat in an element of the system, the difference in pressure head is analogous to temperature difference, and the resistance of restrictions to fluid flow corresponds to resistance to heat flow in the thermal system.

The material presented in this paper is in the nature of a progress report of research being carried on as an extension of the program initiated by the papers of C. E. Mason, G. Philbrick, and A. Spitzglass.[2] In the work to be described, the hydraulic-thermal analog is used in an attempt to predict the dynamic behavior of a simple heat exchanger. Theoretical results based on the analog are compared with experimental observations.

The heat exchanger employed is shown in Fig. 1. It consisted of a glass coil immersed in a constant-temperature bath. Liquid of specific heat c flows at a constant rate of w pounds per minute through the coil, the entering temperature T_i being held at a constant value. When steady-state conditions are reached, w pounds per minute of the liquid leave at a constant exit temperature T. In the first trial it was assumed that the heat capacity of the glass tubing was so small that one half of it could be lumped with the capacity of the water in the exchanger tube and the other half lumped with the capacity of the bath. The enclosing container was very large relative to the tube, the contents of which were stirred during the process to produce a uniform temperature T_s throughout the bath. Thus the heat capacity of the bath could be considered to be infinite.

The exchanger described was subjected to a known input-temperature disturbance and the resulting dynamic response of the output temperature was calculated and also measured.

The exchanger may be represented as shown in Fig. 2. The variation in temperature along the tube would follow some curve similar to A, Fig. 2, for a constant input temperature T_a. For a constant input temperature T_b the steady-state temperature distribution would be represented by a curve similar to B of Fig. 2. If input and output temperatures are measured, the steady-state temperature distribution may readily be calculated by the well-established principles of heat transfer.

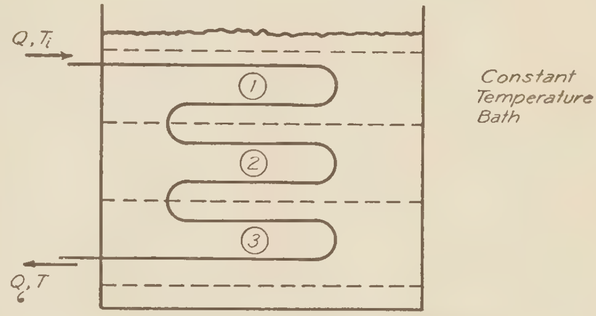

FIG. 1 TYPE OF HEAT EXCHANGER EMPLOYED

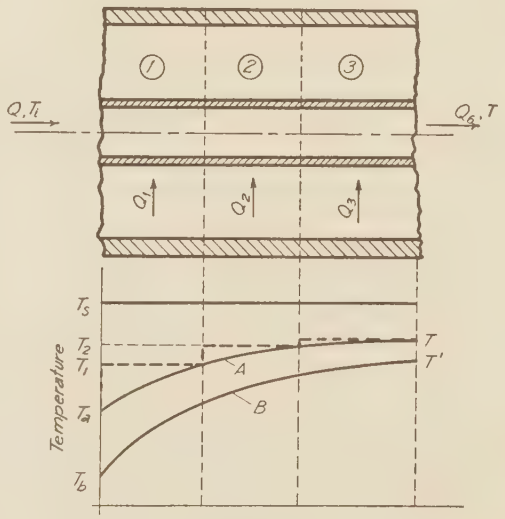

FIG. 2 REPRESENTATION OF HEAT-EXCHANGER AND TEMPERATURE CURVES

Determining Output Temperature Versus Time Relation

For a known input-temperature disturbance T_i, it is desired to determine the corresponding output temperature versus time relation. To demonstrate the method it was assumed that the physical conditions prevailing in the actual system could be approximated by considering the tube to be divided into a number of sections. As an example of the method, three equal sections will be considered, see Figs. 1 and 2.

In addition it was assumed that the temperature of the fluid in section (1) was T_1 throughout, that the temperature of the fluid in section (2) was T_2, and that the temperature of the fluid in section (3) was T throughout. This assumption means that

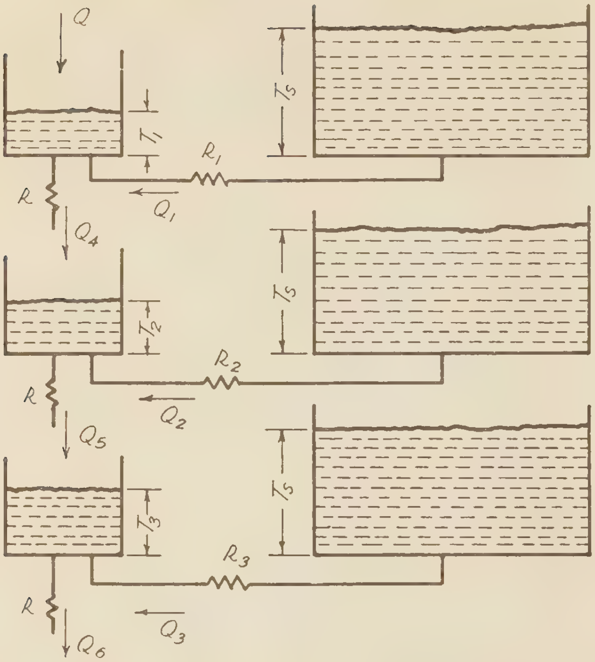

Fig. 3 Hydraulic Analog of Heat Exchanger

step jumps in temperature will occur at the ends of each section. This situation is inconsistent with the actual physical conditions. Nevertheless, the problem was solved on this basis with the results which are reported.

Under the foregoing assumptions, the heat exchanger may be represented by the hydraulic analog shown in Fig. 3, in which the weight of fluid in a tank corresponds to the quantity of heat in an element of the system, the difference in pressure head is analogous to temperature difference, and the resistance of restrictions to fluid flow corresponds to resistance to heat flow in the thermal system.

S represents a large storage reservoir with a constant pressure head T_s. This is the hydraulic equivalent of the thermal energy stored in the constant-temperature bath.

Tanks (1), (2), and (3) are small with respect to S and are fed from the main storage tank through restrictions having the resistances R_1, R_2, and R_3, respectively. For clarity of presentation the large storage tank is represented as three separate units, all having the same pressure head T_s. The weight of water contained in tank (1) corresponds to the heat-energy content of the water in section (1) of the heat exchanger. The pressure head of tank (1) is analogous to the temperature of section (1). Tanks (2) and (3) hold similar positions in the analogy with respect to sections (2) and (3). The resistance R_1 corresponds to the over-all thermal resistance of section (1) between the liquid of the bath and that flowing through the exchanger tube. R_2 and R_3 have the same significance with respect to sections (2) and (3). The resistance R determines the flow of thermal energy from one section to the following section and is a function of the rate of flow through the tube.

To make the analogy complete a linear relationship between rate of flow and pressure difference was assumed. Thus

$$Q_1 = \frac{T_s - T_1}{R_1}$$

where Q_1 is the flow per unit time from the storage tank (1). Under the assumptions previously mentioned the areas of the tanks (1), (2), and (3) were considered equal to the thermal capacity of the water in each section (Wc) plus one half of the thermal capacity of the glass wall of the section.

From a consideration of the rate of flow to and from tank (1), (2), and (3), the following equations can be written

$$a_1 \frac{dT_1}{dt} + \left(\frac{1}{R_1} + \frac{1}{R}\right) T_1 = \frac{T_i}{R} + \frac{T_s}{R_1} \qquad [1]$$

where $a_1 \dfrac{dT_1}{dt}$ = rate of change of fluid within tank (1)

$\dfrac{Ti}{R}$ = rate of flow of fluid into tank (1) from source

$\dfrac{T_s - T_1}{R_1}$ = rate of fluid flow from storage tank

$\dfrac{T_1}{R}$ = rate of fluid flow into following tank (2)

Similar quantities with subscripts $_2$ and $_3$ represent corresponding quantities for the other tanks as follows

$$a_2 \frac{dT_2}{dt} + \left(\frac{1}{R_2} + \frac{1}{R}\right) T_2 - \frac{T_1}{R} = \frac{T_s}{R_2} \qquad [2]$$

$$a_3 \frac{dT_3}{dt} + \left(\frac{1}{R_3} + \frac{1}{R}\right) T - \frac{T_2}{R} = \frac{T_s}{R_3} \qquad [3]$$

If these three equations are solved for T, the following third-order differential equation is obtained

$$\frac{d^3T}{dt^3} + A\frac{d^2T}{dt^2} + B\frac{dT}{dt} + HT = D\frac{d^2T_s}{dt^2} + E\frac{dT_s}{dt} + FT_s + GT_i \qquad [4]$$

where T_i is the input temperature. The complete solution for Equation [4], together with the values for the coefficients, is included in the Appendix.

The general solution of Equation [4] is

$$T = T_{ss} + K_1e^{-t/\tau_1} + K_2e^{-t/\tau_2} + K_3e^{-t/\tau_3} + C_4\Delta T_i \qquad [5]$$

Where T_{ss} is the steady-state exit temperature and ΔT_i is a function of time and represents the difference between the steady-state value of input temperature and the input temperature at any time t. τ_1, τ_2, and τ_3 are the characteristic times of sections (1), (2), and (3), respectively, and are given by the following equations

$$\frac{1}{\tau_1} = +\frac{1}{a_1}\left[\frac{1}{R_1} + \frac{1}{R}\right] \qquad [6]$$

$$\frac{1}{\tau_2} = +\frac{1}{a_2}\left[\frac{1}{R_2} + \frac{1}{R}\right] \qquad [7]$$

$$\frac{1}{\tau_3} = +\frac{1}{a_3}\left[\frac{1}{R_3} + \frac{1}{R}\right] \qquad [8]$$

If, as assumed, all sections are equal, then the characteristic times are equal and Equation [5] takes the following form

$$T = T_{ss} + C_4\Delta T_i + (K_1 + K_2t + K_3t^2)e^{-t/\tau_1} \qquad [9]$$

When steady-state conditions are reached, Equation [4] becomes

$$T_{ss} = \frac{F}{H}T_s + \frac{G}{H}T_i \qquad [10]$$

$$\text{where}\left\{\begin{aligned} &\frac{G}{H} = \left(\frac{\frac{1}{R}}{\frac{1}{R_1} + \frac{1}{R}}\right)^3 \\ &\frac{F}{H} = 1 - \frac{G}{H} \end{aligned}\right\} \text{for case where } R_1 = R_2 = R_3$$

T_s is the bath temperature; T_{if} is the steady-state input temperature. If all sections are assumed equal and the over-all resistance per unit length of the tube does not vary substantially over the temperature range involved, then $R_1 = R_2 = R_3$. It should also be observed that any transfer of heat between particles of the liquid flowing through the tube is neglected.

The values of T_{ss}, T_s, and T_{if} were observed and R_1 was calculated from Equation [10]. An attempt was then made to impose a step jump in input temperature to the heat exchanger. However, due to experimental difficulties this was temporarily given up and the actual input temperature–time relation given by a quick opening three-way valve was measured. The observed data were closely fitted by the following equation

$$T_i = T_{if} - (T_{if} - T_{i0})e^{-t/\tau_F} \quad \text{[11]}$$

Where T_{i0} is the steady-state value of input temperature at time $t < 0$. τ_F is the characteristic time of the input-temperature disturbance.

If Equation [11] is substituted in Equation [4] and a solution for T is obtained (see Appendix) the result is

$$T = T_{ss} + C_4 e^{-t/\tau_F} + e^{-t/\tau_1}[K_1 + K_2 t + K_3 t^2] \quad \text{[12]}$$

The coefficients may be determined by using the relations when $t = 0$

$$\left.\begin{aligned} T_0 &= T_{ss} + K_1 + C_4 \\ \frac{dT}{dt} &= 0 \\ \frac{d^2T}{dt^2} &= 0 \end{aligned}\right\} \quad \text{[13]}$$

Thus

$$K_1 = T_0 - T_{ss} - C_4$$

$$K_2 = +\left(\frac{C_4}{\tau_F} + \frac{K_1}{\tau_1}\right)$$

$$K_3 = -\frac{C_4\left(\frac{1}{\tau_F}\right)^2 + K_1\left(\frac{1}{\tau_1}\right)^2 - 2K_2\left(\frac{1}{\tau_1}\right)}{2}$$

$$C_4 = \left[\frac{1}{a_1 R\left(\frac{1}{\tau_1} - \frac{1}{\tau_F}\right)}\right]^3 [T_{i0} - T_{if}]$$

where $\frac{1}{R} = wc$ Btu per deg F per min. The result of this analysis is shown as curve B, Fig. 4, and was obtained from Equation [13a].

$$T = 64 + 274e^{-11t} - [224 + 2720t + 12{,}580t^2]e^{-25.6t} \quad \text{[13}a\text{]}$$

Curve C, Fig. 4, is a plot of the observed output behavior. Similar calculations were carried out for one, two, and four equal sections, the results of which are shown in Fig. 5. Expressions for any number of equal sections n were also derived and are presented as follows:

$$T = T_{ss} + C_4 e^{-t/\tau_F} + (K_1 + K_2 t + K_3 t^2 + \ldots K_n t^{n-1})e^{-t/\tau_1} \quad \text{[14]}$$

$$C_4 = \left[\frac{1}{aR\left(\frac{1}{\tau_F} - \frac{1}{\tau_1}\right)}\right]^n [T_{i0} - T_{if}] \quad \text{[15]}$$

$$\frac{1}{R_1} = \frac{1}{R}\left[1 - \left(\frac{T_{ss} - T_s}{T_{if} - T_s}\right)^{1/n}\right] \quad \text{[16]}$$

$$\frac{1}{\tau_1} = -\frac{1}{a_1}\left(\frac{1}{R_1} + \frac{1}{R}\right) \quad \text{[17]}$$

$$K_1 = T_0 - T_{ss} - C_4 \quad \text{[18]}$$

$$K_n = -\left[\frac{C_4\left(-\frac{1}{\tau_F}\right)^{n-1} + K_1\left(-\frac{1}{\tau_1}\right)^{n-1}}{(n-1)!} + \frac{\left(-\frac{1}{\tau_1}\right)^{n-2}}{(n-2)!}K_2 + \frac{\left(-\frac{1}{\tau_F}\right)^{n-3}}{(n-3)!}K_3 + \ldots\ldots \left(-\frac{1}{\tau_1}\right)K_{n-1}\right] \quad \text{[19]}$$

Conclusions

For the case of the three equal sections, curve B, Fig. 4, is the calculated result. There are marked deviations from the experimental results shown by curve C. Although the general outline is reasonably well matched, the sharpness of the initial lag is not accurately predicted. The time to reach substantially steady-state exit-temperature conditions is accurately shown although the calculated response between 0.15 and 0.5 min is in considerable error. The sharpness of the initial effect on the output temperature or the lag is more accurately predicted as more sections are used in the solution. To show the trend of results as more sections are employed additional calculations were made for one, two, and four equal sections. The results are plotted in Fig. 5 where the experimental data are again reproduced as curve A. Increasingly better prediction of the lag is obtained as more sections are used. The improvement in the latter part of the response is small.

The failure of the calculated results to match experimentally determined values could be caused by a combination of the following reasons:

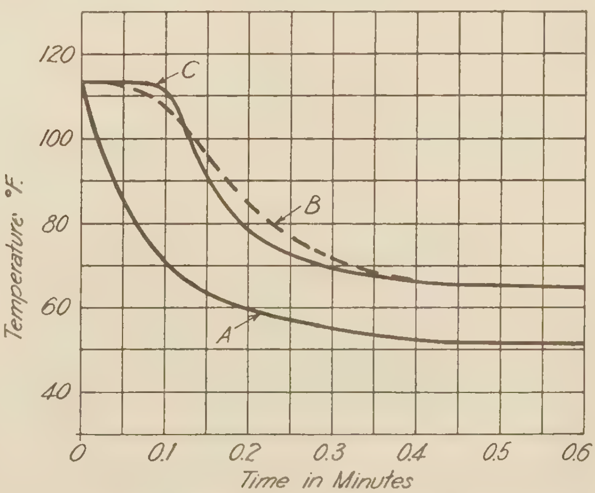

Fig. 4 Observed Output Behavior for Case of Three Equal Sections

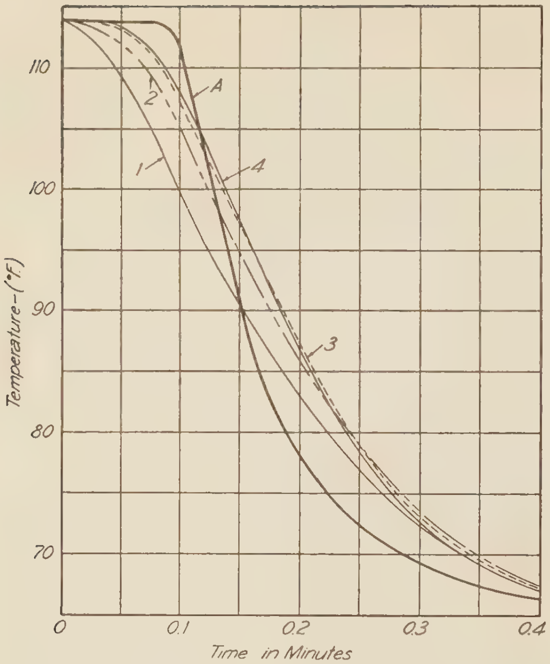

Fig. 5 Curves for One, Two, and Four Equal Sections

1 Instrument lag and errors.
2 Errors in making observations of temperature and time.
3 The choice of an insufficient number of sections.
4 Improper choice of the size of the sections.
5 The simplified analogy is not representative of the actual system.

The response of the temperature-measuring system to a step function is substantially exponential. The characteristic time was about 1.25 sec. This means that transient effects from a step function should become negligible in an interval between 3 and 4 sec. A forced response delay would be present after the transient is over. However, in the present case, instrument errors would have changed the observed effects in a fashion to improve the agreement between experimental and theoretical results. It is reasonable to conclude that the discrepancy was not due to instrument errors.

The time intervals involved were small and the rate of change of temperature rapid. A series of readings on identical runs indicated that the error at points where the curve was changing rapidly could be as great as 4 deg F. The plotted results are the average of three readings where the maximum deviation was 4 deg.

As already pointed out, the choice of a larger number of sections produces increasingly better results. However, the net improvement in the second half of the dynamic-response prediction is small and there is considerable doubt that even a very large number of sections would produce the accuracy that might be desired.

Finally, the inaccuracies may result because the simplified analog employed does not represent the process as closely as it should. The capacity of the exchanger tube wall was lumped with those of the section and the storage tank. If this wall capacity is introduced as a separate energy-storage tank, the analogy for section (1) becomes the one illustrated in Fig. 6. The storage capacity of the tube wall is represented by the tank w having an area a_w which corresponds to the heat capacity of

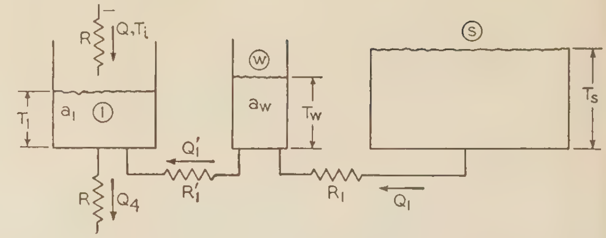

Fig. 6 Analogy for Section (1) When Wall Capacity Is Introduced as Separate Energy-Storage Tank

the tube wall per deg F. T_w represents the temperature of the tube wall. Thus each section of the tube would now be described by a differential equation of second order instead of the first-order one used in the former analogy. This will increase the difficulty of solution but the exit-temperature response may be readily calculated by first solving equations for T_1.

$$\left.\begin{aligned} a_1\frac{dT_1}{dt} &= \frac{T_i}{R} + \frac{T_w - T_1}{R_1'} - \frac{T_1}{R} \\ a_w\frac{dT_w}{dt} &= \frac{T_s - T_w}{R_1} - \frac{T_w - T_1}{R_1'} \end{aligned}\right\} \ldots\ldots [19a]$$

T_1 may then be used as a forcing function for section (2) and the procedure repeated for each section used.

It is hoped that the results of such calculations will soon be available.

Appendix

Nomenclature

c = specific heat, Btu per lb per deg F
w = rate of flow through exchanger, lb per min
T_i = entering temperature at time t, deg F
T = exit temperature at time t, deg F
T_s = temperature of bath, deg F
T_1, T_2, T_3 = temperature of water in sections (1), (2), and (3), respectively, deg F
R_1, R_2, R_3 = over-all thermal resistances of sections (1), (2) and (3), respectively, $\frac{\text{min, deg F}}{\text{Btu}}$
$R = \frac{1}{wc}$ equivalent thermal resistance between the sections $\frac{\text{min, deg F}}{\text{Btu}}$
W = weight of water in each section, lb
a_1, a_2, a_3 = thermal capacities of sections (1), (2), and (3), respectively, Btu per deg F
T_{ss} = steady-state output temperature, deg F, when $t > 0$
T_0 = steady-state output temperature, deg F, when $t < 0$
τ_1, τ_2, τ_3 = characteristic times for sections (1), (2), and (3), respectively, min
T_{if} = steady-state input temperature, deg F, when $t > 0$
T_{i0} = steady-state input temperature, deg F, when $t < 0$
τ_F = characteristic time of input-temperature disturbance, min

Calculation of Results

The Equations [1] to [3], inclusive, are rewritten using the operator p to represent $\frac{d}{dt}$.

$$\left(a_1p + \frac{1}{R_1} + \frac{1}{R}\right) T_1 = \frac{T_s}{R_1} + \frac{T_i}{R} \quad \text{[20]}$$

$$\left(a_2p + \frac{1}{R_2} + \frac{1}{R}\right) T_2 - \frac{T_1}{R} = \frac{T_s}{R_2} \quad \text{[21]}$$

$$\left(a_3p + \frac{1}{R_3} + \frac{1}{R}\right) T - \frac{T_2}{R} = \frac{T_s}{R_3} \quad \text{[22]}$$

Using the method of determinants, the solution for T is readily found

$$T = \frac{\Delta_2}{\Delta_1} \quad \text{[23]}$$

where

$$\Delta_2 = \begin{vmatrix} \left(a_1p + \frac{1}{R_1} + \frac{1}{R}\right) & 0 & \left(\frac{T_i}{R} + \frac{T_s}{R_1}\right) \\ -\frac{1}{R} & \left(a_2p + \frac{1}{R_2} + \frac{1}{R}\right) & \frac{T_s}{R_2} \\ 0 & -\frac{1}{R} & \frac{T_s}{R_3} \end{vmatrix}$$

$$\Delta_1 = \begin{vmatrix} \left(a_1p + \frac{1}{R} + \frac{1}{R}\right) & 0 & 0 \\ -\frac{1}{R} & \left(a_2p + \frac{1}{R_2} + \frac{1}{R}\right) & 0 \\ 0 & -\frac{1}{R} & \left(a_3p + \frac{1}{R_3} + \frac{1}{R}\right) \end{vmatrix}$$

therefore

$$T = \frac{\frac{1}{a_1a_2a_3}\Delta_2}{\left[p + \frac{1}{a_1}\left(\frac{1}{R_1} + \frac{1}{R}\right)\right]\left[p + \frac{1}{a_2}\left(\frac{1}{R_2} + \frac{1}{R}\right)\right]\left[p + \frac{1}{a_3}\left(\frac{1}{R_3} + \frac{1}{R}\right)\right]} \quad \text{[24]}$$

The denominator of Equation [24] is the characteristic equation of the process and has the roots $-\frac{1}{\tau_1}$, $-\frac{1}{\tau_2}$, and $-\frac{1}{\tau_3}$ given in Equations [6], [7], and [8]. The expansion of Equation [24] gives

$$\frac{d^3T}{dt^3} + A\frac{d^2T}{dt^2} + B\frac{dT}{dt} + HT = D\frac{d^2T_s}{dt^2} + E\frac{dT_s}{dt} + FT_s + GT_i \quad \text{[25]}$$

The coefficients are

$$A = +\left(\frac{1}{\tau_1} + \frac{1}{\tau_2} + \frac{1}{\tau_3}\right) \quad \text{[26]}$$

$$B = \frac{1}{\tau_1\tau_2} + \frac{1}{\tau_2\tau_3} + \frac{1}{\tau_3\tau_1} \quad \text{[27]}$$

$$H = +\frac{1}{\tau_1\tau_2\tau_3} \quad \text{[28]}$$

$$D = \frac{1}{a_3R_3} \quad \text{[29]}$$

$$E = \frac{1}{a_2a_3R_2R} + \frac{1}{a_3R_3}\left[\frac{1}{\tau_1} + \frac{1}{\tau_2}\right] \quad \text{[30]}$$

$$F = \frac{1}{a_3R_3\tau_1\tau_2} + \frac{1}{\tau_1a_2a_3RR_2} + \frac{1}{a_1a_2a_3R^2R_1} \quad \text{[31]}$$

$$G = \frac{1}{a_1a_2a_3R^3} \quad \text{[32]}$$

The bath temperature is constant

$$\therefore \frac{d^2T_s}{dt} = \frac{dT_s}{dt} = 0$$

Thus the solution for Equation [25] becomes

$$T = T_{ss} + K_1e^{-t/\tau_1} + K_2e^{-t/\tau_2} + K_3e^{-t/\tau_3} + C_4\Delta T_i \quad \text{[33]}$$

If equal sections are used, the characteristic times τ_1, τ_2, and τ_3 become equal and the solution is

$$T = T_{ss} + C_4e^{-t/\tau_F} + [K_1 + K_2t + K_3t^2]e^{-t/\tau_1} \quad \text{[34]}$$

where the initial conditions are

$$T_0 = T_{ss} + K_1 + K_4$$

$$\frac{dT}{dt} = 0$$

$$\frac{d^2T}{dt} = 0$$

The coefficients are found to be

$$K_1 = T_0 - T_{ss} - C_4 \quad \text{[35]}$$

$$K_2 = \frac{C_4}{\tau_F} + \frac{K_1}{\tau_1} \quad \text{[36]}$$

$$K_3 = -\frac{\frac{C_4}{\tau_F^2} + \frac{K_1}{\tau_1^2} - 2\frac{K_2}{\tau_1}}{2} \quad \text{[37]}$$

$$C_4 = \left[\frac{1}{a_1R\left(\frac{1}{\tau_1} - \frac{1}{\tau_F}\right)}\right]^3 [T_{i0} - T_{if}] \quad \text{[38]}$$

If the foregoing procedure is repeated for n equal sections, the general Equations [14] to [19] are obtained.

Heat-Exchanger Data

Length of tube, in.	32
Inside diameter of glass tube, mm	9
Outside diameter of glass tube, mm	12
Temperature of bath (T_s), deg F	114
Steady-state input temperature (T_{if}), deg F	50.5
Steady-state input temperature (T_{i0}), deg F, $t < 0$	114
Rate of water flow through exchanger (w), lb per min	0.965
Steady-state output temperature (T_{ss}), deg F	64
Input temperature–time function (T_i)	$50.5 + 63.5e^{-11t}$

For these data:

$$T = 64 + 274e^{-11t} - (224 + 2720t + 12{,}580t^2)e^{-25.6t}$$

The values of coefficients for one, two, three, and four equal sections are listed in Table 1.

TABLE 1 SUMMARY OF CALCULATED RESULTS

Number equal sections chosen	Capacity of each section, Btu per deg F	Resistance of section, Btu per deg F per min	Root of characteristic equation, (1/min)	C_4	K_1	K_2	K_3	K_4

Discussion

J. J. Grebe.[3] The work done by the author, both experimentally and mathematically, is very much worth reporting and should not be apologized for. It has shown that the lag due to transferring materials or energy through a resistance or a series of resistances and capacities results in a response curve of the familiar *S*-curve shape. What is more, it shows that this transfer or head lag can easily be resolved into an equivalent amount of velocity-distance lag, or dead time and a straight storage or capacity lag.

The fact that the theoretical curves, based on incomplete assumptions, do not exactly check the experimental data does not detract from the fact that the analysis accounts for the major portion of the observed function. A maintenance man should be able to operate a heat-interchange system from the observations on the response curves. He should be able to tell how much fouling of the surfaces there might be.

G. A. Philbrick.[4] It may add to the utility of the author's fine exposition to add an extension of the method used by him to model systems having a somewhat larger number of sections. While it might seem that an exact method, using a continuous model, would be preferable to the use of a large number of "lumps," this is not the case when simulating machinery of the discontinuous variety is available.

If a model with n sections is considered, the generic-level equation for the jth and kth sections, using the symbols of the paper, may be written operationally as

$$T_k = \frac{R}{R + R_k} T_s + \left[\frac{R + R_k}{R_k} + aRp\right]^{-1} \cdot T_j$$

Passing to the over-all relationship and applying the external conditions considered, yields with the aid of the shifting rule

$$T_n = T = T_s + (T_{if} - T_{i0})[\alpha^n(1 + \alpha\gamma p)^{-n} - \beta^n \epsilon^{-t/\tau f}(1 + \beta\gamma p)^{-n}]\cdot I(t)$$

where

$$\alpha = \frac{R_k}{R + R_k};\ \beta = 1\bigg/\left[\frac{1}{\alpha} - \frac{\gamma}{\tau_f}\right];\ \gamma = aR;\ I(t) = \text{unit step-}$$

function.

Computation of the result involves evaluation of a pair of definite integrals of the form

$$\int_0^t \frac{i}{(n - i)!} \frac{t^{n-i}}{(\alpha\gamma)^n} \epsilon^{-\left(\frac{t}{\alpha\gamma}\right)} dt$$

which is formidable if attacked straightforwardly. If, however, the integrand itself is evaluated (as a function of time), and a simple Simpson integration performed, the work is not great.

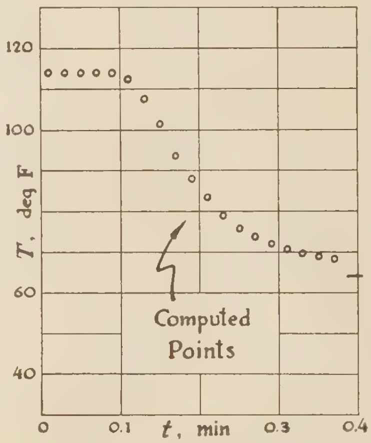

Fig. 7 Operational Result for Twenty-One Equal Sections

Such a solution has been carried out for $n = 21$ (21 sections), and the response is shown in Fig. 7 of this discussion. A corresponding solution by classical methods would be enormously more tedious.

As is evident in Fig. 7, and by comparison with the experimental curve shown in the paper, the initial delay in the response of the output temperature is reproduced rather faithfully. The divergence from the experimental curve is very nearly representable as a stretching of the time dimension, and this could be accounted for by irregularities in the data which were not as consequential in the $n = 4$ solution.

Author's Closure

Mr. Grebe's discussion indicates the industrial usefulness of the results obtained. It is hoped that further correlation of the results of simplified mathematical analyses and empirical data will lead to a wider application of the rational mathematical solution of control problems.

Mr. Philbrick's extension of the mathematics of the paper is a very interesting and valuable one. In order to render comparison easier, the results obtained by dividing the heat exchanger into twenty-one sections by Mr. Philbrick have been reproduced in Fig. 8 together with observed empirical results and calculated values for four equal sections. The calculated response based on twenty-one equal sections follows the observed data, curve A, rather closely. The initial lag is very closely reproduced. The divergence at higher time values is more marked. However, it will be noted that while the curve based on twenty-one equal sections predicts the observed result during the initial stages with considerably more accuracy than the calculations based on four equal sections, little improvement results at higher time values.

Optimum Settings for Automatic Controllers

By J. G. Ziegler[1] and N. B. Nichols,[2] Rochester, N. Y.

In this paper, the three principal control effects found in present controllers are examined and practical names and units of measurement are proposed for each effect. Corresponding units are proposed for a classification of industrial processes in terms of the two principal characteristics affecting their controllability. Formulas are given which enable the controller settings to be determined from the experimental or calculated values of the lag and unit reaction rate of the process to be controlled. These units form the basis of a quick method for adjusting a controller on the job. The effect of varying each controller setting is shown in a series of chart records. It is believed that the conceptions of control presented in this paper will be of assistance in the adjustment of existing controller applications and in the design of new installations.

A PURELY mathematical approach to the study of automatic control is certainly the most desirable course from a standpoint of accuracy and brevity. Unfortunately, however, the mathematics of control involves such a bewildering assortment of exponential and trigonometric functions that the average engineer cannot afford the time necessary to plow through them to a solution of his current problem.

It is the purpose of this paper to examine the action of the three principal control effects found in present-day instruments, assign practical values to each effect, see what adjustment of each does to the final control, and give a method for arriving quickly at the optimum settings of each control effect. The paper will thus first endeavor to answer the question: "How can the proper controller adjustments be quickly determined on any control application?" After that a new method will be presented which makes possible a reasonably accurate answer to the question: "How can the setting of a controller be determined before it is installed on an existing application?"

Except for a single illustrative example, no attempt will be made to present laboratory and field data, to develop mathematical relations, or to make acknowledgment of material from published literature. A paper covering the mathematical derivations would be quite lengthy as would also a paper covering laboratory and field-test results. Work on these phases of the subject is still under way, and it is expected that the results will be published at a later time when convenient. It is believed advisable to publish the present paper without delay in order to make the information available for use by the many persons interested in the application of automatic-control instruments. To these persons the present subject matter is of much greater interest than the other phases of the study which are being omitted.

To simplify terminology we will take the most common type of control circuit in which a controller interprets the movement of its recording pen into a need for corrective action, and, by varying its output air pressure, repositions a diaphragm-operated valve. The controller may be measuring temperature, pressure, level, or any other variable, but we will completely divorce the measurement portion of the control circuit and speak only of the pen movement in inches; 1 in. of pen movement might represent 1 or 1000 deg F, or a flow of 1 or 1000 gpm. The actual graduation will be of no moment in a study of control.

Our controller will translate pen behavior into behavior of a valve; the relation between the two behavior patterns is determined by the setting of each control effect. The term valve covers any similar device, i.e., a damper or rheostat which must be operated by the controller in order to maintain correct process conditions.

Proportional Response

In spite of the multitude of air, liquid, and electrically operated controllers on the market, all are similar in that they incorporate one, two, or at most three quite simple control effects. These three can be called "proportional," "automatic reset," and "pre-act."

Proportional Response. By far the most common effect is "proportional response," found in practically all controllers. It gives a valve movement proportional to the pen movement, that is, a 2-degree pen movement gives twice as much valve movement as a 1-degree pen movement. Simple spring-loaded pressure-reducing valves are really proportional-response controllers in that, over a short range of pressure, the valve is moved proportionally from one extreme to the other.

Sensitivity. The measure of proportional response is called "sensitivity" or "throttling range;" the former being valve movement per pen movement, the latter its reciprocal or the pen movement necessary to give full valve movement. Either sensitivity or throttling range describes the magnitude of proportional response, though in this paper each response will be measured in units which increase as the relative valve action per pen action increases. In the case of proportional response, the unit will accordingly be called "sensitivity."

Proportional-response sensitivity in some controllers is not adjustable; in most, however, it may be adjusted either continuously or in steps over a considerable range. If we define sensitivity as the output pressure change per inch of pen travel, it is apparent that the limits would be from zero (manual control) to infinitely high (on-off control). Perhaps the widest range of adjustment is found in one controller with sensitivity continuously variable from 1000 to 1 psi per in. A sensitivity of 1000 gives 1 psi output change for each 0.001 in. of pen travel.

Sensitivity adjustment is necessary if optimum control stability is to be attained. It is common knowledge that control with infinitely high proportional response is always unstable, oscillating continuously. True, on certain applications the oscillation may be of such small magnitude that it is not objectionable and, if the surges in supply are not serious in their effect on other portions of the process, the control obtained may be entirely acceptable.

Industry generally demands control of the "throttling" type rather than "on-off" since a proportional-response controller, set in any sensitivity below some maximum, will produce a damped oscillation and eventually straight-line control.

Amplitude Ratio. Sensitivity adjustment affects primarily the stability of control. On any application there is a definite and

[2] Engineering Research Department, Taylor Instrument Companies.

Contributed by the Committee on Industrial Instruments and Regulators of the Process Industries Division and presented at the Annual Meeting, New York, N. Y., December 1–5, 1941, of The American Society of Mechanical Engineers.

easily determined point called the "ultimate sensitivity" (S_u), above which any oscillation will increase to some maximum amplitude, and below which an oscillation of any size will diminish to straight-line control. Stability may be measured in terms of "amplitude ratio," the relative amplitude of any wave to that of the wave which preceded it. A controller set at the ultimate sensitivity gives an oscillation with an amplitude ratio

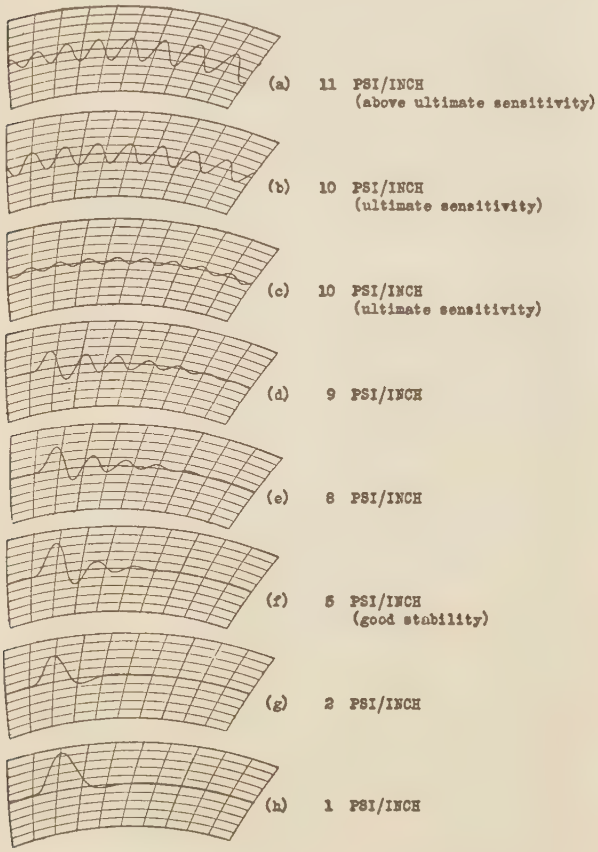

Fig. 1 Amplitude Ratio Versus Sensitivity
(Effect of disturbance.)

of 1; above the ultimate sensitivity, an amplitude ratio greater than 1; and below the ultimate, an amplitude ratio less than 1.

Amplitude Ratio Versus Sensitivity. Fig. 1 shows the effect of sensitivity adjustment on a typical application. The oscillation was started by a momentary change in valve position. Curves (*b*) and (*c*) were produced at the ultimate sensitivity, which in this case was 10 psi per in. Curve (*a*) was produced at a sensitivity of 11 psi per in. (110 per cent of S_u). Curves (*d*) to (*h*) show the successively smaller amplitude ratios produced as the sensitivity was lowered to 90, 80, 50, 20, and 10 per cent of the ultimate (9, 8, 5, 2, and 1 psi per in.).

In Fig. 1 and succeeding charts, each division is 0.1 in. and each time interval represents 0.625 min.

Regardless of the ultimate sensitivity of any control application, the relationship between amplitude ratio and sensitivity, given as per cent of ultimate sensitivity, remains about as shown in Fig. 2. The ultimate sensitivity thus appears to be a good common point for consideration of sensitivity adjustment on most control applications.

Offset and Load Change. In considering the curves of Fig. 1, the most desirable setting from a stability standpoint would be (*h*), produced at quite a low sensitivity (10 per cent of ultimate). It should be noted in passing, however, that as sensitivity is reduced the period of oscillation increases slightly, which in itself is undesirable. The real drawback of using sensitivity settings a great deal lower than the ultimate value stems from the limitation of proportional response, e.g., that only one valve position can be maintained when the pen is at the desired set point. A "load change," any disturbance in the process requiring a sustained alteration of valve position, will cause the pen to shift away from the set point far enough to give the required valve movement. The magnitude of this shift or "offset" varies inversely with the sensitivity setting used and directly with the required change in

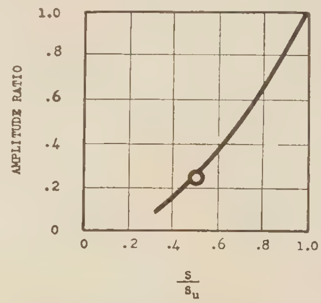

Fig. 2 Amplitude Ratio Versus Sensitivity

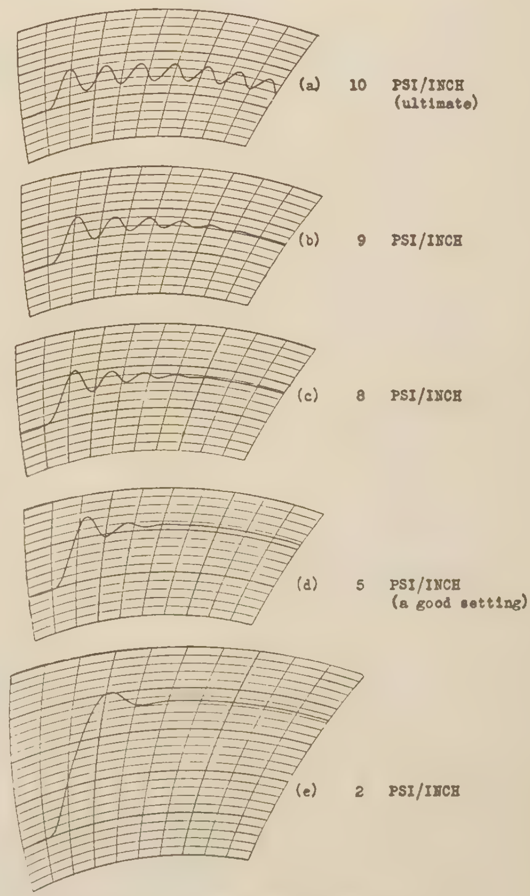

Fig. 3 Offset Versus Sensitivity
(Effect of load change.)

valve position. Fig. 3, curves (*a*) to (*e*), illustrates this point. Curve (*a*) shows the offset caused by a load change requiring a 2.8 psi change in output pressure with sensitivity at 10 psi per in. Since this is the ultimate setting, an amplitude ratio of 1 results and a lower setting is indicated. As the sensitivity is decreased to 9, 8, 5, and then 2 psi per in., the offset from this load change increases and the amplitude ratio decreases.

Amplitude Ratio Versus Offset. The rational adjustment of proportional-response sensitivity is then simply a matter of balancing the two evils of offset and amplitude ratio. For most applications a good compromise is the sensitivity which gives an amplitude ratio of 25 per cent. This sensitivity will be very nearly one half that of the ultimate sensitivity, as shown in Fig. 2. An excellent and rapid method of sensitivity adjustment is to find the ultimate sensitivity and then simply cut it in half. Fig. 1, curve (*f*), shows that an amplitude ratio of 25 per cent is achieved by this setting on the application under test. Fig. 3, curve (*d*), shows the result of a load change requiring a 2.8 psi change in controller output pressure. The sensitivity setting of 5 psi per in. allows an offset of 2.8/5 or 0.56 in. with a 25 per cent amplitude ratio.

On most air-operated controllers, the sensitivity adjustment is calibrated either in terms of sensitivity or throttling range. On such instruments the trick of halving the sensitivity to obtain a good setting is quite simple; on those calibrated in throttling range the setting should be doubled, since this unit is the reciprocal of sensitivity. The sensitivity of older instruments with arbitrary adjustment scales may be easily found by moving the pen a definite distance and noting the resulting output-pressure change. This test run at a few points will enable the user to plot a sensitivity-conversion scale.

The statement that a sensitivity setting of one half the ultimate with attendant 25 per cent amplitude ratio gives optimum control must be modified in some cases. At times a lower sensitivity is preferable. For example, the actual level maintained by a liquid-level controller might not be nearly as important as the effect of sudden valve movements on further portions of the process. In this case the sensitivity should be lowered to reduce the amplitude ratio even though the offset is increased by so doing. On the other hand, a pressure-control application giving oscillations with very short period could be set to give an 80 or 90 per cent amplitude ratio. Due to the short period, a disturbance would die out in a reasonable time, even though there were quite a few oscillations. The offset would be reduced somewhat though it should be kept in mind that it can never be reduced to less than one half of the amount given at our previously defined optimum sensitivity of one half the ultimate.

On processes involving wide changes in load, one condition is often encountered which must be considered here. A controller perfectly adjusted for one load condition may start oscillating under another load. If the ultimate sensitivity is checked at the new more difficult load, it will be found lower than at the original easy load condition. Consequently, the sensitivity must always be adjusted so that the correct stability is achieved under the most difficult load condition. Obviously the amplitude ratio will then be lower at the easy load.

Automatic-Reset Response

The second most common response found in modern controllers is "automatic reset." Its only purpose is to eliminate offset. In action it detects any disparity between pen and set point and gives a slow continuous valve movement in the proper direction to correct the offset. Furthermore, the rate of valve movement is proportional to the distance between pen and set point. Automatic reset then may be defined as a response giving valve velocity proportional to pen displacement from set point.

Some controllers give a constant valve velocity with the direction depending upon whether the pen is above or below the set point. This is a special case and will not be considered further. Neither will those controllers having automatic reset alone (floating response) be considered in this paper. It appears that the floating response controller is most useful on partially "self-controlling" processes.

Reset Rate. As sensitivity was the measure of proportional response, "reset rate" becomes the corresponding measure of automatic-reset response. The units of reset rate are minutes^{-1} or the number of times per minute that automatic reset duplicates the proportional-response correction caused by the disparity between pen and set point.

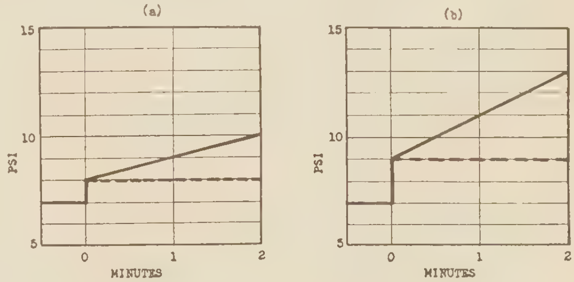

Fig. 4 Reset Rate
(Reset rate = 1 per min.)

Fig. 4(*a*) and (*b*) shows the course of output pressure with time for a reset rate of 1 per min. The dotted lines show the corresponding proportional response pressure. In Fig. 4(*a*), the pen was moved and held far enough from the set point to give a 1 psi change in proportional response. The reset proceeds at the rate of 1 psi per min per 1 psi original change. Fig. 4, curve (*b*), shows a reset rate of 2 psi per min per 2 psi original change. In both cases the reset rate is 1 per min.

In most controllers using automatic reset, some adjustment of the reset rate is provided, though continuous adjustment appears in only a few. In one, the reset rate is adjustable from zero to 20 per min. In order to determine reset rates on an instrument without a calibrated dial, it is only necessary to move the pen away from the set pointer far enough to cause a 1 psi output change and note the additional output-pressure change per minute. The same value can be put on the reset adjustment in controllers other than those of the air-operated type, by making a sustained pen change from the set point, noting the altered valve position which results from proportional response and the additional travel at the end of 1 min from automatic reset. The reset rate is the travel from reset divided by the travel from proportional.

Optimum Reset Rate. Fig. 5(*a*) to (*e*) shows the effect of reset-rate adjustment on control. Fig. 5, curve (*a*), resulted from a load change equivalent to 2.8 psi output pressure with a reset rate of zero, in other words, only proportional response. This curve is the same as Fig. 2(*d*) except that the sensitivity is reduced from 50 per cent of ultimate to 45 per cent of ultimate. A reset rate of 0.5 per min gives the slow return toward the set point shown in Fig. 5(*b*). As the reset rate is increased to 1, to 1.5, and to 2, in Fig. 5(*c*), (*d*), and (*e*), the return becomes more and more rapid. At the same time, instability and period of oscillation increase. In general, curve (*d*) of Fig. 5 would be considered the optimum in that it gives reasonably rapid return without excessive loss of stability or excessive increase in period.

Optimum Reset-Rate Adjustment. The actual reset rate which gives a recovery curve similar to Fig. 5(*d*) varies widely on different control applications. As will be pointed out later, the reset

rate appears to vary inversely as the time lag of the application. At present, however, we are more interested in finding a simple method for determining the correct setting.

It has been found that the period of oscillation (P_u) produced at the ultimate sensitivity (S_u) is a good index of required reset-rate adjustment. This period should be measured when the amplitude of oscillation is quite small, such as on curve (*c*) of Fig. 1, where the period is about 0.8 min. The optimum setting of reset rate, that which produces a recovery curve similar to Fig. 5(*d*), is usually about $1.2/P_u$. On the process being tested, the reset rate of 1.2/0.8 or 1.5 was used for curve Fig. 5(*d*).

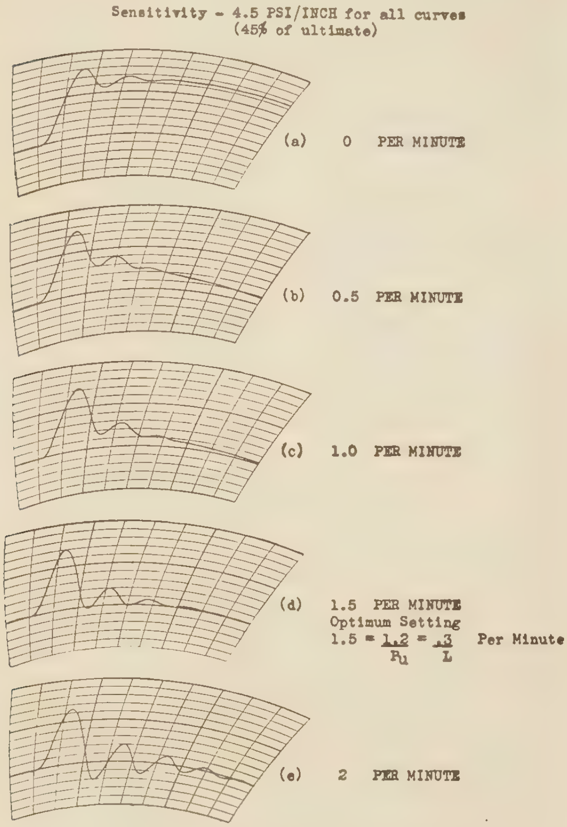

Fig. 5 Reset Rate Versus Recovery
(Load change.)

In adjusting a controller with proportional and automatic-reset responses, the sensitivity which just gives a small sustained oscillation should be determined (S_u), and the period of oscillation (P_u) in minutes noted. Optimum controller settings will then be approximately

$$\text{Sensitivity} = 0.45S_u$$
$$\text{Reset rate} = 1.2/P_u$$

Note that the recommended sensitivity has been reduced from $0.5S_u$ to $0.45S_u$. Were this not done, the addition of automatic reset would have increased markedly the amplitude ratio. This tendency of automatic reset to decrease stability is one of its bad features; the other is its tendency to increase the period of oscillation.

While a reset rate of $1.2/P_u$ is generally recommended, recovery curves with the same amplitude ratio may be obtained at a higher reset rate and lower sensitivity. In general, however, this procedure results in recovery curves with longer period and greater initial deviation, both of which are detrimental.

Pre-Act Response

The latest control effect made its appearance under the trade name "Pre-Act." On some control applications the addition of pre-act response made such a remarkable improvement that it appeared to be an embodiment of mythical "anticipatory" controllers. On other applications it appeared to be worse than useless. Only the difficulty of predicting the usefulness and adjustment of this response has kept it from being more widely used.

This pre-act effect is as distinct a response as proportional and automatic reset. Pre-act simply gives an additional valve movement proportional to the rate of pen movement. It is used only in conjunction with proportional response.

Pre-Act Time. Since pre-act response is an additional output pressure change per rate of pen movement, its unit is the "pre-act time" in minutes

$$\text{(psi) per (psi per min)} = \text{min}$$

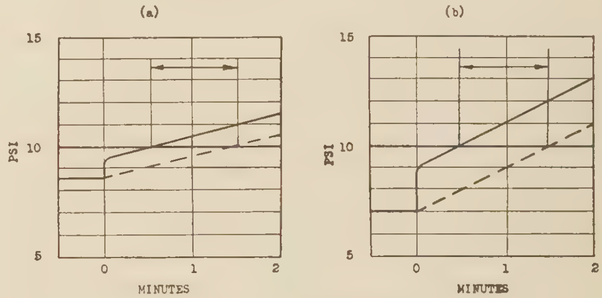

Fig. 6 Pre-Act Time
(Pre-act time = 1 min.)

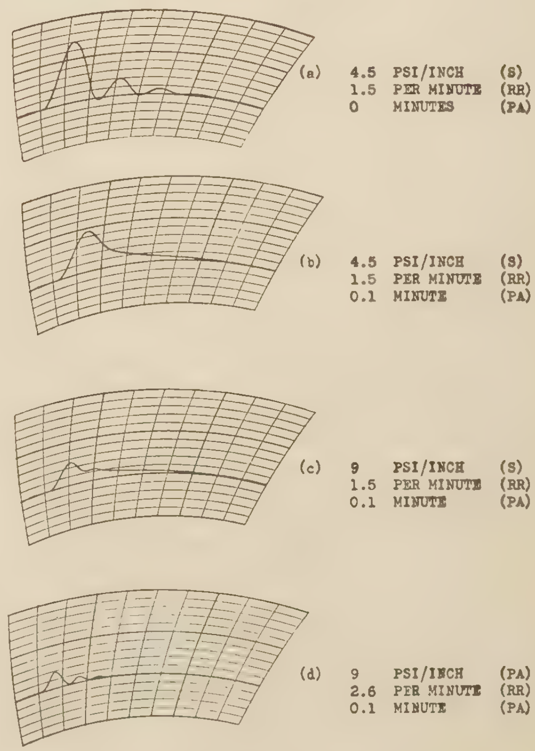

Fig. 7 Control With Pre-Act
(Load change.)

To visualize this unit, assume a controller pen moving away from the set point at such a rate that a proportional-response output change of 1 psi per min results (dotted line of Fig. 6(*a*)). Addition of 1 min pre-act time will cause the controller output to follow the solid line 1 psi higher, i.e., the pre-act response is 1 psi additional for 1 psi per min proportional-response change. Without altering the pre-act setting, a pen velocity twice as great would give 2 psi additional pressure, as shown in Fig. 6(*b*). The time by which the solid line of Fig. 6(*a*) and (*b*) leads the dotted line is the pre-act time, in this case 1 min.

Recently, several industrial instrument companies have made this control effect available in a more or less adjustable form. In one, the dial is calibrated in terms of pre-act time over a range of 0.2 to 10 min.

Use of Pre-Act Response. Pre-act response has been successfully used on applications which give a period of oscillation greater than about 0.4 min. It is not generally useful on pressure- or flow-control applications and rarely on control of liquid level, though this is not a hard and fast rule. To date, it has been used most widely on temperature-control applications.

The effect of pre-act on control is shown in Fig. 7. Fig. 7 curve (*a*) repeats curve (*d*) of Fig. 5, which represented about the optimum control obtainable with proportional and reset responses only. Without altering these settings, the addition of 0.1 min pre-act time changes the recovery curve for the same 2.8 psi load change to that shown at (*b*). The increased stability is an indication that a higher sensitivity may be used, so it is accordingly increased to 9 psi per in. The resulting curve (*c*) shows a much smaller initial deviation without excessive amplitude ratio, but an excessively slow return toward the set point, indicating that a faster reset rate is needed. (Compare with Fig. 5(*b*).) Increasing the reset rate to 2.6 per min produced the curve Fig. 7(*d*), representing approximately optimum control using the three responses.

A comparison of curves, Fig. 7(*a*) and (*d*), discloses that the pre-act response has improved control in several respects. Maximum deviation from the set point has been cut 71 per cent, period of oscillation has been reduced 43 per cent, and the time required for the oscillation to die out has been halved.

Pre-act response does not replace automatic-reset response since it ceases to act when the pen becomes stationary. However, while reset increases period of oscillation and decreases stability, the effect of pre-act is just the opposite. On the debit side for pre-act lies only the increased difficulty of adjusting three responses instead of two, but the use of the basic unit, pre-act time, allows the setting to be determined from the period of oscillation.

Optimum Pre-Act Time Adjustment. It has been found that, for a wide range of control applications, the optimum pre-act time depends directly upon the period of oscillation used to determine the adjustment of the reset rate. In fact the pre-act time should be about $^1/_8$ of the period of a small-amplitude oscillation at the ultimate sensitivity.

To adjust a controller with proportional, automatic reset, and pre-act responses, determine the ultimate sensitivity (S_u) and note the period (P_u) of a small-amplitude oscillation at this sensitivity. The optimum settings will then be approximately

$$\begin{aligned} \text{Sensitivity} &= 0.6S_u \\ \text{Reset rate} &= 2/P_u \text{ per min} \\ \text{Pre-act time} &= P_u/8 \text{ min} \end{aligned}$$

On some applications, the sensitivity with pre-act can be greater than $0.6S_u$. This is illustrated by the test application which allowed a sensitivity of $0.9S_u$ (Fig. 7(*d*)). We have found that the setting is generally between $0.6S_u$ and $1S_u$; in many applications, a sensitivity of $0.6S_u$ will be sufficiently near the optimum setting.

If, at these settings, the amplitude ratio is too high, each adjustment should be reduced slightly. When using the system of units proposed in this paper, a decrease in the setting of any response increases stability. (Actually pre-act increases stability up to its optimum setting and, above that, again gives less stability.) In general, oscillations with a period approximately the same as those occurring at the ultimate sensitivity are due to too high a sensitivity; automatic reset gives longer periods and pre-act shorter periods.

Process-Reaction Curves

A control circuit consists of a controller and a process, the valve being considered a portion of the latter. Pen movement

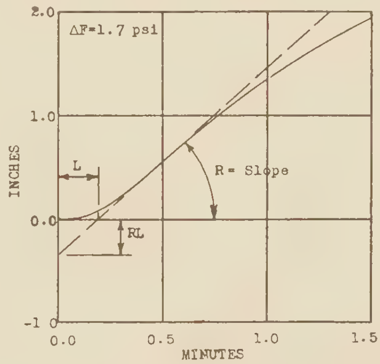

Fig. 8 Reaction Curve

gives an output-pressure change, which affects the process, which in turn affects the pen. So far, we have considered control effects, the portion of the control circuit tying pen movement to output-pressure-behavior pattern. We have also considered the effect of altering this pattern on the entire control circuit, taking as evidence the pen recovery from disturbances and load changes.

We will now eliminate the controller from the circuit, make certain output-pressure changes, and show how the resulting pen behavior can be used to evaluate controllability of the process and predict optimum controller settings.

Process-Reaction Curve. In any control circuit, there are several time lags. The lag of inflating the valve is present in all. Some time lag occurs in the measuring portion between a change at the thermometer bulb or pressure connection and the indication of that change at the pen. Added to these two may be series of lags in the apparatus under control.

The difficulty of dealing mathematically with processes involving a series of lags or even of applying values to the various lags and adding them is very great indeed. However, having a process, a pen, and a means of controlling the process (a valve), it becomes possible to get the summation of all the lags by simply altering the valve position and analyzing the resulting curve traced by the pen.

To be more explicit, suppose that we have an application with a controller installed and cut the air line connecting the controller to the diaphragm valve. Then, if we connect an air-reducing valve to the diaphragm-operated control valve, it will be possible to apply the air pressure necessary to hold the control valve in any position. We will thus be able to make a change in the pressure applied to the control valve in the same manner as the controller would do it (this can still be called an output pressure because its effect will be the same as though it came from the controller) and note the resulting pen behavior.

With a control circuit so arranged, we may, by applying the

correct pressure to the control valve, first bring the recording pen to the desired point on the chart. If then a sudden sustained change in pressure on the control valve of ΔF psi is made, the pen will trace an S-shaped curve which we will call a "reaction curve." Fig. 8 shows a reaction curve for the process which we have been considering.

While Fig. 8 represents a typical reaction curve, an infinite number of variations are possible. On some applications, notably liquid-level control, the curve may come to a maximum slope and continue indefinitely (or until the tank runs over). This type of process is not "self-controlling." On others a definite dead period or velocity-distance lag exists, and the reaction curve shows no pen movement for a finite time after the change in valve position; it then either starts at the maximum rate or builds up to the maximum.

In discussing optimum controller settings, when using pre-act response, we noted that a sensitivity between $0.6S_u$ and $1S_u$ could be used. The best value appears to depend upon the shape of the reaction curve prior to the maximum slope; a lag predominantly of the dead-period type calls for sensitivities toward $0.6\ S_u$.

Optimum Settings From Reaction Curve

Two characteristics of the reaction curve are used to fix the proportional-response sensitivity. The "reaction rate" (R), i.e., the maximum rate at which the pen moves occurs at the point of inflection in the reaction curve. A line drawn tangent to this point intersects the initial pen position a certain length of time after the change in valve position. This time we will call the "lag" (L) of our control circuit. The optimum setting of sensitivity for a controller is inversely related to the product of R and L, determined from the reaction curve. If the tangent line is projected until it intersects the vertical axis, the product RL is graphically determined, as shown in Fig. 8. Good control is generally obtained when proportional-response sensitivity is so adjusted that a pen movement of RL in. gives a pressure change of ΔF psi.

On the reaction curve of Fig. 8, a 1.7 psi valve change was made so the optimum sensitivity setting is approximately

$$\text{Sensitivity} = \frac{\Delta F}{RL} \text{ psi per in.}$$

where

$$\begin{aligned} R &= 1.7 \text{ in. per min} \\ L &= 0.2 \text{ min} \\ RL &= 0.34 \text{ in.} \\ \Delta F &= 1.7 \text{ psi} \end{aligned}$$

The predicted sensitivity of 1.7/0.34 or 5 psi per in. gave curves Fig. 1(f) and Fig. 3(d). These curves were previously selected as giving good stability, that is, an amplitude ratio of approximately 0.25.

Unit Reaction Rate. No justification has been given for calling the distance L on the reaction curve the lag of the process, but there appears to be a good reason. On most processes, reaction curves, caused by different valve-pressure changes ΔF, are similar in shape, differing only in the value of R, that is, the reaction rate caused by a 1 psi change is about twice as great as that from a 0.5 psi change, but the intersected distance L remains constant regardless of ΔF.

When taking a reaction curve, it is sometimes necessary to make ΔF quite small, in order to prevent undue disturbance to the process being tested. The resulting reaction rate is then converted to a "unit reaction rate" (R_1), that which would be caused by 1 psi pressure change on the control valve. This is done by dividing the reaction rate found by ΔF

$$R_1 = \frac{R}{\Delta F} \frac{\text{in. per min}}{\text{psi}}$$

The formula for a good sensitivity setting may then be written

$$\text{Sensitivity} = \frac{1}{R_1 L} \text{ psi per in.}$$

The ultimate sensitivity will be about twice as great

$$S_u = \frac{2}{R_1 L} \text{ psi per in.}$$

At the ultimate sensitivity, the period of oscillation is about $4L$ min, increasing to about $4.6L$ as the sensitivity is lowered to one half the ultimate.

An approximate description of the characteristics of a process is given by values of the two quantities, unit reaction rate and lag. True, these two are only a rough measure of the entire reaction curve, telling nothing about its shape before and after the point of inflection, but they give enough of the story to allow a prediction not only of optimum sensitivity and period of oscillation but of optimum reset rate and pre-act time settings as well.

It should be kept clearly in mind that the controller settings are determined from the reaction curve caused by an output-pressure change (control-valve-position change) and not by the reaction curve which is caused by a load change.

Reset-Rate Determination From Reaction Curve. Since the period of oscillation at the ultimate sensitivity proves to be 4 times the lag, a substitution of $4L$ for P_u in previous equations for optimum reset rate gives an equation expressing this reset rate in terms of lag. For a controller with proportional and automatic-reset responses, the optimum settings become

$$\text{Sensitivity} = \frac{0.9}{R_1 L} \text{ psi per in.}$$

$$\text{Reset rate} = \frac{0.3}{L} \text{ per min}$$

At these settings the period will be about $5.7L$, having been increased by both the lowering of sensitivity and the addition of automatic reset.

Pre-Act Time Determination From Reaction Curve. Using again the relationship between L and P_u, we find that the optimum pre-act time depends directly upon the lag and is normally equal to $L/2$. This tells us that pre-act will not normally be used on applications in which the reaction curve shows a lag smaller than 0.2 min, since the minimum pre-act time available on industrial controllers is about 0.1 min. It will be useful on all applications with lags greater than 0.2 min.

The optimum settings determined previously for all three control effects, when expressed in terms of unit reaction rate and lag, appear as follows

$$\text{Sensitivity} = \frac{1.2}{R_1 L} \text{ to } \frac{2}{R_1 L} \text{ psi per in.}$$

$$\text{Reset rate} = \frac{0.5}{L} \text{ per min}$$

$$\text{Pre-act time} = 0.5L \text{ min}$$

Control-Valve Characteristics

In general, any change of a control circuit which allows a higher controller sensitivity and faster reset rate to be used will improve the control results obtained. We have seen that the addition of pre-act response gives both of these improvements.

At times certain changes in the process can be made which allow a higher sensitivity and reset rate.

Any decrease in the lag of a process permits an increase in reset rate and attendant reduction in period of oscillation, since the reset rate is inversely related to lag and the period directly related. Any decrease in the lag of a process if it is not attended by an increase in reaction rate permits an increase in sensitivity since the sensitivity is inversely related to the lag. Any decrease in the unit reaction rate of a process, if not attended by an increase in lag, allows higher sensitivities, since sensitivity is inversely related to reaction rate.

Stated more concisely, any decrease in the value of R_1L increases the optimum sensitivity, and any decrease in L increases the optimum reset rate. Also any decrease in L decreases the period of oscillation.

Some applications, as we have already noted, call for widely different sensitivity settings at different load conditions. In these cases, we have said the sensitivity must be set low enough to give stability at the most difficult load even though the control is penalized at easy load conditions. This phenomenon is due to the fact that the unit reaction rate generally changes with load. The lag normally remains about constant. Control valves with special flow-lift characteristics have been used in an attempt to correct for this change in unit reaction rate with load. The optimum characteristics vary with the application under control and are not always "logarithmic" or "equal percentage" as is commonly thought.

Process Classification

Since either the ultimate sensitivity and attendant period or the unit reaction rate and the lag may be used to determine optimum controller settings, it follows that the latter values may be determined from the former. This suggests that, without running a reaction curve on a process, values of R_1 and L may be determined during adjustment of the controller.

Knowing the ultimate sensitivity (S_u) and the period at this sensitivity (P_u), a rearrangement of preceding equations shows how these values may be converted into L and R_1.

$$L = P_u/4 \text{ min}$$

$$R_1 = \frac{8}{P_uS_u} \ \frac{\text{in. per min}}{\text{psi}}$$

Classification of processes in terms of their unit reaction rates and lags would appear to be a decided improvement over present arbitrary methods.

Conclusions

We have proposed a system of units for measuring the control effects which are now in common use. When using these units, the values of the sensitivity, reset rate, and pre-act time all increase as the relative valve action per pen action increases.

The lag and unit reaction rate have been introduced as a quantitative measure of the controllability of processes, and we believe they form a good basis for a classification of processes.

Formulas have been presented which enable the controller settings to be obtained from an analysis of the process-reaction curves (that is, unit reaction rate and lag).

We have presented a simple method for adjusting the controller when it is installed on an application, making use of the ultimate sensitivity and period. Having shown that the controller settings can be obtained from the reaction curve, it will be possible for the equipment designer to calculate an approximate reaction curve for certain applications and thus determine the controller settings even before the equipment is built.

The usefulness of each particular control effect has been shown by examining its effect on the quality of control.

It has been pointed out that valve characteristics should be matched to each process so that a constant unit reaction rate prevails at all loads. This incidentally gives a rational explanation for the use of valves with special flow-lift characteristics.

Examination of pre-act response has shown that it improves control by increasing stability, reducing period, and allowing larger settings for the other responses. The relation between the pre-act setting and lag (or ultimate period) has simplified its adjustment. A summary of control effects is given in Table 1.

TABLE 1 SUMMARY OF CONTROL EFFECTS

Response	Action	Measure	Unit
Proportional	$\frac{\text{Valve movement}}{\text{Pen movement}}$	Sensitivity	Psi per in.
Automatic reset	$\frac{\text{Valve velocity}}{\text{Pen movement}}$	Reset rate	Per min
Pre-act	$\frac{\text{Valve movement}}{\text{Pen velocity}}$	Pre-act time	Min

Note that proportional response action may also be expressed as a valve velocity per pen velocity.

Summary of Controller Adjustments

Determine the ultimate sensitivity (S_u) and period (P_u), or the unit reaction rate R_1 and lag L. For the three types of controllers the optimum settings are as follows:

Proportional

$$\text{Sensitivity} = 0.5S_u = \frac{1}{R_1L}$$

Proportional plus reset

$$\text{Sensitivity} = 0.45S_u = \frac{0.9}{R_1L}$$

$$\text{Reset rate} = \frac{1.2}{P_u} = \frac{0.3}{L}$$

Proportional plus reset plus pre-act

$$\text{Sensitivity} = 0.6S_u = \frac{1.2}{R_1L}$$

$$\text{Reset rate} = \frac{2.0}{P_u} = \frac{0.5}{L}$$

$$\text{Pre-act time} = \frac{P_u}{8} = 0.5L$$

Discussion

E. S. Bristol.[3] The authors have presented a procedure for analyzing control and process characteristics which is logical, comparatively simple, and avoids the use of involved mathematics. The paper thus constitutes a worth-while contribution to the literature sponsored by the Committee on Industrial Instruments and Regulators in its endeavors to formulate standardized methods of approaching automatic-control problems.

Some of the terms and relations employed by the authors can be modified to advantage, in order to make the treatment more general in scope. From this point of view, it is believed preferable to express control action in terms of valve travel rather than in terms of actuating pressure on a diaphragm-operated valve. The latter procedure affords a basis for direct comparison of re-

[3] In charge, Combustion Control Division, Engineering Department, Leeds & Northrup Company, Philadelphia, Pa. Mem. A.S.M.E.

sults only for fluid-operated control valves having the same working pressure range. On the other hand, measurement of control action in percentage of full valve travel would apply to electrically operated, as well as fluid-operated power elements, regardless of the range or mode of application of the actuating media, and should not result in complicating the terminology. As a corollary of such a change the authors' "unit reaction rate," or rate of change resulting from 1 psi at the valve diaphragm, would be expressed as rate of change corresponding to full valve travel or to a stated fraction of full valve travel.

While it may be desirable in studying a controller mechanism to consider merely the action resulting from a pen movement measured in inches, this simplification presents difficulties when applied to any specific installation. Thus, on a temperature-control application, the significant characteristic is actual temperature variation and not the resultant pen motion of the particular recorder employed, which motion would vary with the individual scale range without reference to the inherent characteristics of the process. Possibly it is the authors' intention that the actual scale interval equivalent to 1 in. of pen travel be substituted in their relations, when dealing with any specific application.

It is noted that the authors' relation "reaction rate" multiplied by "lag" or RL is actually equivalent to the pen deviation that would occur in time L, with the pen moving at rate R. In other words, control sensitivity is found to be inherently related to the reciprocal of a hypothetical pen deviation. Attention is called to the fact that a simple manual simulation of two-position control can be imposed upon a process to investigate its reaction rate and lag characteristics. This can be done by watching a recorder measuring the variable to be controlled and manually opening or closing the valve whenever the pen crosses an arbitrarily selected control point. The slope of the resultant oscillating record where it crosses the control point constitutes a significant reaction rate. Also, the period of the resultant oscillation is related to the time required for valve change to affect the controlled variable. The product of the rate of change and the period as thus obtained constitutes another hypothetical pen deviation which can be used for a basis of correlation with the optimum throttling range or control sensitivity. The width of the pen band, obtained on a two-position test of this nature, is related to the rate of pen motion at the control point, and the period of oscillation, so that the pen band in itself is also a significant term for correlation with the optimum throttling range. The two-position test method for field checks is believed to be a particularly simple means for obtaining an indication of the response characteristics of a process.

G. A. Philbrick.[4] The authors exhibit the response given by the proportional-control action, on the one hand, when augmented by a differentiation, "pre-act," and on the other, when augmented by an integration, "reset." While such responses serve graphically to define these characteristics, it is striking that different generating functions are used in the two cases. Cannot these various classical control actions be better compared on the basis of some common impressed condition? To dispel the illusion of subterfuge, it is suggested that the authors exhibit in their closure the response of both sets of control actions when both varieties of change are imposed; or more simply, perhaps, the composite response of the three-term characteristic itself, for typical values of the three adjustables, when a sudden deviation occurs.

P. W. Keppler.[5] The authors have made a much-needed and highly useful contribution to the problem of setting regulators. However, in connection with the type of optimum transient curve recommended, it should be kept in mind that requirements vary over a wide range regarding uniformity of controlled flow, maximum deviation, average deviation, and stability. For example, any oscillation though damped may be hazardous if resonance can be set up by some other regulator connected to the same process.

The authors have also made a valuable comparison of control functions. To complete this comparison we should consider control based on measurement of the independent energy flow that causes the disturbance. This control function is widely used, generally by proportioning the controlled flow in some exact manner with the independent disturbing flow, and has therefore been called "exact correction."

While of course countless modifications are possible for this control function, in this exact form it requires no adjustment whatever and cannot possibly support any oscillation. It makes the admittedly undesirable "automatic reset" function unnecessary.

To illustrate "exact correction," a specific example is necessary, although it is universally applicable. For this purpose the writer has chosen a single-capacity process with dead time (velocity-distance) lag. In Fig. 9 of this discussion regulator E controls temperature T_4 of tank G, which is kept uniform by mixer H. Regulator E varies temperature T_3 entering pump F by moving gates C and D. Tanks A and B are assumed kept full with fluid at temperatures T_1 and T_2. Pump F maintains constant mass flow through the long pipe line M that introduces dead time lag. The manually operated gate K produces the independent energy flow that causes the disturbance. Float-controlled gate I keeps tank G full, but the constant temperature T_5 is below T_4. Tem-

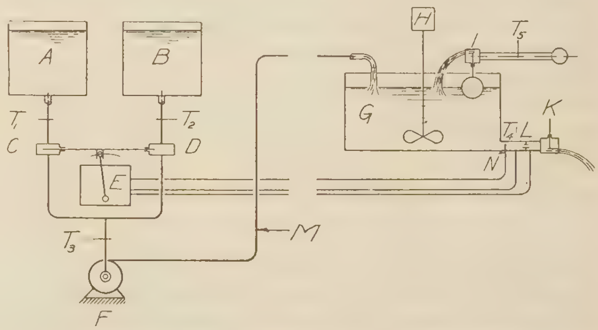

Fig. 9 Single-Capacity Process With Velocity-Distance Lag to Demonstrate "Exact Correction"

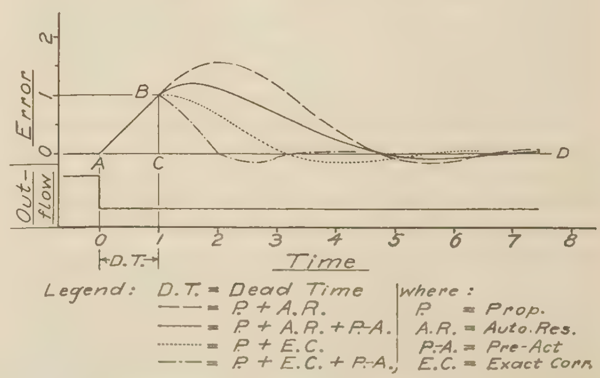

Fig. 10 Nondimensional Curves, Showing Advantages of "Exact Correction"

---

[4] Research and Development, The Foxboro Company, Foxboro, Mass. Jun. A.S.M.E.

[5] Engineer, Sanderson & Porter, New York, N. Y. Mem. A.S.M.E.

perature T_4 is transmitted to regulator E by bulb N for proportional and other control functions, and "exact correction" is obtained by suitably connecting E with the orifice L. This control function keeps the heat flow at E equal to the difference between that at K (neglecting variations in outlet temperature) and that at I. It is also assumed that T_4 must be measured so closely that the effect of self-regulation of T_4 is negligible.

The nondimensional curves, shown in Fig. 10 of this discussion, obtained by graphical step-by-step integration, demonstrate the advantage of "exact correction" for any single-capacity process having dead time lag and lacking self-regulation. The unit of time is the dead time of the process, and the unit of error is the error at time 1. The disturbance is the indicated drop in outflow, and the ideal accuracy obtainable is the broken line *A-B-C-D*.

The curves shown give very nearly the minimum average error obtainable from the control function of each curve. The regulators containing exact correction are not only shown to give much better accuracy, but they are also much easier to adjust since they contain fewer adjustments.

The added cost of orifice, etc., is of course a disadvantage, but there are ways of overcoming this, so that in many cases a marked reduction in first cost results from exact correction.

J. J. Grebe.[6] This paper gives the simple rules for adjusting the control constants of commercial instruments to have the proper characteristics for any one plant. These rules have been checked in actual plant operations on many types of instruments made by different manufacturers and one homemade unit that the writer described in 1933. The much disputed assertion that a good automatic control system using deviation, rate of change, and second-derivative responses, which are also called reset, proportional, and third response or pre-act, should be able to bring about a new balance in the system, within less than twice the elapsed time of the velocity distance lag or the dead time, has been proved by the work of the present authors.

The third response, which in general is a damped second-derivative function so as to fade out at the time when the second derivative works against good control, serves to counteract the effect of the dead time or the velocity-distance lag called L in Fig. 8 of the paper. Contrary to the opinions of some individuals, such lags are quite common, especially in the chemical industry where long dead times up to several minutes are encountered in processes where considerable time is required to make a change felt through chemically resistant but poor thermal conductors, or where it takes considerable time for solid reagents such as lime slurry to come to equilibrium with the solution.

For this reason, the importance of the third response cannot be overemphasized. In fact, if one were to build a universal instrument suitable for any application, it would be better to have a wide range of adjustment on the third response and reduce the flexibility of adjustment of the second, the proportional-position response. In other words, with a good third-response element, the throttling range can be quite narrow for almost any condition.

Let us hope that the authors may continue to develop the art and improve the maintenance and operation of control installations by following up this good work.

Authors' Closure

Mr. Bristol's suggestion that valve travel replace pressure on a diaphragm-operated valve is sound and should be further considered. In the opinion of the authors, it stems from a universal desire to express sensitivity in terms of a dimensionless unit or at least in terms of a unit applicable to all types of controllers. For this paper "psi per inch" was chosen rather than "per cent valve travel per per cent pen travel" principally because the latter did not appear to be a very euphonious combination. In addition, the "per cent per per cent" unit gives the false impression of being dimensionless. One disadvantage of using percentage of full valve travel is that limiting the stroke of a control valve would alter the sensitivity given in that unit but would not change the sensitivity given as psi per inch.

Inches of pen movement was used rather than per cent of scale range or degrees Fahrenheit since the former was thought to be a more general unit. Degrees Fahrenheit would be a good basis for comparing temperature-control applications, but there would be no analogy between that and the feet of water change in liquid level on another application.

The search for a dimensionless sensitivity ratio is not new. Ivanoff[7] had one in his "Over-All Sensitivity," the ratio of uncontrolled or potential deviation to controlled deviation. In the language of this paper, that would be the final deviation in inches of a reaction curve for a one psi pressure change divided by the reciprocal of controller sensitivity or the inches of pen movement necessary to give a one psi change in output. Ivanoff, however, was dealing with "self-controlling" processes which had a definite potential deviation for each valve opening. On some processes, valve movement determines only the reaction rate and the reaction curve never levels out. The potential deviation on these processes is infinite and Ivanoff's over-all sensitivity is infinite regardless of the controller sensitivity setting and hence meaningless. Even on this type of process, however, the authors' value of R_1L is finite and their ultimate sensitivity a definite value. It appears that controller sensitivity settings can be more universally referred to either ultimate sensitivity or R_1L than to potential deviations. In fact, a controller setting given as "per cent of ultimate sensitivity or as sensitivity $\times R_1L$ is dimensionless and is possibly the answer to the problem.

Another clue in the search for a sensitivity yardstick comes from a scrutiny of control quality. The area under curves such as Fig. 5(d) might be taken as a measure of poorness of control on either a temperature or liquid-level control application. This area in inch-minutes, easily convertible to either "feet-of-water minutes" or "degrees-Fahrenheit minutes" will be directly related to the product of R_1L, L, and ΔF, where ΔF is the difference in output pressure before and after the largest sudden load change to which the process will be subjected. On any process, a load change will give an area under the recovery curve of $(K)(\Delta F)(R_1)(L^2)$, where K is a constant determined by the point in the process at which the load change occurs and by the dimensionless quantities of controller settings, namely, sensitivity $\times R_1L$; reset rate $\times L$; and pre-act time/L. It can be seen that any valve-motion unit may be selected for use in R_1, ΔF, and sensitivity as long as it is used consistently in all three.

A method of interpreting the oscillating record obtained by impressed two-position control would certainly be a worthwhile contribution to the study of automatic control. It is hoped that Mr. Bristol will soon publish a detailed method of quantitatively determining application data by such a test. It would be extremely useful if small valve movements giving a record like Fig. 1, curve (c) could be accurately interpreted. Generally industrial processes cannot be disturbed by making large valve movements.

The old concept of pre-act response as a "kicker" may have

[6] Director, Physical Research Laboratory, The Dow Chemical Company, Midland, Mich. Mem. A.S.M.E.

[7] Theoretical Foundations of the Automatic Regulation of Temperature," by A. Ivanoff, *Journal of the Institute of Fuel*, Vol. 7, no. 33, Feb., 1934.

prompted Mr. Philbrick's request for showing its response to a sudden pen movement. In the interest of clarity the authors used a sustained pen deviation to show reset rate and a constant rate of pen movement to illustrate pre-act time. The course of output pressure from a controller with proportional plus automatic reset responses for a constant rate of pen movement would be as shown in Fig. 11. The proportional response is 2 psi per minute as in Fig. 6(*b*) and the reset rate one per minute. At any instant the output pressure from automatic reset is rising at a rate equal to the proportional-response output change times the reset rate. The addition of pre-act response will give an additional output pressure equal to the rate of output pressure change due to the proportional response times the pre-act time.

Analysis of pre-act response from an impressed sudden pen

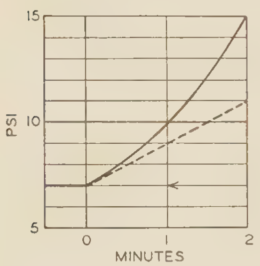

Fig. 11

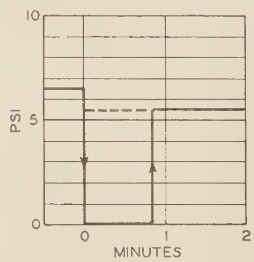

Fig. 12

movement is purely hypothetical because instantaneous pen movements are not met with in practice. A true derivative mechanism would give, for such a pen action, an infinite output change. Actually air-operated controllers do not give an output pressure lower than atmospheric nor higher than their supply pressure. A controller with proportional and pre-act responses would give an output pressure change as shown in Fig. 12 if a sudden pen motion were impressed equivalent to 1 psi proportional-response change. The pre-act time in Fig. 12 is 5 min.

As Mr. Keppler points out, control requirements on certain applications may be so strict that the improvement given by pre-act response may still not hold a pen within the tolerance required. In these cases it is necessary to cast about for another variable upon which a separate or related response may be based. While the study of these multiple controller systems is beyond the scope of this paper, it may be said that they are commonly used and are often very necessary to achieve desired control results. Grebe[8] has called this "metered control."

The type of multiple controller system shown by Mr. Keppler makes use of a separate flow measurement as an indication of demand, to reset the temperature controller. This removes the need for an automatic-reset response working on a basis of temperature pen deviation. The elimination of automatic reset in the temperature controller, however, would allow an offset if any other load change came into the system, for example, a change in temperature of one of the three incoming flows. Also, it would be rather difficult mechanically to convert the reading of flow into an exact mixed liquid temperature unless gates C and D reproduced flows exactly.

The more common multiple controller system is one in which one controller calls, not for a valve opening, but for a set point change on another controller capable of correcting for the major load change from a measurement at a point of favorable lag. Explaining this from Fig. 9, if the major load change in the system were not the position of gate K but temperature T_1, the control system would consist of two temperature controllers. One temperature controller would measure T_3 and operate gates C and D to maintain T_3. The second controller measuring T_4 would call for the required T_3 necessary to maintain T_4. The first controller would quickly correct for changes in T_1 and T_2 or partial clogging of gates C and D. The second controller would raise or lower T_3 to correct for the minor load changes such as temperature T_5 or flow through I.

Report on Tubular Creep Tests

By F. H. Norton[1] and C. R. Soderberg,[2] Cambridge, Mass.

This report comprises the results obtained on tubular specimens tested under internal pressure as measured for circumferential and longitudinal creep. In addition, tensile-test specimens of the same material were run as a comparison. This work follows closely an investigation[3] reported upon previously. The apparatus and method of testing are exactly as described in that report. Preliminary reports[4,5] were presented at the 1940 Annual Meeting.

1—SUMMARY OF TEST RESULTS

Specimens

Seven tubular specimens, which were made up for this test by The Babcock & Wilcox Company, consisted of tubes 4 in. OD, having either a 3/8-in. or 1/8-in. wall, with hemispherical ends welded in place. The specimens were turned out of thick tubes of carbon-molybdenum steel of the composition reported in the previous test.[3]

Scope of the Test

In this program seven tubular specimens and four tensile specimens were tested. The pressure in the tubes was computed by Professor Soderberg to give stresses equivalent to those obtained in the tensile specimens. Five of the seven tests have been completed and two are to be allowed to run for another period of six or eight months.

Results on Tensile-Test Specimens

These specimens, which were cut from the wall of the tubes from which the tubular specimens were formed, were run in the regular creep-testing apparatus, using a 10-in. gage length. The temperature distribution over the gage length was kept within ±1 deg F, and the temperature of the specimen did not vary more than 1 deg F during the test. The elongation of the specimen was measured by telescopes with a precision of 3 parts in 1,000,000. The elongation curves of these four specimens are shown in Figs. 1 to 4, inclusive. It will be noted that the total period of approximately 16,000 hr gives a stable rate on all but the specimen at 1050 F and 8000 psi load. This specimen toward the end of the test showed an increase in rate and would undoubtedly break if sufficient time were allowed. It should be noted that in the illustrations it was possible to plot only every fifth experimental point on the curves. In Table 1 is shown the average creep rate for various time intervals.

Creep of Tubular Test Specimens

The elongation curves of these specimens, both circumferential and longitudinal, are shown in Figs. 5 to 11, inclusive. Here

again it will be seen that in most cases we have apparently reached a fairly stable rate of flow, and this is particularly true on the specimen which has been run 9000 hr. It should be realized that the creep rate as determined on the 4-in. diam has less than one half the precision of the tensile-test specimens, because of the shorter gage length. In all cases the longitudinal creep is substantially zero, although it will be noted that there is in some cases very small but definite creep over the entire period of time, sometimes positive and sometimes negative. This longitudinal creep is probably due to directional effects in the metal itself. It should be noted that one of the specimens at 1050 F and 1911 psi pressure developed a leak and had to be shut off at a period of 2200 hr. The specimen at 900 F and 4780 psi pressure had to be shut off for the same reason at 2700 hr. A description of the cause of these leaks was discussed in the previous progress report[4] because they seem of practical interest in the design of tubular pressure vessels. In Table 2 are shown the average flow rates for various intervals of time.

A complete discussion of the microstructure as well as a series of photomicrographs are included in Appendix 1 of this report.

2—COMPARISON OF TEST RESULTS WITH THEORY

Calculation of Tubular Creep Rates From Tension Creep Rates

As shown in the previous report on these tests,[5] the calculation of the creep rates of the tubes from the creep rates obtained by tensile tests is as follows:

1 A tension test is available which has given the creep rate u at the stress s.

2 A tube of the same material is tested at the same temperature and at an internal pressure determined by $p = 2/\sqrt{3} \cdot st/R$, where R and t are mean radius and wall thickness in inches, respectively.

3 At this pressure, the predicted tangential creep rate, expressed as change in mean radius, is $\sqrt{3}/2 \cdot u$, while the predicted axial creep rate is zero.

4 The measured creep rate at the mean radius is obtained by increasing the measured creep rate at the outside radius in the square of the ratio of the radii, or $\left(1 + \dfrac{t}{2R}\right)^2$.

The creep rates thus calculated from the tension tests are given in Table 3 for the three time intervals 1000 to 2000 hr, 2000 to 3000 hr, and 3000 to 9000 hr. Upon completion of this test the tubular specimens were sectioned and the actual wall thicknesses measured. To allow for the slight difference between

	8000	3/8	0.373	1911	7.0	8.5	7.8	6.5	7.9	7.8	....	....	9.5

the nominal and actual thickness, the actual stress intensity was determined from the dimensions of the tube; the tension creep rate was determined by extrapolation in the log-log plot, and the corrected tangential creep rate based on this new value of the tension creep rate. The correction in stress is small, but the greatest increase in creep rate is of the order of 17 per cent.

Comparison of Measured and Calculated Creep Rates

Table 4 shows the results of the comparisons which are available thus far. In reviewing these results, it should be kept in mind that the lower creep rates are quite uncertain, and a considerable range of values must be considered as equally probable. To avoid giving an erroneous impression of the relative accuracy of the results, it has been considered necessary to give a probable range of these values. The values presented have been obtained by a careful study of Prof. Norton's original plots. In some instances slight deviations will be found between these results and those previously presented[4,5] but the changes do not affect the general trend of the results.

The comparative creep rates have been listed for the three time intervals 1000 to 2000 hr, 2000 to 3000 hr, and 3000 to 9000 hr. With the exception of the $^1/_8$-in. tube tested at 1050 F and 372 psi, the time interval 2000 to 3000 hr carries the greatest significance. It should be noted that the transition to the steady state does not necessarily run parallel in time for the tension tests and the tubes, but too little is known about this aspect of the problem to make any other interpretation possible.

On the whole, it is apparent that the agreement between measured and calculated creep rates is as good as can be expected, at least for the higher creep rates, where the accuracy of measurement is reasonably satisfactory. The tendency toward higher creep rates in the thin tubes, which was suggested in the previous results[4,5] can now be explained by the fact that the $^1/_8$-in. tubes were slightly under thickness.

If the results presented in Table 3 are taken at their face value, it is possible to read into them a tendency toward somewhat higher observed rates than those calculated by the present theory. At the high creep rates, the difference is probably less than 10 per cent while, for the lower creep rates, larger differences may exist. However, the measured values are too uncertain to make a closer estimate of this difference possible. As already noted, the axial creep rates were zero in most cases, the only exception to this rule being the $^1/_8$-in-thick tube at 1050 F and 372 psi, where a small axial creep was found.

It may be stated in conclusion, therefore, that the test program thus far has generally verified the present theory of creep under triaxial stress systems.

Approximation Involved for Large Wall Thickness

As already indicated, the test results available at the time of our last report suggested a systematic difference between the thick and the thin tubes, the latter having a larger creep rate than that demanded by the theory. It was suggested by Mr. Clinedinst, in the discussion[6] to the original paper, that this difference might be due to the fact that the thin-tube theory, when applied to the $^3/_8$-in-thick tubes, involved some approximation.

While the correction for deviations from the nominal size has largely eliminated this systematic difference in the test results, it is of interest to clarify this question. In the following discussion, a solution is given which may be applied to thick tubes.[7]

In the steady state of flow, it is assumed that cross sections of the tube remain plane, reducing the problem to one of plane strain, for which $\sigma_3 = {}^1/_2\,(\sigma_1 + \sigma_2)$. This reduces the intensity of stress at any radius to $s = \sqrt{3}/2\,(\sigma_1 - \sigma_2)$. The creep rates at any radius then become by Equation [9] of the previous paper[5]

$$u_1 = \frac{\sqrt{3}}{2}\,u\,(s);\;\; u_2 = -\frac{\sqrt{3}}{2}\,u\,(s);\;\; u_3 = 0 \ldots\ldots [1]$$

To maintain the cross sections plane it is necessary that the radial displacement at any point of the tube vary inversely as the radius; that is, the tangential-creep rate must vary inversely as the square of the radius. If the creep rate also varies as the nth power of the stress intensity, it is evidently necessary to have

$$s = s_0\left(\frac{R}{r}\right)^{2/n} \ldots\ldots [2]$$

where s_0 is the intensity of stress at the mean radius r.

The condition of equilibrium also demands that $\sigma_1 - \sigma_2 = r\dfrac{d\sigma_2}{dr}$ so that

$$s = \frac{\sqrt{3}}{2}\,r\,\frac{d\sigma_2}{dr} \ldots\ldots [3]$$

Equating [2] and [3] and integrating, we obtain for σ_2

$$\sigma_2 = -\frac{n}{\sqrt{3}}\,s_0\left(\frac{R}{r}\right)^{2/n} + \text{const} \ldots\ldots [4]$$

At the inner radius $r = r_1$, $\sigma_2 = -p$; at the outer radius $r = r_2$, $\sigma_2 = 0$. The latter condition gives

$$\sigma_2 = -\frac{n}{\sqrt{3}}\,s_0\left[\left(\frac{R}{r}\right)^{2/n} - \left(\frac{R}{r_2}\right)^{2/n}\right] \ldots\ldots [5]$$

and in order to fulfill the first condition

$$s_0 = \frac{\sqrt{3}}{n}\,p\,\frac{1}{\left(\dfrac{R}{r_1}\right)^{2/n} - \left(\dfrac{R}{r_2}\right)^{2/n}} \ldots\ldots [6]$$

Introducing $r_1 = R - \dfrac{t}{2}$, $r_2 = R + \dfrac{t}{2}$ and expanding in terms of $t/2R$ this gives

$$s_0 = \frac{\sqrt{3}}{2}\,p\,\frac{R}{t}\left[1 - \left(\frac{t}{2R}\right)^2\right]^{2/n} \ldots\ldots [7]$$

[6] Discussion of paper, reference 3, by W. O. Clinedinst appeared in *Mechanical Engineering*, vol. 61, 1939, p. 757.

[7] The nomenclature in the following discussion is the same as that used in reference 5.

showing that in the thick tube the mean stress s_0 is slightly smaller than demanded by the theory of thin tubes.

It may be expected, therefore, that the deviation from the thin-tube solution should appear in the form of a factor

$$\left[1 - \left(\frac{t}{2R}\right)^2\right]^2$$

to be applied to the creep rate at the mean radius. The values of this factor for the two tube thicknesses are as follows:

t	R	$\frac{t}{2R}$	$\left[1 - \left(\frac{t}{2R}\right)^2\right]^2$
$^1/_8$	$^{31}/_{16}$	$^1/_{31}$	.998
$^3/_8$	$^{29}/_{16}$	$^3/_{29}$	.979

showing that the approximation involved for the $^3/_8$-in-thick tube is of the order of 2 per cent.

This result is essentially the same as that presented by Mr. Clinedinst in the discussion[8] to the 1940 papers. It may be concluded that no appreciable systematic difference in creep rates can be expected from this cause.

ADDENDA

Since the tests reported herein, tubular specimens F-10 and F-11 have been continued under test, with the results as shown in Appendix 5.

These long-time tests tend to substantiate the report as made prior to these tests.

APPENDIX 1

Microstructure

The carbon-molybdenum bottles and tensile coupons, referred to in the main body of this report, were made from one heat of steel, namely, No. 37239. This heat was rolled into 5-in. rounds and then pierced to form 4-in-OD × $^3/_4$-in-minimum-wall seamless tubes.

All of the material used for making tubular-creep coupons and standard tensile-creep coupons were made from two of these tubes as follows.

Tube No. 37239-B4

Tube No. 37239-B4 was used to prepare the following material:

Four carbon-molybdenum cylinders for tubular creep. These were marked F-1, F-2, F-3, and F-4.

Four tensional creep coupons marked T-1, T-2, T-3, and T-4.

Tubular creep coupons F-1 and F-4 were tested at 800 F.

Tubular creep coupons F-2 and F-3 were tested at 1050 F.

These four coupons were not cut for microexamination, either as part of the report previously published,[3] or as part of this Appendix. The microstructure of the four tensile coupons is being reported herewith.

Tube No. 37239-B3

Seven tubular creep coupons, F-5 to F-11, inclusive, were cut from this tube, and the microstructure of the original tube as well as five of the coupons at the end of the tests are being reported herewith.

Photomicrographs

The photomicrographs, Figs. 12 to 21, accompanying this report, and the comments appearing with them, were prepared by Mr. H. D. Newell of The Babcock & Wilcox Tube Company, Beaver Falls, Pa.

[8] Discussion of papers, references 4 and 5, by W. O. Clinedinst appeared in Trans. A.S.M.E., vol. 63, 1941, pp. 740–741.

Two photomicrographs for each specimen are designated by a single figure number. In all cases, the specimens were etched with 4 per cent nital prior to examination and photographing. In each case the photomicrograph at the top is at 100 diameters and the one below at 2000 diameters.

General Comments

A study of the microstructure of the four tensile coupons, Figs. 13 to 16 inclusive, indicates that there has been very little, if any, microstructural change at 900 F. This is true irrespective of the load, whereas, at 1050 F, the effect of temperature has been to bring about partial spheroidization with some diffusion in the tensile coupons.

In the case of the tubular-creep coupons Figs. 17 to 21, inclusive, the same remarks apply in general, although it would appear that the degree of spheroidization might be a little greater at 1050 F in coupon F-6, Fig. 18. The $^1/_8$-in-wall tubular specimen F-9, Fig. 21, appears to show some recrystallization of the ferrite

Appendix 2

METHOD OF MEASURING TUBULAR SPECIMENS

Serial No.—

Wall —Nominal wall thickness

Internal pressure —Pressure during test, psi gage.

Average OD —Average of 6 points on A axis and 6 points on B axis; A and B 90 deg apart
- Two points each on axes at center line
- Two points each on axes 1 in. from center line
- Two points each on axes 2 in. from center line

Average ID —Measured in same manner as OD

Mean radius —Average of averaged OR and IR

$$OR = \frac{OD}{2}$$

$$\text{Average wall} = \frac{OD - ID}{2}$$

$$\text{Stress} = \frac{PR}{t} \text{ where } P = \text{pressure; } R = \text{mean radius; } t = \text{average wall}$$

Deviation, per cent—The stress at each measured transverse plane was first calculated and then averaged; this value given in previous column as stress. The maximum deviation, at any plane, from the average was calculated in terms of per cent of average. With two exceptions, the average and mean stress were the same. For the two exceptions, both the plus and minus maximum deviations are shown.

A Review of Heat-Transfer Coefficients and Friction Factors for Tubular Heat Exchangers

By B. E. SHORT,[1] AUSTIN, TEXAS

This paper presents a summary of experimental and analytical work carried out on heat-transfer rate and pressure drop on the shell side of shell-and-tube exchangers. A comparison is made between the different methods which have been used in correlating the data, with the conclusion that no rational base has been established, except in so far as the fluid properties, fluid velocity, and dimensions of the exchangers are involved. However, an attempt is made to show that the effective velocity as used has a rational foundation.

Nomenclature

The following nomenclature is used in this paper:

A_a = net area of annular space at baffle of disk-and-doughnut baffles, sq ft
A_b = net area at baffle of half-moon baffles, sq ft
A_h = net area of hole in baffle of disk-and-doughnut baffles, sq ft
A_o = total annular area of clearance between baffle holes and tubes of orifice baffles, sq ft
A_s = cross-sectional area of shell minus total cross-sectional area of tubes, sq ft
B_h = height of half-moon baffle, ft
c = specific heat at constant pressure for shell fluid at mean stream temperature, Btu per deg F per lb
c_t = specific heat at constant pressure for tube fluid at mean stream temperature
D = inside diameter of tube, ft
D_o = diameter of holes in orifice baffles, ft
D_s = inside diameter of shell, ft
D_t = outside diameter of tube, ft
f = friction factor in Fanning equation, dimensionless
F = friction and roughness factor obtained from Fig. 6 for particular baffle type, dimensionless
g = acceleration due to gravitational force = 32.2 ft per sec per sec
G = mass velocity of the tube fluid, lb per sq ft per hr
G_a = velocity through annular space of disk-and-doughnut baffles, lb per sq ft per hr
G_b = velocity through opening at half-moon baffle, lb per sq ft per hr
G_h = velocity through hole in disk-and-doughnut baffle, lb per sq ft per hr
G_o = velocity through annular spaces of orifice baffle, lb per sq ft per hr
G_p = velocity perpendicular to tubes between baffles of half-moon baffles, lb per sq ft per hr
G_r = velocity perpendicular to tubes, radially, in disk-and-doughnut baffles, lb per sq ft per hr
G_s = velocity between baffles parallel to tubes of orifice baffles, lb per sq ft
G_z = effective velocity, lb per sq ft per hr
h_s = film coefficient for outside of tubes, Btu per deg F per sq ft per hr
h_t = film coefficient for inside of tube, Btu per deg F per sq ft per hr
k = thermal conductivity of shell fluid at mean stream temperature, Btu per deg F per sq ft per hr
k_t = thermal conductivity of tube fluid at mean stream temperature, Btu per deg F per sq ft per hr
L = heated or cooled length of exchanger, ft
μ = absolute viscosity of shell fluid at mean stream temperature, lb per ft per hr
μ_t = absolute viscosity of tube fluid at mean stream temperature, lb per ft per hr
N_b = number of baffles
Δp = pressure drop across shell side of exchanger, psf
P = center to center distance of tubes, ft
S = baffle spacing, ft
ρ = specific weight of the shell side fluid, lb per cu ft

Introduction

In the field of heat transmission by forced convection from one fluid to another across a separating wall is the general case of baffled tubular heat exchangers. This type of exchanger generally consists of a tube bundle with one fluid flowing through the tubes and the other fluid flowing across or along, or both across and along the tubes. Quite frequently, the rate of flow of one of the fluids is much less than the other, so that its film coefficient of heat transfer would be considerably lower than that of the other fluid, if the two were flowing at the same linear velocity. Also, quite frequently, the properties of one fluid are such as to cause a much lower transfer rate if the two fluids have the same linear velocity; or one may need to be lowered or raised through a much greater temperature range than the other. The designer has found that he can compensate for these differences and obtain a more economical design by using turbulence-promoting devices on the outside of the tubes in a shell-and-tube-type exchanger; he can increase the area of contact for the fluid which has the lower unit transfer rate; or he can increase the number of times that one fluid flows across or along the second fluid. The first scheme is that of using baffles of different kinds, the second scheme is the one of using fins or extended surfaces, and the third scheme results in the multipass exchanger.

Because of the complexity of the flow conditions on the outside of the tubes in the baffled exchanger, this paper is presented in an effort to review certain phases of the work that has been done on this type of unit, to compare the different methods that have been used in correlating the data, and to make a further examination of the possibilities of a rational correlation of the data on such units.

---

[1] Professor of Mechanical Engineering, The University of Texas. Mem. A.S.M.E.

Contributed by the Heat Transfer Division and presented at the Spring Meeting, Houston, Texas, March 23–25, 1942, of The American Society of Mechanical Engineers.

A detailed discussion is presented in which the factors the author used in correlating the data that he obtained in a series (11)[2] of experiments with different baffle types, baffle sizes, tube spacings, tube sizes, and rates of flow for the shell-and-tube exchanger, are critically examined.

Baffle Types

The more common baffles used in these exchangers are the orifice, half-moon, and disk-and-doughnut types, shown in Fig. 1.

The tube holes in orifice-type baffles are large enough to allow the fluid to flow parallel to the tube through the annular space between the tube and the edge of the tube hole in the baffle. Between the baffles, the flow is likewise generally parallel to the tubes.

In the case of half-moon baffles, the flow at the baffles is through the segmental opening between the shell and the flat edge of the baffle. From this opening, the fluid flows diagonally across the tubes to the segmental opening at the next baffle.

For disk-and-doughnut baffles, the flow at the "doughnut" baffle is parallel to the tubes through the circular opening in the baffle, then diagonally and radially to the annular space at the disk baffle. This annular space is formed by the shell and the edge of the disk baffle. The flow through this annular space is approximately parallel to the tubes.

Factors Affecting Transfer Rate and Pressure Drop

Variations in the construction of a shell-and-tube exchanger which affect the heat-transfer rate and the drop in pressure are

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

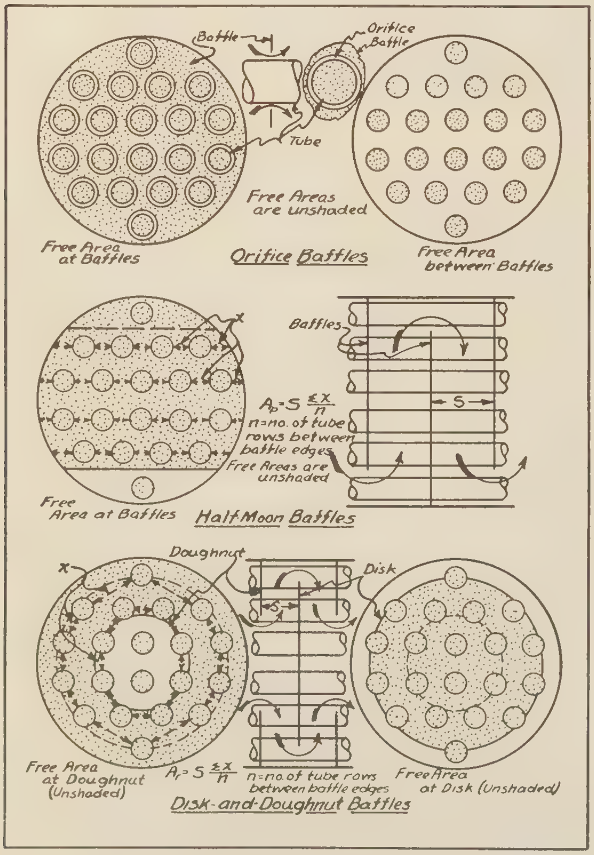

Fig. 1 Common Types of Baffles Used in Shell-and-Tube Exchangers

tube size, tube spacing, baffle type, baffle spacing, baffle size length of exchanger, and diameter of the exchanger shell.

The size of the tube affects the pressure drop and transfer rate since the turbulent condition on the trailing side of the tube is affected directly by the width of the tube. In the case of heat transfer, the smaller tube gives a higher transfer rate than the larger tube since the fluid sweeps the back side of the tube more completely for the same fluid and same velocity. For the pressure drop, the reverse is true as the larger tube presents a greater frontal area for the fluid.

A variation in the spacing causes a variation in the transfer rate since a wider tube spacing increases the thickness of the stream flowing between the tubes and also allows a longer time for the mixing of the fluid after it has passed over the tube surface. The increased width of the fluid stream causes a decrease in the transfer rate but this is more than offset by the increased mixing on the trailing side of the tube, thus causing the transfer rate to increase with increases in the tube spacing. The pressure drop is increased by a decrease in the tube spacing because the number of changes in direction are increased per unit length of the path of flow.

The same transfer rate can be obtained with one baffle type as with another; but the pressure drop is greater with the orifice-type baffle for the same transfer rate than is true for either of the other two forms which have been named. This is shown graphically in Fig. 2.

An increase in the baffle spacing for a given exchanger length, if orifice baffles are used, increases the mixing time following flow through the baffle but this effect is not as great as the effect of the decrease in number of baffles resulting from this increase in spacing, and the net result is a lowering of the transfer rate with increase in baffle spacing. An optimum baffle spacing for the orifice baffle would be roughly 4 times the effective flow diameter of the region between the baffles. This optimum baffle spacing is nearly approached in the case of the orifice baffles shown in Fig. 3.

An increase in baffle spacing for either half-moon or disk-and-doughnut baffles decreases the velocity of the fluid across the tubes between the baffles and thus tends to decrease the transfer rate. This increase in spacing, however, allows a longer mixing time following the flow of the fluid through the opening at the baffle and this tends to increase the transfer rate, but a decrease in the baffle spacing produces a sharper turning of the fluid over or through the baffle which results in a better sweeping of the transfer surfaces. Since this decrease in spacing also increases the velocity of flow across the tubes between the baffles, the net result is an increase in the transfer rate with decreased baffle spacing. This decrease in baffle spacing also increases the pressure drop because of the increased velocity and increased turbulence.

The larger baffle heights for the half-moon baffles and smaller openings for the disk-and-doughnut baffles increase the velocity at the baffle and the distance that the fluid moves outward toward the next baffle. The net result is a general increase in the transfer rate even though it decreases the transfer surface in the baffle opening for the same tube spacing, which would tend to decrease the over-all transfer rate. For the orifice-type baffle, a decrease in orifice size increases the transfer rate, as is true for the other two types, since the velocity of the fluid at the baffle is so much greater than that between the baffles. The general effect is to increase the average velocity through the exchanger. Also, the thickness of the stream over the tube through the orifice is decreased with decreases in the orifice size for a given tube size. The drop in pressure is increased by anything that increases the average velocity and, of course, a decrease in the size of the openings at the baffles increases the restriction to the flow of the fluid as is true for any orifice. The effect of baffle spacing and

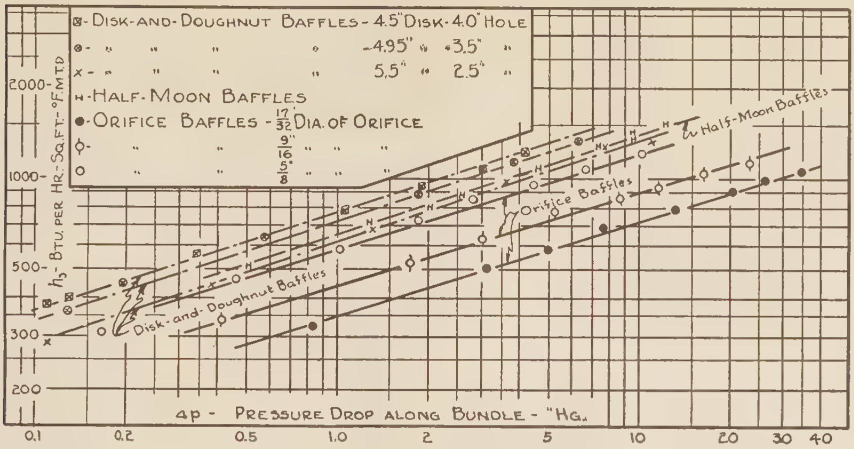

Fig. 2 Comparison of Relation Between Transfer Rate and Pressure Drop for Different Baffle Types for a Baffle Spacing of 2.39 In.

baffle size on the transfer rate and pressure drop are shown graphically in Figs. 2 and 3.

The length and diameter of the exchanger shell affect the general flow pattern of the fluid and their effects are those of increased or decreased times of mixing either for longitudinal or cross flow. More specifically, the longer shell length for the same baffle spacing increases the number of turns in the fluid stream and thus increases the mixing rate, whereas, the larger shell diameter for the same tube spacing and baffle spacing decreases the number of turns in the fluid stream per unit of heat-transfer surface.

Possibilities of Rational Determination of Average Velocity

The flow pattern on the outside of the tubes for this shell-and-tube heat exchanger is quite complex and difficult to analyze rationally. The increased number of turns in the path of flow, which would be occasioned by an increased number of baffles for a unit length of exchanger, produces a more effective mixing of the fluid as it flows over the transfer surface, both as a result of the inertial effect of the fluid and as a result of the rotational effect produced by the turn in the fluid stream.

The orifice effect produced by the baffle, whether disk-and-doughnut, half-moon, or orifice type, on the flow pattern immediately following the restriction is one of the easiest to picture; yet, as a result of the internal boundary that is formed by the tube over which the fluid flows and the number of individual obstructions in the path, this effect is difficult to estimate rationally.

If the flow across the tubes, in between the baffles, was always perpendicular to the tubes for half-moon and disk-and-doughnut baffles the average velocity in this region could be obtained, but the shortness of the path in this direction causes very little of the flow to be perpendicular to the tubes. Some have shown a condition in this region which would indicate the flow pattern to be one that extends diagonally from one baffle opening to the next.

The periodic dividing of the flowing stream as it strikes one tube and then another also minimizes the possibility of describing the flow pattern in a rational manner.

In connection with a discussion of these direct effects on the flow pattern, it should be stated that some of the factors affecting the heat transfer and pressure drop, as discussed previously, indirectly affect the flow pattern and, therefore, the effective or average velocity. It is difficult, for example, to say that the diameter and length of the exchanger shell affect the average velocity. It is certainly evident that these two factors do not affect the velocity at any one point in the fluid path, unless the total number of turns around the baffle edges increases the rotational motion of the fluid, but each can have its effect on the average velocity for the entire exchanger. For a given baffle opening and tube spacing, an increase in the shell diameter will increase the length of the path of flow across the tubes and thus decrease the effect of the velocity at the baffle, that is, a "weighted" average would show a smaller effect for this baffle velocity. On the other hand, an increase in the shell length for a particular shell size, baffle spacing, and baffle height would increase the total transfer surface without affecting the crossflow

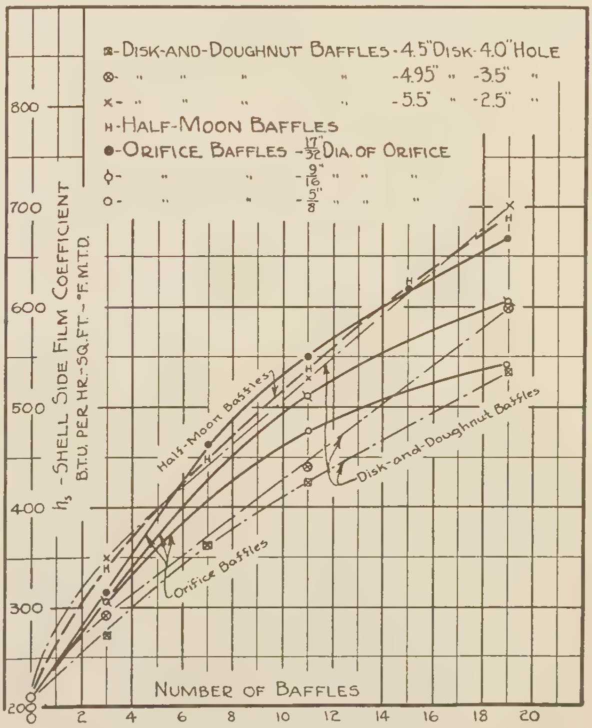

Fig. 3 Comparison of h_s for All Baffle Types for 1/2-In. Tube, 25/32-In-Pitch Tube Bundle at a Shell Fluid (Water) Rate of 10,000 Lb per Hr

velocity and this could, as indicated previously, increase the rotational effect on the fluid. For longer shell lengths, the effect at entrance to and exit from the exchanger shell would be less than for the shorter lengths and would thus have, approximately, the same effect as the flow inside of pipes in the viscous and critical-flow regions.

Previous Analysis for Shell-and-Tube Exchanger

From the standpoint of the designer, it has appeared simpler to use the velocity at some particular point in the exchanger or to use a velocity that would exist if a particular type of construction were used. For example, the writer and M. M. Heller (1), in 1931, published the results of a series of tests on a shell-and-tube exchanger in which the flow was assumed to be parallel to the tubes in correlating the results. This flow was assumed to be parallel to the tubes through an area equal to the cross-sectional area of the shell minus the cross-sectional area of all of the tubes. To correlate the data of these tests with those of McAdams and Frost (2) and Morris and Whitman (3), for flow through tubes, an equivalent diameter was used which was equal to the diameter of a circle with the same area as the "free" area given previously. The exchanger, however, which was used in these tests did not have cross baffles.

In 1933, McAdams (4) presented results of tests on several heat exchangers. The exchangers on which these tests were made had half-moon, orifice, and disk-and-doughnut baffles. To present these results, he used the same velocity that would be obtained if there were no baffles and the flow was entirely parallel to the tubes. Even though commercial exchangers are designed so that corresponding velocities in the different sections are in about the same ratio in different-sized units, McAdams found as much as 500 per cent variation in the transfer rate when based on this velocity.

Heinrich (5) performed some tests on small vertical heat exchangers in 1914, and Stückle presented these results in 1925, but the tube-fluid velocities were too low to permit accurate determination of the shell-side coefficients. A study of the effect of different relative movements of the oil and water in the exchangers on the over-all transfer rate seemed to be Stückle's primary object in his correlation.

Colburn (6) showed, in 1933, that transfer coefficients for the flow across the outside of tubes in a tube bank could be correlated by using the maximum velocity of flow across the tube banks. Sieder and Scott (7), in 1932, used this same velocity for the correlation of the pressure drop across tube banks with the flow perpendicular to the tubes.

In 1934, the author and T. F. Stack (8) published the results of a series of pressure-drop tests on tube bundles which had half-moon baffles. In making this study, an attempt was made to use an equivalent diameter with the velocity that McAdams had used. This method did not prove satisfactory and the data were correlated by means of an empirical combination of the velocity at the baffle and the average maximum velocity between the baffles. The combination of these two rates of flow was arrived at by assuming that the pressure drop was proportional to the square of the effective velocity, which velocity squared, when multiplied by the exchanger length, was equal to the distance through which the fluid flowed at each rate, multiplied by the square of its respective rate of flow.

In 1935, Perrone (9), with data from a series of half-moon-baffled exchangers, used a scheme similar to that which the author and Stack had used. Perrone, however, assumed that the cross-flow distance for the pass between each pair of baffles was from the center of gravity of the segment-shaped opening for flow at one baffle to the center of gravity of the corresponding opening for the next baffle. For the relatively narrow range of variables covered by the data Perrone used, his results showed close correlation.

Bowman (10), in 1935, published his correlation of a series of tests on shell-and-tube exchangers with half-moon baffles. These data covered several sizes of exchangers, several different ratios of baffle heights to shell diameter, several different tube diameters, and several different tube spacings. Bowman used a velocity equal to that obtained with the fluid flowing across all tubes during each pass, in conjunction with an arbitrarily assumed leakage factor. He found that his data followed closely Colburn's curve under these conditions.

The author presented a correlation (11) in 1935–1936 of data which covered tests on exchangers that were equipped with half-moon, orifice, and disk-and-doughnut baffles. These exchangers covered a wide range of tube spacings and tube sizes, as well as several sizes of disk-and-doughnut and orifice baffles. The author assumed that the most usable method of correlation would be one based on a combination of the velocity at the baffles and the velocity between the baffles in a manner that would show the effect of the different variables of the exchanger except the effect of the tube spacing, which effect was shown in the general transfer equation. It was found that the results from the empirical combination of these rates of flow correlated closely for all baffle types and that they were relatively close to Colburn's curve for tube banks and those of other investigators for single tubes. These results also showed a fair correlation with most of Bowman's data, as well as that of two other sources on orifice-baffled exchangers.

Grimison (12), in the fall of 1936, presented a correlation of the data of Huge and Pierson on the flow of air across tube banks, which covered a wide range of tube spacings and tube sizes. Grimison used the same effective velocity that Colburn had used and accounted for the variation in the physical dimensions of the apparatus from which his data were obtained by making use of an arrangement or correlating factor that gave the ratio of the film coefficient for a particular unit to that of the reference unit.

The author recorrelated (13) his own data in 1939, using the same method of approach that he had used in 1935–1936, but keeping the factors on a dimensionless-ratio basis since it was found that his earlier results did not apply very closely to exchangers differing widely in size from the ones which he had originally used. In order to make this new correlation, the author made use of Bowman's data as well as other data supplied by the Foster Wheeler Corporation and the Ross Heater and Manufacturing Company. In this last correlation, a series of equations was also presented which made use of the velocity that McAdams had used. These equations presented, in addition to the velocity effect, the effects of the tube spacing, tube size, shell diameter and length, baffle spacing, and baffle size.

Discussion of Heat-Transfer Correlation

To obtain the film coefficient of heat transfer (11) in this 1939 correlation on the outside of the tubes, the coefficient on the inside of the tubes was determined by the author by means of the equation

$$\frac{h_t D}{k_t} = 0.0225 \left(1 + \frac{50D}{L}\right)\left(\frac{c_t \mu_t}{k_t}\right)^{0.4}\left(\frac{DG}{\mu_t}\right)^{0.8} \quad \ldots\ldots [1]$$

It was found, in the earlier (11) correlation, that the tube-side coefficients, when calculated by an equation similar to Equation [1] without allowance for the end effects, were lower than would be expected for the values of Reynolds number obtained, and that the shell-side coefficients were abnormally high. It was also found that the shell-side coefficients thus obtained were not

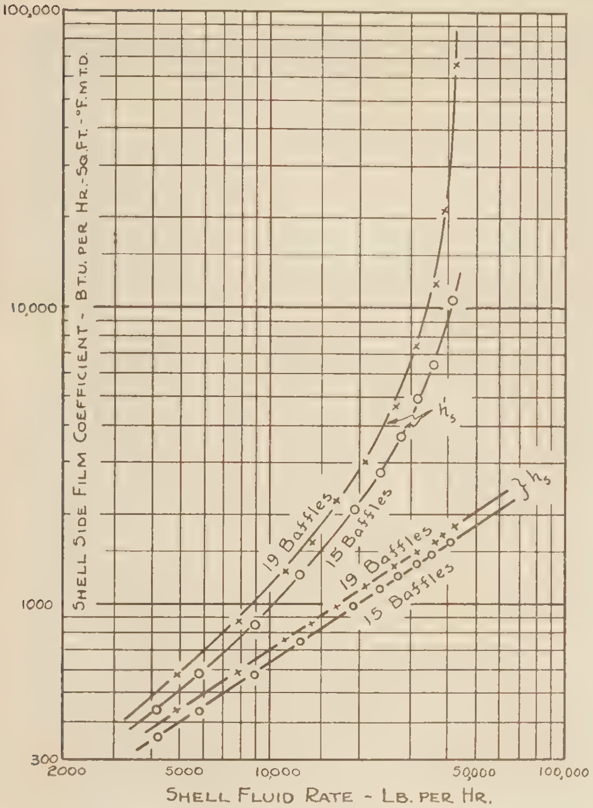

FIG. 4 EFFECT OF INTRODUCTION OF $\phi(D/L)$ INTO COMPUTATION OF h_t WHICH IS USED TO COMPUTE h_s

simple exponential functions of the rate of flow but varied in a rather complex manner. Fig. 4 shows a plot of the shell-side coefficients obtained when using the term $\left(1 + \frac{50D}{L}\right)$ in the tube-side-coefficient equation as contrasted with that obtained when it was omitted; h_s' being the shell-side coefficient obtained without this factor, and h_s being the one obtained when it was used. Results similar to those without the end effects being considered are obtained if Sieder and Tate's (14) curve for heating and cooling of petroleum oils inside of tubes is used.

In so far as the data are concerned on which this study was made, the difficulty discussed may be avoided by using a larger constant in the equation than 0.0225. Hinton's (15) work as well as that of Purday (16) justifies an increase in this constant, but to do this would require a constant that would suit the larger tube sizes which were used, and this did not appear justifiable. A constant could have been selected that would change with tube diameter without being affected by the tube length. Work done by W. A. Randle (17) in 1940 indicates that the end effects are more noticeable at higher Reynolds numbers for the flow through tubes of tube bundles than is true for single tubes. With these two things as a basis, the author feels justified in using the relation given by Equation [1].

The over-all transfer coefficients which were obtained from the test data and from which the shell-side coefficients were calculated were determined by the use of the logarithmic-mean temperature difference. In this correlation, the principal data were from exchangers which had single-pass flow for both the tube fluid and shell fluid. A few tests were used where the tube fluid made two passes with the shell fluid making a single pass through the exchanger. The results from these last tests were close enough to the single-pass tube-fluid results to ignore the effect on the mean temperature difference. The effect of crossflow between the baffles in the half-moon- and disk-and-doughnut-baffled exchangers was such as to cause the true temperature difference to be between the arithmetic mean and the logarithmic mean but with counterflow, as in these tests, and with the closeness of the terminal differences, the difference between the arithmetic and logarithmic means was not greater than 2 per cent as Perrone pointed out.

The fluid properties, as used in the correlation, were evaluated at the mean stream temperature because the properties evaluated at the mean temperature of the wall surface and stream did not improve the correlation. Since the tube-wall temperatures could not be measured accurately, these temperatures had to be determined by a trial-and-error method, and it was considered that the greater ease in using the mean stream temperature outweighed the use of the more rational film temperature.

The effective velocity used in this correlation for each of the three types of baffles is given by the following equations

Orifice baffles

$$G_x = G_s \left(\frac{L}{S}\right)^{0.55} \left[\frac{(D_o - D_t)D_t}{PD_s}\right]^{0.83} + G_s \left(\frac{L}{S}\right)^{0.55} \left(\frac{D_t^2}{A_o}\right)^{0.43} \quad \ldots\ldots\ldots [2]$$

Half-moon baffles

$$G_x = G_b \left(\frac{L}{S}\right)^{0.5} \left(\frac{A_b}{A_s}\right)^{0.5} \left[37.1 \left(\frac{D_t}{D_s}\right)^2\right] + G_p \left(\frac{S}{L}\right)^{0.5} \left(\frac{A_s}{A_b}\right)^{0.8} \quad \ldots\ldots [3]$$

Disk-and-doughnut baffles

$$G_x = G_h \left(\frac{L}{S}\right)^{0.5} \left(\frac{A_h}{A_s}\right)^{0.6} \left(\frac{D_t}{D_s}\right)^{0.86} + G_a \left(\frac{L}{S}\right)^{0.5} \left(\frac{A_a}{A_s}\right)^{0.5} \left(\frac{D_t}{D_s}\right)^{0.86} + G_r \left(\frac{S}{L}\right)^{0.5} \left(\frac{A_h}{A_s}\right)^{0.1} \left[50 \left(\frac{D_t}{D_s}\right)^{1.17}\right] \quad \ldots\ldots\ldots [4]$$

The film coefficient for the shell-side fluid is given by the equation

$$\frac{h_s D_t}{k} = 0.37 \left(\frac{P - D_t}{P}\right)^{0.5} \left(\frac{c\mu}{k}\right)^{0.32} \left(\frac{D_t G_x}{\mu}\right)^{0.6} \quad \ldots\ldots [5]$$

If the velocity, which would be obtained for a shell and its tube bundle without baffles, is used to determine the heat-transfer rate, the following equations show the resulting correlation

Orifice baffles

$$\frac{h_s D_t}{k} = 2.5 \left(\frac{c\mu}{k}\right)^{0.32} \left(\frac{P - D_t}{P}\right)^{0.5} \left[\frac{D_t G_s}{\mu} \left(\frac{L}{S}\right)^n \left(\frac{D_t}{D_s}\right)^{1.5}\right]^{0.6} \quad \ldots [6]$$

where

$$n = \frac{0.3}{\left[\frac{(D_o - D_t)D_t}{P^2}\right]^{0.25}} \quad \ldots\ldots\ldots\ldots\ldots [7]$$

Half-moon baffles

$$\frac{h_s D_t}{k} = 15.8 \left(\frac{c\mu}{k}\right)^{0.32} \left(\frac{P - D_t}{P}\right)^{0.5} \left[\frac{D_t G_s}{\mu} \left(\frac{B_h}{L}\right)^{1.72} \left(\frac{D_t}{D_s}\right)^{0.86} \left(\frac{L}{S}\right)^{0.55}\right]^{0.6} \quad \ldots\ldots\ldots [8]$$

Disk-and-doughnut baffles

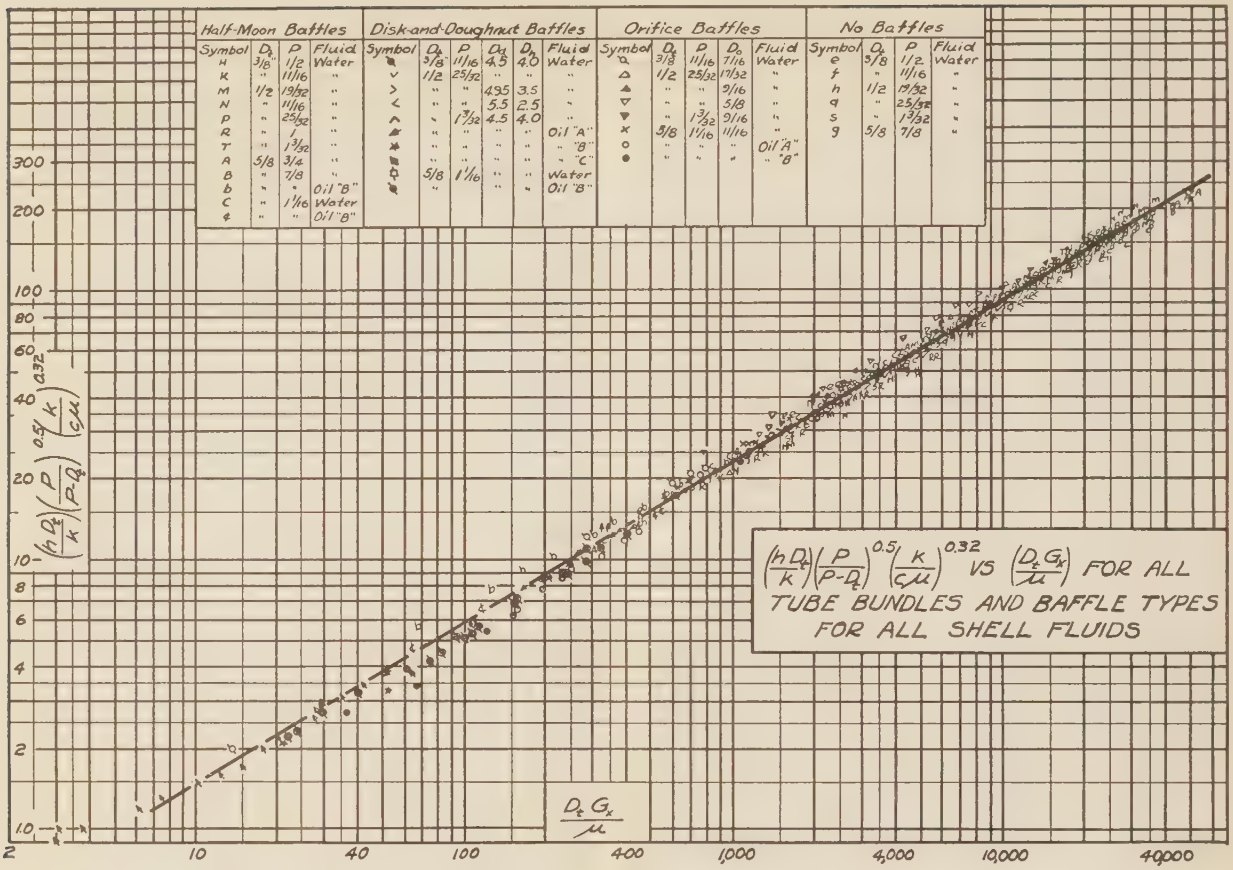

Fig. 5 Data From Tests Used in Original Correlation

$$\frac{h_sD_t}{k} = 0.45\left(\frac{c\mu}{k}\right)^{0.32}\left(\frac{P-D_t}{P}\right)^{0.5}\left[\frac{D_tG_s}{\mu}\left(\frac{L}{S}\right)^{0.5}\left(\frac{A_s}{A_h}\right)^{0.48}\left(\frac{D_t}{D_s}\right)^{0.6}\right]^{0.6} \qquad [9]$$

In these equations, the symbols have the same meaning as in Equations [2 to 5].

From the standpoint of design, as was mentioned previously, Equations [6 to 9] have a greater utility than Equations [2 to 5] but these equations cannot be expected to approximate a rational basis. The effective velocity as given by Equations [2], [3], and [4] represents an empirical combination of two types of flow in the exchanger. It could be said that the two "components" of flow involved are those that would be found in an ideal exchanger of this type. That is, basically, in an exchanger, for example, with half-moon baffles, it would be expected that the flow would be parallel to the tubes at the baffles and perpendicular across the tubes between the baffles. In the actual exchanger, the fluid would cut diagonally across from one baffle opening to the next and would flow parallel to the tubes only at the outer edge of the turn around the baffle. Consequently, in the actual exchanger, the height of the baffle or the shell diameter, the distance from one baffle to the next, the size of the opening for flow at the baffle, the tube size and spacing, and the shell length would affect the actual stream path and, in that way, the cross-sectional area of the stream path and hence the effective velocity. The total length of the exchanger would, as has been mentioned previously, control the total number of turns around the baffle edge, with a given baffle spacing, thus affecting the rotation of the fluid stream.

The effect of the length on the velocity for the orifice type can be justified only as an end effect, which effect should decrease as the length of the exchanger is increased. In this correlation, however, it was assumed that the over-all transfer coefficient was constant for the entire transfer surface, but with petroleum oils with an appreciable change in temperature this is not true. For a cooling of the shell fluid, a decrease would take place in the over-all transfer coefficient. This change in the over-all transfer coefficient would increase with the length of the exchanger and, since this correlation was made from the basis of the heat-transfer rate, the length would enter into the resulting relations. This length effect is shown, by Equation [2] for the effective velocity and Equation [6] for the heat-transfer coefficient with G_s, to cause an increase in the effective velocity or the heat-transfer rate, respectively, approximately as a square-root function of the length.

The data which were used in the orifice-baffle correlation were obtained from exchangers that had lengths of 5, 10, and 19.6 ft, respectively, all other factors being relatively the same for these units. Part of this variation with length may be a result of the method of calculating the coefficient for the tube side, since the longer exchangers would have a calculated tube-side coefficient lower than the shorter ones. Other conditions being the same, the resultant shell-side coefficient would be higher. The experimental data, however, show an increase of only 3.5 and 9 per cent, respectively, for the 10- and 19.6-ft-length exchangers when the tube length is omitted from the calculations for the tube-side

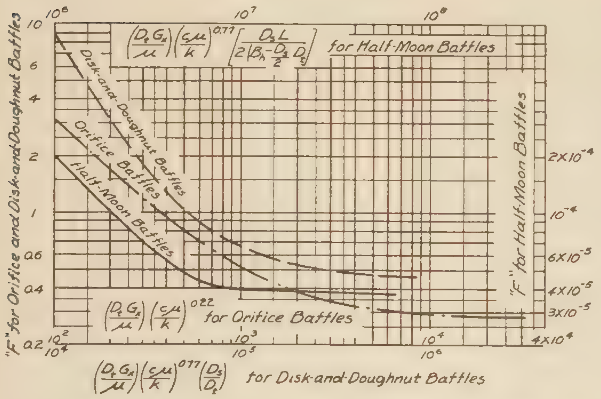

FIG. 6 FRICTION FACTOR-ROUGHNESS CURVES FOR SHELL-AND-TUBE HEAT EXCHANGERS

[For the correlation of data for the curves in Fig. 6, see pp. 29, 31, and 32 of reference (13).]

coefficient, as compared with the coefficient calculated with the tube length in the equation.

Fig. 5 shows all of the data from the tests used in the original correlation, plotted with the use of the effective velocity given by Equations [2], [3], and [4].

PRESSURE-DROP RELATIONS

The drop in pressure through the shell side of these exchangers may be obtained by means of the Fanning equation and the curves of Fig. 6, that is, the pressure drop is given by Equation [10], if the friction factor has been obtained for the particular baffle type from Fig. 6 and Equations [11], [12], and [13].

$$\Delta p = \frac{fLG_x^2}{2(3600)^2\,\rho g D_t} \qquad [10]$$

Orifice baffles

$$f = \left(\frac{P - D_t}{P}\right)^2 \left(\frac{D_s}{D_o - D_t}\right) \frac{F}{(N_b - 2.5)^{0.15}} \qquad [11]$$

Half-moon baffles

$$f = \left(\frac{D_s}{S}\right)^{0.7} \left[20 + \left(\frac{P - D_t}{P}\right)\left(\frac{D_s}{D_t}\right)\right]^{2.87} F \qquad [12]$$

where

$$(S/D_s)^{0.7} = 0.795 \text{ for } S \gtreqless 0.36 \text{ ft}$$

Disk-and-doughnut baffles

$$f = \left(\frac{P - D_t}{P}\right)\left(\frac{A_s}{A_h}\right)^{0.8} F \qquad [13]$$

Rather than have individual curves for each exchanger design and arrangement, which would be normal when compared to the different degrees of roughness in a pipe, and also in order to allow for the orifice effects as a roughness factor, all of the factors which appear to affect the flow resistance in any way are used as a roughness effect and introduced as a correction to the friction factor. Likewise, the effect of heating and cooling is shown by the Prandtl number function by which the Reynolds number is multiplied.

GENERAL CONCLUSIONS

The author has attempted to present a résumé of most of the experimental and analytical work which has been done on the heat-transfer rate and pressure drop on the shell side of the tubes of shell-and-tube exchangers, pointing out, in a more or less progressive manner, the factors which affect the heat transfer and pressure drop, and how these factors could affect these quantities. The correlations presented are not rationally based, except in so far as the fluid properties, fluid velocity, and dimensions of the exchanger are involved, but an attempt has been made to show that the effective velocity as used has a rational foundation. If a fluid flows through an irregular-shaped passage so that its velocity changes periodically, the average velocity will be an average of the instantaneous rates at different points and it may be necessary to make use of the physical dimensions of the passage to obtain the weighted average. The basic error involved in this correlation, as the author sees it, is that the heat-transfer coefficient was used as the governing indicator of what factors caused a variation in the velocity and thus determined what things should be used to determine what weight should be placed on the velocity in each repeating section.

Condensation of Saturated Freon-12 Vapor on a Bank of Horizontal Tubes

By F. L. YOUNG,[1] QUINCY, MASS., and W. J. WOHLENBERG,[2] NEW HAVEN, CONN.

The condensate film formed on tubes below the top tube, in a vertical bank of horizontal tubes, differs from that formed on the top tube because condensate formed on higher tubes drops or runs off to lower tubes, thus affecting the rate of heat transfer at the lower tubes. This paper includes the results of an experimental investigation of such effects on the heat transfer when saturated Freon-12 vapor condenses on the outsides of such a bank of tubes. The result as to film coefficient is correlated with Nusselt's number for condensation and reasonably good agreement is found with the results deduced from Nusselt's theory of condensation in so far as trends are concerned.

Nomenclature

The following nomenclature is used in the paper:

- A = area of heat-transfer surface, sq ft
- D = outside diameter of tube, ft
- Γ = weight rate of condensate flow per unit perimeter, lb per ft per hr
- g = acceleration due to gravity, 4.18×10^8 ft per hr per hr
- h = film coefficient of heat transfer, Btu per sq ft per deg F per hr
- k = thermal conductivity, Btu per sq ft per deg F per ft per hr
- μ = viscosity of condensate, lb per ft per hr
- n = number of pipes high in horizontal condenser
- N_c = Nusselt's number for condensation $\dfrac{r\rho^2\, k^3 g}{D\mu\,\Delta t}$
- ρ = specific weight, lb per cu ft
- r = latent heat, Btu per lb
- t_g = temperature of saturated gas in condenser, deg F
- t_p = temperature corresponding to condenser pressure, deg F
- t_s = temperature of tube surface, deg F
- Δt = temperature difference between gas and tube surface $(t_g - t_s)$, deg F
- W = average weight of water flowing through each condenser tube, lb per min

Introduction

Much information has been published about the condensation of vapor upon a single horizontal tube. This applies to the performance of the top tubes in a condenser but, in the lower tubes in a bank, the rate of condensation decreases because of the fact that condensate falling from above increases the film thickness on the lower tubes and thus increases their resistance to heat flow. For the condition in the lower tubes of a bank, adequate experimental results have not been available. In lieu of this, Nusselt's (1)[3] theoretical approach to the problem may be employed. The results of his theory show the variation in heat-transfer coefficient from tube to tube in a vertical bank of horizontal tubes. One object of the present investigation is to compare Nusselt's theoretical results with those from experiment.

Because few data have been published for condensing Freon-12 (dichlorodifluoromethane), which is widely used in the refrigeration and air-conditioning industries, the experiment was performed with this fluid. Thus, the experimental results add to the information on heat transfer for a single tube, as well as furnish the data necessary for a check on Nusselt's theory for a bank of tubes.

Apparatus

The experimental work was conducted with a horizontal condenser, Fig. 1, consisting of 5 copper tubes, $^3/_4$ in. OD, 41 in. long, with axes in a vertical plane. The shell was composed of a piece of 10-in. pipe with welded heads. A 4-in. flanged side outlet was provided at the center to permit observation of the central portion of all the tubes through a $2^1/_4$-in. sight glass during operation. This outlet facilitated assembly and furnished a convenient space for the glands through which insulated thermocouple leads were brought out.

The tubes were fastened into the heads with tubing fittings. To insure accurate alignment and spacing of the tubes, holes for the fittings were bored and tapped on a horizontal boring machine.

Thermocouples were installed on the outer surface of the tubes to indicate surface temperature and inside the tube to indicate the temperature of the cooling water. The condenser and all gas pipes were insulated with 2 in. of hair felt.

Cooling water was supplied to the tubes from a header. Low velocities of flow were used to obtain satisfactory temperature rise of the cooling water between the thermocouple stations within the tubes. Swirl strips were inserted through the full length of tubes in order to agitate the water. This insured that the thermo-

[3] Numbers in parentheses refer to the Bibliography at the end of the paper.

couples would indicate the average temperature rather than the core temperature of the water.

To provide steady operating conditions and to prevent contamination of the Freon-12, a closed circuit operating at one pressure was employed. This consisted of the condenser, a small receiver, a steam-heated evaporator, a gas heater, and a separator. The general features of this system had previously been employed by the York Ice Machinery Corporation, York, Pa., in experiments on Freon. The particular arrangement employed in these tests is shown diagrammatically in Fig. 1.

The evaporator was placed at the bottom of the Freon circuit. The gas from the evaporator flowed through the superheater into the separator, where entrained liquid was removed, and then into the condenser shell. Condensate passed through the receiver and returned to the evaporator by gravity. The water temperature in the superheater was controlled by injecting steam into it.

A steady flow of condenser cooling water was obtained by using a large constant-head tank, which discharged into a mixing chamber, where the water could be steam-heated to any desired temperature. A calibrated orifice was placed in each of the tubes at the header to insure equal distribution of cooling water among the tubes.

Tube-Surface Temperature Measurement

Since this was an investigation of only the film coefficient and not the over-all coefficient for condensing Freon-12, it was important to measure surface temperatures as accurately as possible. This was done by means of copper-constantan thermocouples installed in the manner employed by Colburn and Hougen (2). Three slots, 1 in. long, 0.025 in. deep, and 12 in. apart, were milled into the central section of each tube. The thermocouples were butt-welded so that they could fit into the slots. The junctions were soldered into the centers of the grooves and the leads wrapped with thread and pressed into a litharge-glycerine compound, one lead running in each end of the slot. The soldered junctions were filed flush with the tube wall. This construction left the condensing surface practically unaltered and offered thermal contact for the leads, hence heat flowing along the wire from the hot gas was transferred to the tube rather than to the junction. Also, the leads were electrically insulated from the tubes so that the surface temperature at the junction rather than an average temperature was measured.

Baker and Mueller (3) have found that on a horizontal condenser tube, the average surface temperature is found on the side near a point 90 deg from the vertical. Since it was important to measure average temperature, and because the least mechanical difficulties would be encountered in this position, the thermocouples were placed in the tube wall 90 deg from the vertical.

Water-Temperature Measurement

Water temperatures were measured by traveling thermocouples supported inside the condenser tubes by $^3/_{16}$-in-OD stainless-steel tubes. Two thermocouples were carried in the end of each. These extended slightly beyond and to the side of the end of the supporting tube, so that the distance between the junctions was approximately $^3/_8$ in. The end of each tube was fitted with two fingers which guided it through a slot in the center of each swirl strip, thus preventing the thermocouples from contacting the strip.

In order to overcome end effects, the thermocouples were inserted approximately 6 in., so that a 24-in. test section was established in the center of each tube. The location of these almost coincided with the wall thermocouples, so that the surface and water temperatures could be measured at the beginning and end of each test section.

Calibration of Thermocouples

The tube-wall thermocouples were calibrated in place on the tubes before and after installation in the shell, and curves were drawn.

The water thermocouples were wired to the switchboard and then calibrated together. A single curve sufficed for these. There were 37 thermocouples in the apparatus. To avoid interconnection and current flow along the tube, each hot junction had its own cold junction in an oil bath kept at 32 deg F. Double-pole copper switches were connected with a potentiometer which was accurate to 0.3 deg F.

Other Measuring Instruments

The condenser pressure was measured by a 300-lb test gage, graduated in 1-lb intervals. Two thermometers with 1-deg divisions were placed in shielded wells 6 in. from each end of the shell to measure gas temperature. Two thermocouples inside the shell also measured gas temperature. The temperature of the gas at the condenser inlet was measured by a thermometer with 1-deg divisions.

Charging the System

Before charging, the system was evacuated with a laboratory pump capable of reducing the pressure to 10^{-3} in. of mercury. The system was then charged with Freon gas until the pressure rose to 10 psi. After standing for 24 hr, the system was again evacuated and then charged with 85 lb of commercially pure Freon-12.

Experimental Procedure

In operating the system, the condenser pressure was controlled by regulating the steam flow to the evaporator. Surface temperature of the tubes was controlled by varying both the initial temperature and velocity of the cooling water. In order to insure mixing, the rate of water flow through each tube was kept above 4 lb per min. At the same time, conditions were controlled so that there was at least a 5-deg temperature rise of the water flowing through each test section.

After test conditions had been established, the system was allowed to run for one hour before data were taken. Then the following measurements were made; three temperatures on each tube wall, two water temperatures at the inlet and outlet of each test section, four condenser-gas temperatures, the temperature of the gas entering the condenser, condenser pressure, total weight of water flowing through all the tubes, and the weight of water flowing through each individual tube. A run consisted of taking three complete sets of these data. Check runs were also made, but only two sets of data were taken during these.

After the bank of five tubes had been tested, the consistency of the data was investigated by blanking off the top tubes, one at a time, and operating this smaller number of tubes over the range of test conditions. For example, the first tube in the bank was plugged so that no cooling water ran through it, thus making it inactive as a condensing surface. Hence, there were only four tubes in the bank, the original second tube now becoming the first. This process was carried on until banks of five, four, three, and two tubes had been tested. In this manner, each tube was tested in a number of relative positions in the tube bank. During these later investigations, observations were made frequently to be certain that the inactive top tubes were not condensing gas.

Experimental Results

A total of 73 runs was made with saturated Freon-12 vapor at condensing temperatures varying according to the following schedule:

Saturation temperature, F	Mean temperature difference ($t_g - t_s$)
85	10
95	10, 15
105	10, 15, 20
115	15, 20, 25, 30
125	30

In order to insure reasonable accuracy in the determination of temperature differences, the apparatus was operated so that the temperature difference between the gas and the tube walls exceeded 10 deg F; the cooling-water temperature rise in the test sections was at least 5 deg F; the cooling-water flow rate was 4 or more pounds per minute to insure turbulence; and the measured condenser-gas temperature was within ± 1 deg F of t_p.

Characteristics of Film

Observation of the tube through the sight glass showed that, under all conditions and rate of condensation, a very quiet, streamline film formed on the first tube in the bank. At the bottom of the tube, the liquid formed drops which fell to the second tube. These did not always fall from the same point; at times the point of origin of each moved back and forth along the tube. At high rates of condensation, these drops became small streams.

The films on all the tubes below the first in the bank were definitely disturbed at all rates of condensation. Their characteristics are best illustrated by conditions existing when condensation started. A quiet, streamline film formed on all the tubes. A drop falling from above struck a tube and fell down over the top of the existing smooth film. This formed a rivulet approximately 1/4 in. wide which increased the film thickness around that part of the tube. As the rate of condensation increased, the number of rivulets became greater until all but the first tube exhibited a rapidly moving, rippled film. For all but the lowest rates of condensation, the liquid fell off the bottom of each of the lower tubes in steady streams. Condensate drained vertically down each tube wall and, upon reaching the bottom, immediately dropped off, thus showing that all the tubes were horizontal. Under no conditions was any liquid seen to break away from the film and drop off the tube before reaching the bottom.

End Effects

Several tests were made to determine end effects. This was done by including a greater length of the tube as a test section than the usual 24-in. length employed in the run of tests. With tube-wall temperatures of 95 deg F, among the highest used in testing, average values of h were only slightly different from those found in the regular runs. It was concluded that whatever end effects did exist were small.

Comparison of Results

In order to compare Freon-12 with other fluids, all test results are given in terms of heat-transfer coefficient, h, and Nusselt's number, N_c. This also simplifies the analysis and permits all data to be plotted against only two variables, since Nusselt's number takes into account the slight changes in physical properties of the fluid in this temperature range. In computing the data, the total surface of each 24-in. test section was used as the area for heat transfer. The heat flow through it was computed by multiplying the cooling-water rate by the water-temperature rise. The mean temperature difference between the gas and the tube wall was obtained by plotting the three wall temperatures and the gas temperature and then integrating the plot with a planimeter. In evaluating Nusselt's number, the physical properties of the fluid were taken at an average between the wall and the gas temperatures.

Experimental results for a bank of five tubes are given in Table 1. Results of the tests upon banks of four, three, and two tubes are summarized in Tables 2, 3, and 4. Tubes are designated A to E, going from the top to the bottom of the bank. Relative positions in the bank are numbered from 1 to 5, counting from the top tube. For example, tubes B, C, D, and E were in relative position 2 during the tests upon banks of five, four, three, and two tubes, respectively.

The data are plotted in Figs. 2 to 7, inclusive. A straight line with the theoretical slope of Nusselt's equation is drawn through each set of points. This is justified by McAdams' (4) correlation

of condensation data, which shows that Nusselt's curve gives a fairly good correlation throughout the range of N_c.

To obtain the curve for any one tube position, data for all the individual tubes in that position are plotted and averaged. This is done by drawing the curve so that the sum of the differences between the curve and the points above the line is equal to a similar sum below the line. Thus, results from tubes B, C, and D are combined to obtain the curve for No. 1 tube in the bank. The data show quite a deviation from the average, but this is small in comparison with the wide spread of most experimental data.

While the variation in film coefficient, h, with tube position, as shown in Fig. 8, is similar to that predicted by Nusselt, it is not so great. This may be explained by the fact that Nusselt developed his theory by assuming streamline conditions, while in the actual case the condensate film on the lower tubes is rippled and disturbed by drops from the upper tubes. These ripples produce convection as well as conduction in the condensate layer, thus increasing the rate of heat flow through the film. Furthermore, as shown by Nagle and Drew (5), the presence of ripples on the tubes can account for these higher rates, because thermal resistance is reduced more by a trough than it is increased by a crest.

From these curves, the following set of equations for the film coefficient, h, on the gas side of a horizontal multitubular condenser are given. The experimental values are compared with theoretical values predicted by Nusselt and by McAdams. The equations are as follows:

This experiment	Nusselt	McAdams
Tube 1 $h = 0.655\ \sqrt[4]{N_c}$	$0.725\ \sqrt[4]{N_c}$	$0.725\ \sqrt[4]{N_c}$
Tube 2 $h = 0.576\ \sqrt[4]{N_c}$	$0.493\ \sqrt[4]{N_c}$	$0.61\ \sqrt[4]{N_c}$
Tube 3 $h = 0.551\ \sqrt[4]{N_c}$	$0.436\ \sqrt[4]{N_c}$	$0.551\ \sqrt[4]{N_c}$
Tube 4 $h = 0.498\ \sqrt[4]{N_c}$	$0.401\ \sqrt[4]{N_c}$	$0.513\ \sqrt[4]{N_c}$
Tube 5 $h = 0.464\ \sqrt[4]{N_c}$	$0.375\ \sqrt[4]{N_c}$	$0.485\ \sqrt[4]{N_c}$

An attempt was made to correlate the total weight of condensate flowing over each tube with Reynolds number $4\Gamma/\mu$, but no relationship could be established.

Variation of Δt in the Tube Bank

Cooling water entered all tubes at the same temperature; however, the wall temperature decreased going down the tube bank. Therefore, the temperature difference ($t_g - t_s$), increased as the tube was placed lower in the bank. This variation is shown in Fig. 9, which indicates that the change in Δt is affected by condensing temperature. This is explained by the fact that an increase in temperature will decrease the thermal conductivity of the liquid. At the same time, the latent heat decreases, thus allowing more vapor to condense for a given rate of heat flow. This increased condensation will counteract the tendency of the film to become thinner due to a decrease in viscosity, hence the decrease in thermal conductivity will create a greater temperature drop across the condensate film.

Acknowledgment

The authors wish to express their appreciation to Prof. M. L. Wiedmann for his most helpful assistance in the design and construction of the apparatus, and for his many suggestions and interest while the experimental work was in progress.

Discussion

Max Jakob.[4] The authors seem to have been the first to check experimentally Nusselt's theory of the heat transfer in multitubular condensers. Their contribution is particularly valuable because the experiments were performed with Freon-12, one of the least conducting of liquids, whereas water, most frequently used in condensing experiments, is the best conductor of the nonmetallic liquids.

The values of the film coefficient h, measured on tube A, were discarded, their average being 25 per cent below that of the values for the three other tubes when each of them was used as the uppermost in the condenser. The maximum deviations of the latter values from the adopted mean lines were of the order of $\pm$ 20 per cent, whereas the averages of the deviations were well in the range of $\pm$ 10 per cent. This is not excessive compared with the results of similar experiments. The lines, according to Nusselt's theory shown in Fig. 7 of the paper, deviate by 10 to 20 per cent from the adopted experimental lines. Thus the agreement as an average is quite satisfactory.

However, the differences between the experimental and theoretical values have a systematical trend which may be explained. It seems to be due mostly to an apparent deficiency in Nusselt's theory and partly to a difference of the present experimental conditions from those supposed in the theory.

The questionable point in the theory is that it leads to an infinitely thick layer of liquid on the top line of any horizontal tube except the uppermost one. The same holds for the bottom line of each tube, but this does not greatly affect the result; for, even so close to the bottom as $^1/_{20}$ of the circumference, the film is not appreciably thicker than at any place around the tube, and drops on the bottom have practically the same insulating effect which an infinitely thick layer would have.

It is different at the top line. There, an infinitely thick layer would not be stable, but the liquid falling upon the top of the tube will cause a considerable heat transfer under impact conditions spread over a somewhat extended region at the top of the tube. This holds whether drops or streams hit the tube. In the former case, however, the film will be very thin between the spots hit by drops, so that in these regions the heat transfer will be as good as on the top of the first tube. On the places upon which drops fall, turbulent flow must start as observed by the authors. This, however, may turn into streamline flow even in the observed rivulets, for these can be maintained by differences in the thickness of the liquid film as well as by turbulence.

Whether the conditions of turbulence will persist can be checked by Nusselt's theory, which includes formulas for the thickness and velocity of the film at any place. The writer has performed this calculation for the middle between the top line and the bottom line of tubes in position No. 2, under the conditions which existed in runs Nos. 30, 51, and 71. These runs differ only slightly from one another, the average data being t_g = 104.8 F, t_s = 89.8 F, Δt = 15 F, N_c = 2.94 (10^{10})B^{4}hr^{-4} ft^{-8} F^{-4}, and h = 258 Bhr^{-1} ft^{-2} F^{-1}, in good agreement with $h \approx 254$ at the corresponding point of the experimental line 2 in Fig. 7.

The best known data for the pertinent physical properties at the mean temperature t_m = 97.3 seem to be r = 57.6 Btu per lb, ρ = 79.8 lb per cu ft, k = 0.0483 Bhr^{-1} ft^{-1} F^{-1}, and μ/g = 1.417(10^{-9}) lb hr ft^{-2}. With these values, N_c = 3.10(10^{10}) is derived in satisfactory agreement with the value mentioned.

Using $N_c = 3(10^{10})$, Nusselt's theory, applied to the liquid film at the mid-point between top and bottom of a horizontal tube in row No. 2, yields the film thickness s = 0.000194 ft; the mean liquid velocity v_m = 702 ft per hr, and the Reynolds number $\mathbf{R} = \frac{4v_m s\rho}{\mu} = 75$. The latter being far below its critical value, the flow actually tends to become streamlined again after the described disturbance on the top of the tube, and the same thing will occur in the following tubes although there s, v_m, and $\mathbf{R}$ will have greater values. However, the disturbance on the top will be sufficient to explain most of the difference between calculation and observation in the positions Nos. 2 and 5, as shown in Fig. 7 of the paper.

In addition to this, it must be considered that Nusselt's theory is based on the assumption of a constant temperature difference Δt all over the tube bank. In the present experiments, however, according to the tables and Figs. 9 and 10, Δt increases between the first and fifth row by about 20 per cent of its original value. This is due to the decrease of the temperature drop between the inner tube surface and the cooling water. This decrease comes from reduction of the radial heat flow, owing to the increase in thickness of the liquid film between positions Nos. 1 and 5.

Nusselt's theory includes a constant of integration C which is increasing by 3.4278 from one row to the next one. This, however, holds only for Δt = const. If Δt increases, then C increases less than 3.4278, and the increase of the film thickness is likewise reduced. By this in the equation $h = K\sqrt[4]{N_c}$, the decrease of N_c from one row to the next one which is caused by the increase of Δt is partly compensated by an increase of K. The theory allows calculating this increase, and the writer did it approximately for tube positions Nos. 2 and 3. It was found that K for the second row is to be increased by $^3/_4$ per cent and for the third row by 2 per cent. The writer estimates that for the fourth and fifth rows of the bank K will increase by $3^1/_2$ and $5^1/_2$ per cent, respectively. This means that h, as represented in Fig. 7 of the paper by dotted lines Nos. 2 to 5, should be raised by $^3/_4$ to $5^1/_2$ per cent for comparison with the full lines.

It may be concluded that using Nusselt's theory for multitubular condensers, the change of Δt, if appreciable, should be taken care of in the calculation of N_c as well as of K, and about 10 per cent should be added to h at all tube rows except the first one, in order to compensate for the deficiency in the theory, as explained.

Concerning the nomenclature, it seems to be inconvenient to use the expression "Nusselt's number" for N_c as has been done in the headings of the tables, because a dimensionless group which, in the present case would be hs/k, is generally called Nusselt's number.

Byron E. Short.[5] The authors state that several tests were made to determine the "end effects." As understood, this would imply that a change in diameter of the tubes, using the same length, would not increase or decrease the transfer rate either on the inside or on the outside. Present published work shows that the end effects become negligible as soon as the Reynolds number values reach 5000 to 6000. The analyses that have been presented are based largely on the correlation of the data of different experimenters and, in many cases, on results which were obtained with calming sections ahead of the heating or cooling section. Lawrence and Sherwood's work was performed without calming sections but with the use of thermocouples on the surfaces of tubes with condensing steam. Moynihan and Jeffrey showed that thermocouples on tube surfaces with condensing steam gave erratic results, and Lawrence and Sherwood's results show no general pattern which is explained by them as a result of the thermocouple usage. So, in the case of the present paper, it seems

[4] Research Professor of Mechanical Engineering, Illinois Institute of Technology and Armour Research Foundation, Chicago, Ill. Mem. A.S.M.E

[5] Professor of Mechanical Engineering, University of Texas, University Station, Austin, Tex. Mem. A.S.M.E.

that the authors are not entirely justified in saying that the end effects were not noticeable, since they used thermocouples on the surfaces with a condensing substance and obtained somewhat erratic results.

In connection with Fig. 7 of the paper, it would appear that the decrease in rate of heat transfer for tubes at lower and yet lower levels in a tube bank should become less, as indicated by Nusselt, and eventually reach a constant value. It seems that a limit should be reached to the thickness of the condensate film formed on the tubes, as lower ones in the bank are reached, since the gravitational and cohesion forces should arrive at a point of equilibrium. Then too, with the increased rate falling from above, the condensate film should move at a higher velocity and thus place a limit on the minimum value of the heat-transfer film. The author's values in Fig. 7, are contrary to this point of view.

S. P. Soling.[6] In presenting data for condensation of saturated Freon-12 vapor on a bank of horizontal tubes, the authors have performed a service of double value. The information on Freon-12 is a welcome addition to the literature. The data on the performance of tubes other than the top tube are also of great value.

There are, however, a number of points that appear to the writer to be questionable, or at least controversial. The clarification of these points would aid in the understanding of the results presented by the authors.

The first, and most important point involves the question of temperature difference. The authors cite the work of Baker and Mueller (3) to justify the use of a point 90 deg away from the vertical, as giving an average temperature. However, in the paper referred to, Baker and Mueller point out in their conclusions,[7] "the assumption that the position of the thermocouple halfway between the top and bottom will give the average temperature is erroneous." They further state, "there is no location for the thermocouple that can be depended upon to give correct average readings for the tube temperature."

Baker and Mueller's statements appear justified in the case of the present work and apparently explain the erratic behavior of the (Δt)'s tabulated in Table 1. Variations in water quantities through the different tubes would also account for the behavior. The lines drawn by the authors in Figs. 9 and 10 would not give the trend of various runs, as No. 37 for example.

The second point also involves the temperature difference. Nusselt presented equations for determining the coefficient for any tube in a multitube bank. The equation for the nth tube in a bank involved the condensate from the $(n - 1)$ tubes above the one in question and was assumed by Nusselt to be the theoretical amount determined by the equations he proposed. He also assumed that the temperature difference was the same for all tubes. If, therefore, the condensation rate for the first tube is considerably below the theoretical value, then the amount of condensate dropping onto the second tube would be considerably less than the theoretical amount that would justify the use of Nusselt's equation for the second tube. For this case, the film on the second tube would be too thin, and the actual coefficient obtained could readily be much greater than that obtained from Nusselt's equation without the need of an explanation regarding turbulence.

Considering run No. 37 in this light, the coefficient for the first tube should theoretically be (using N_c for the second tube)

$$h = 0.725 \sqrt[4]{5.45 \times 10^{10}} = 350$$

and it is apparent that the amount of condensate is $\dfrac{180 \times 8.2}{350 \times 9.7} =$ 43.5 per cent of the theoretical amount required to make the use of Nusselt's equation for the second tube valid.

By the use of the material contained in Nusselt's paper, it is possible to make the correction, but the process is laborious, requiring graphical integration. A possible method of correcting for this will be suggested.

Before dealing with this method, it should be observed that the values attributed to McAdams are numerically correct but do not apply as given. The McAdams' values give the average coefficient for n tubes and not for the nth tube. This relation between the author's theoretical values of Nusselt and McAdams may be checked as follows:

The average coefficient for five tubes would be (from Nusselt's values)

$$h = \frac{0.725 + 0.493 + 0.436 + 0.401 + 0.375}{5} \sqrt[4]{N_c}$$
$$= 0.486 \sqrt[4]{N_c}$$

McAdams value is given as $0.485 \sqrt[4]{N_c}$.

This relation may be found for any of the other values supplied by the authors.

Since the values given by McAdams are readily obtained, depending upon the following equation

$$\text{Average coefficient } h = \frac{0.725}{n^{1/4}} \sqrt[4]{N_c}$$

it can be shown that the coefficient for the nth tube of a bank may be written

$$h \text{ for } n\text{th tube} = 0.725 \sqrt[4]{N_c} \left\{ n^{3/4} - (n-1)^{3/4} \right\}$$

This then suggests a means of dealing with the condensation on a tube when the condensate coming down from the tubes above differs from the theoretical amount. The first four tubes of a bank might conceivably condense as much liquid as would six tubes following Nusselt's equations. The fifth tube in the bank would act only in accordance with the amount of condensate it received and its own temperature difference. If any comparison with theoretical values be made, it is apparent that the comparison should be made with theoretical values for the seventh tube.

Returning now for further consideration of run No. 37, the coefficient for the first tube should be (to permit comparison of actual and theoretical values for the second tube)

$$h = 0.725 \sqrt[4]{5.45 \times 10^{10}} = 350$$

$$\text{Btu per sq ft per hr} = 350 \times 9.7 = 3390$$

$$\text{Actual Btu per sq ft per hr} = 180 \times 8.2 = 1475$$

Since only the condensate corresponding to 1475 Btu per sq ft per hr would reach the second tube, 0.33 tube would produce the same result, if it behaved in the theoretical manner at $\Delta t = 9.7$. This would then make the second tube the same as $n = 1.33$, and therefore

$$h = 0.725 \sqrt[4]{5.45 \times 10^{10}} \, [1.33^{3/4} - 0.33^{3/4}]$$
$$= 350 \times 0.803 = 281$$

The actual coefficient is 316, or 112 per cent of the theoretical. If no consideration be given to the amount of condensate reaching the tube, then the actual coefficient is 132 per cent of the theoretical value.

From this, it should be apparent that consideration of the nth tube by itself is not sufficient. Corrections should be made for deviations of the amount of condensate from that which would theoretically be produced by $(n - 1)$ tubes.

The writer attempted to correlate the coefficient against Rey-

[6] Mechanical Engineering Department, York Ice Machinery Corporation, York, Pa. Jun. A.S.M.E.

[7] Bibliography reference (3), p. 537.

nolds number before realizing that this cannot be done for the individual tube coefficients in a multitube bank, at least not in the laminar-flow region.

Authors' Closure

The authors are indebted to Messrs. Jakob, Soling, and Short for pointing out certain discrepancies and for including additional analyses which aid in the interpretation of the experimental results.

Dr. Jakob points out some of the inadequacies of Nusselt's theory when attempts are made to apply it to experimental information, such as this, when factors considered constant by Nusselt actually varied in the experiment. If the Nusselt, constant C referred to by Jakob had been corrected for the deviation of the actual condensate flow from the theoretical, then corrections noted by Jakob might have been somewhat smaller.

The method for correcting Nusselt's coefficients given by Mr. Soling is actually quite similar to that of Jakob. However, Mr. Soling would consider the variation of actual flow from the theoretical, rather than merely correct for change in Δt. Mr. Soling's choice of example is unfortunate because data for tube 1 in Table 1 of the paper were discarded due to experimental difficulties.

Regarding Mr. Jakob's remark on nomenclature, the authors are attempting to compromise by calling N_c "Nusselt's number for condensation." Since the parameter commonly called the condensation number is not the same as N_c, a name had to be coined. It is hoped this will not be confused with the group hD/k called "Nusselt's number."

In reply to Mr. Soling's remarks on tube-temperature measurement, the authors have realized that the best they could hope for was a temperature that would not deviate far from the average. Baker and Mueller data show that the average wall temperature is found somewhere near the 90-deg position. Their data for a single tube show the highest temperature at the top of the tube, the lowest at the bottom. This is to be expected from the film thickness around the tube predicted by Nusselt's equations. In multitubular condensers, it is quite possible that the temperature distribution around the lower tubes is not quite the same as in the first, but since the variation of heat-transfer coefficient around the lower tubes is nearly the same as in the top tube, the location of the point of average temperature is probably near the 90-deg spot. As a practical matter, the tubes could not be rotated to discover this temperature distribution, and the thermocouple leads had to be carried off at 90 deg in order to interfere least with the condensate film. The authors believe that the erratic behavior of the Δt terms is due to the thermocouple behavior and not to variations in water quantity through the individual tubes. This variation was so small that it can almost be neglected.

The end effects were determined by pulling the traveling waterside thermocouples toward the ends of the tubes, thus lengthening the test section. Since the rate of heat transfer per unit area remained unchanged, it was assumed that a negligible amount of heat was flowing along the tube walls.

Mr. Short's comment on the possibility of a lower limit for the value of h would be more nearly true of steam than of a poor conductor such as Freon-12. Such a limit would probably be a function of Reynolds number.

Heat Transfer, Pressure Drop, and Fouling Rates of Liquids for Continuous and Noncontinuous Longitudinal Fins

By A. Y. GUNTER[1] and W. A. SHAW,[2] NEW YORK, N. Y.

This paper contains test data on continuous and noncontinuous fins for liquids in the laminar-flow region. The data indicate that for longitudinal fin-tube "pipe-within-pipe" type heat exchangers, the transition range begins near $R_h = 200$. Correlation with earlier investigations on air with short longitudinal fins, for $R_h > 600$, indicates fair agreement with the authors' results, when length of fin and inlet turbulence are taken into consideration. Noncontinuous fins promote turbulence in the laminar-flow region and increase fin-side heat-transfer coefficients up to 100 per cent, in the range of $L = 10$ ft. The theoretical aspects of fouling on fin tubes versus bare tubes are graphically illustrated, and actual semi-plant-scale fouling rates are plotted. These data show that fin tubes are affected less by fouling than bare tubes, because the effectiveness of the fin increases when fouling becomes greater.

Nomenclature

THE following nomenclature is used in this paper:

A = $(A_f + A_t)$ = total "exposed" fin-side surface area, sq ft
A_c = net free cross-sectional area for flow on the fin side, sq ft
A_f = surface area of fins only, sq ft
A_i = inside surface area of tube sq ft
A_t = outside surface area of tube only, sq ft
b = height of fin (see Fig. 1*b*), ft
c = specific heat of fluid, Btu per deg F per lb
$D_h = \dfrac{4A_c}{\psi_h}$ = equivalent hydraulic diameter, for determination of heat-transfer coefficient, ft
$D_p = \dfrac{4A_c}{\psi_p}$ = equivalent hydraulic diameter, for determination of pressure drop, ft
f = friction factor, defined by Equation [9], dimensionless
G = ρV = mass velocity of fluid, lb per sq ft per hr
g = acceleration of gravity = 4.17×10^8 ft per hr per hr
h_d = fouling (or deposit) factor, for fin-side fluid, Btu per sq ft per deg F per hr
h_f = fin-side film coefficient (clean), based on A, Btu per sq ft per deg F per hr
h_{fd} = fin-side film coefficient (fouled), (see Fig. 4), Btu per sq ft per deg F per hr
h_i = fin-side film coefficient (h_f), referred to A_i, by correction for effectiveness and tube-wall resistance (see Fig. 4), Btu per sq ft per deg F per hr
h_{id} = fin-side film coefficient (h_{fd}), referred to A_i, by correction for effectiveness and tube-wall resistance (see Fig. 4), Btu per sq ft per deg F per hr
h_t = tube-side film coefficient, Btu per sq ft per deg F per hr
h_w = reciprocal of tube-wall resistance (see Fig. 4), Btu per sq ft per deg F per hr
$J_S = \dfrac{h_f D_h}{k}\left(\dfrac{c\mu}{k}\right)^{-1/3}\left(\dfrac{\mu}{\mu_w}\right)^{-0.14}$ = heat-transfer factor, according to Sieder and Tate (1),[3] dimensionless
$J_A = \dfrac{h_f}{cG}\left(\dfrac{c\mu}{k}\right)^{2/3}\left(\dfrac{\mu}{\mu_w}\right)^{-0.14}$ = heat-transfer factor, according to Colburn (2) with Sieder (1) viscosity correction, dimensionless
k, k_f, k_w = thermal conductivity of fin-side fluid, of fin material, and of wall material, respectively, Btu per sq ft per deg F per hr per ft
L = length of fin section (see Fig. 2), ft
Δ_p = pressure drop of fin-side fluid, due to "friction," psf
$R_h = \dfrac{D_h G}{\mu}$ = Reynolds number, based on equivalent hydraulic diameter for heat-transfer coefficient, dimensionless
$R_p = \dfrac{D_p G}{\mu}$ = Reynolds number based on equivalent hydraulic diameter for pressure drop, dimensionless
U_c = over-all heat-transfer coefficient (clean), steam to fin-side fluid, based on A_i, Btu per sq ft per deg F—log *MTD* per hr
U_d = over-all heat-transfer coefficient (fouled), steam to fin-side fluid, based on A_i, Btu per sq ft per deg F—log *MTD* per hr
V = linear velocity of fin-side fluid (at A_c), fph
δ = thickness of fin (see Fig. 1*b*), ft
η = effectiveness factor of fin (see Fig. 4), dimensionless
η' = total surface effectiveness (see Fig. 4), dimensionless
μ = viscosity of fin-side fluid (evaluated at average fluid temperature), lb per hr per ft
μ_w = viscosity of fin-side fluid (evaluated at tube-wall temperature), lb per hr per ft
ψ_h = total wetted perimeter of heat-transfer surface (fins plus outside of tube), for heat-transfer coefficient only, ft
ψ_p = total wetted perimeter of heat-transfer surface (fins plus outside of tube, plus inner surface of sleeve), for pressure drop only, ft
ρ = density of fin-side fluid, lb per cu ft

Introduction

Tubes with longitudinal fins cast, welded, or mechanically bonded thereon, have been used industrially for a number of years. These tubes have, in most cases, been manufactured in "continuous" lengths up to 22 ft. Their main application has been for heat-exchange duties covering light fluids such as gaso-

[3] Numbers in parentheses refer to the Bibliography at the end of the paper.

line, down to the heaviest tars and asphalts. In air heating and cooling, longitudinal fins of much shorter length, 6 in. and less, are quite often used. The heat-transfer coefficients for air, using very short fin lengths, have been obtained, correlated and analyzed by R. H. Norris and W. A. Spofford (3).

Since longitudinal fins for liquids are nearly always used with $L/D_h > 156$, and their structural shapes are somewhat equivalent to flat ducts, the data reported in this paper are more nearly equivalent to Norris and Streid (4).

The data herein reported refer to pipe-within-pipe-type units and are not strictly applicable to other types of fin-tube units.

The present paper has three objectives, as follows:

1 To furnish test data on liquids in laminar flow for long continuous fins, correlated with published data and theoretical curves for air (3, 4).

2 To indicate the advantages of noncontinous longitudinal fins over long continuous fins for liquids.

3 To present analysis of the theoretical aspects of fouling on fin tubes, as compared with bare tubes, together with a presentation of actual fouling rates encountered in intermittent semi-plant-scale operations.

It must be remembered that the plant-scale conditions of using various fluids from 10,000-bbl storage tanks made it impossible to control inlet temperatures from day to day, and prevented keeping μ constant for the various sets of tests; nor are the conditions of constant surface temperature or constant heat input per unit of length fulfilled, as called for by Norris and Streid (4).

Fig. 2 Tabulation of Heat-Transfer, Friction, and Pressure-Drop Efficiency Factors for Fluids

Terminology

The terms "fin height" and "fin thickness," as used in this paper are illustrated in Fig. 1. The "fin length," L, is also indicated, but it should be pointed out that on the noncontinuous fins, the term fin length, L, is the continuous length between the cut sections, as shown in Fig. 2, and may consist of two, four, or more sections; however, only the length of each section is considered in the L/D_h ratio.

Résumé of Tests

The majority of the tests made utilized the size and type of fin tube and sleeve illustrated in Fig. 1. Other tests were run utilizing fin tubes up to 4 in. diam with varying fin spacing, and $^3/_4$ in. fin height, which are not reported in this paper. As indicated in Fig. 1, steel fins $^1/_2$ in. in height and 0.035 in. in thickness were used from which fin effectiveness could be readily calculated by the method presented by Harper and Brown (5) (see Fig. 4).

The scope of the 300 tests herein reported is shown in Table 1.

TABLE 1 RANGE OF VARIABLES COVERED IN TESTS

Fluid characteristics	See Table 5
Steam temperatures, F	250 to 325
Average oil temperatures, F	115 to 235
Linear velocity, fps	0.3 to 10
$\left(\frac{\mu}{\mu_w}\right)^{0.14}$	0.85 to 1.9
$\frac{c\mu}{k}$	5 to 5000
L/D_h	37.6 to 313

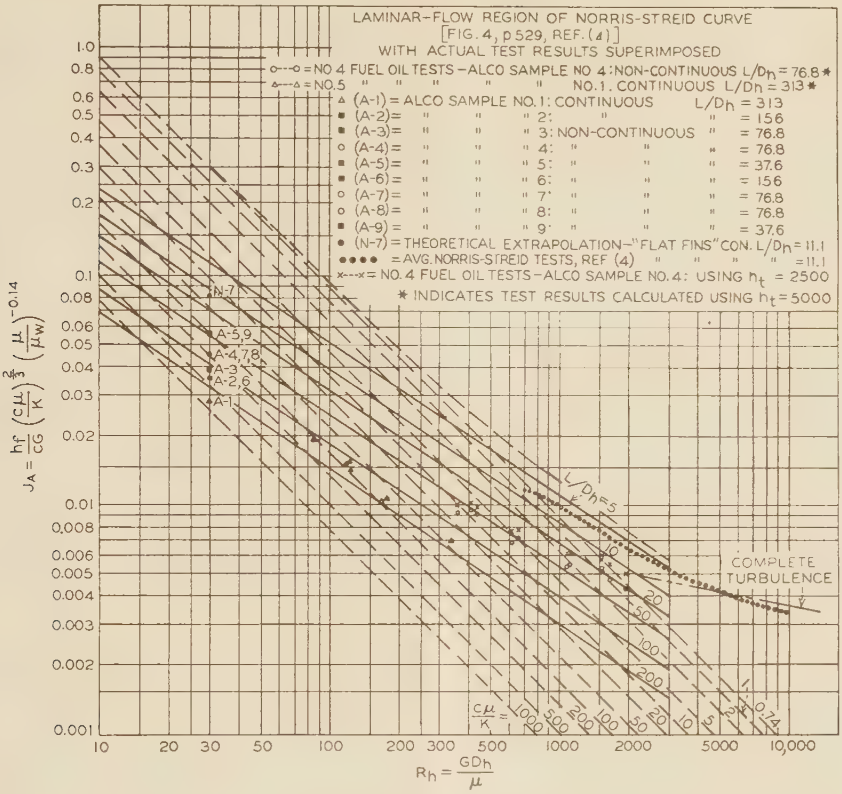

Fig. 3 Correlation of Test Data With Norris and Streid's Suggested Curve
(Reference 4, Fig. 4, p. 529.)

Correlation of Heat-Transfer Data

The original choice of correlation was based on

$$J_S = \frac{h_f D_h}{k}\left(\frac{c\mu}{k}\right)^{-1/3}\left(\frac{\mu}{\mu_w}\right)^{-0.14} \quad \ldots\ldots\ldots\ldots [1]$$

according to Sieder and Tate (1) for the following reasons:

1 This method would give one curve for both heating and cooling using L/D_h parameters.

2 From a practical rating standpoint, it provided the most convenient form for everyday use.

Therefore, all original data were calculated on this basis, using $h_t = 5000$ for the steam-film coefficient. This procedure introduced a factor of safety for h_f on an average of approximately 8 per cent. This is shown in Fig. 3, as a replot for No. 4 fuel oil.

For the purpose of correlating data reported in this paper with Norris and Streid (4), the ordinate expression

$$J_A = \frac{h_f}{cG}\left(\frac{c\mu}{k}\right)^{2/3}\left(\frac{\mu}{\mu_w}\right)^{-0.14} \quad \ldots\ldots\ldots\ldots [2]$$

was used, and these values are shown in Figs. 2 and 3.

As stated in the introduction, the tests on liquids herein reported are governed by L/D_h parameters, since all exceed the limiting values given by Equations [27] and [28] in reference (4). However, to correlate tests on liquids at various temperatures and linear velocities, it is necessary to use the $\left(\frac{\mu}{\mu_w}\right)^{0.14}$ ratio as outlined by Sieder and Tate (1). Further, to compare test results from different tubular units with different fluids, resort must be made to the Grashof number corrections as outlined by Colburn (2) and Sieder and Tate (1).

Fig. 2 has been set up from averages of actual test results to indicate the advantage of changing a long continuous fin tube into a long tube with short noncontinuous sections and turbulence promoters separating the sections. It will be noted that J_A increases up to 100 per cent with the L/D_h ratio decrease, and that $J_A/(f/2)$ of reference (3) remains substantially constant.

The J_A value for sample N-7 is the theoretical value at $R_h = 30$ for L/D_h taken from Fig. 4, reference (4) as there are no test data for air at this Reynolds number. There is no difference in $R_h = 30$ and $R_p = 23.4$, for D_h and D_p definitions give different wetted perimeters for heat transfer and pressure drop as shown in the nomenclature.

The choice of $R_h = 30$ for the tabulation was predicated on the fact that, between $R_h = 100$ and 200, the authors' test results indicate the transition range between laminar and turbulent flow begins. Numerous repeat tests were made to check this point, all giving materially the same result. This fact was believed to be due to the shape of the passages between the fins. Close inspection of Fig. 1 will show that the flow area of the test exchanger is an annular space divided into twenty small trapezoids (depth to width ratio = 0.41) by the fins. Therefore, better correlation was anticipated with published test data for flat or noncircular ducts.

Davies and White (6) have investigated the isothermal flow of fluids in tubes of various shapes. They found that, in the turbulent-flow region, the friction factors for all shapes were in substantial agreement. However, in the laminar-flow region, for shapes other than circular, they point out that the slope of the curve may not be 45 deg, and the friction factors in general are higher. Further, it was determined that the transition range between laminar and turbulent flow might begin as low as $R_h = 200$ for noncircular shapes.

Since the heat-transfer coefficient h_f normally increases with the increase of friction factor f, it would be expected, in view of Davies and White's data (6), that the test results herein reported would show higher J_A values and the transition range beginning well below $R_h = 2100$.

The results, as plotted in Fig. 3, indicate surprising agreement with this hypothesis. It is not intended, in this paper, to cover the entire range of tests in the laminar-flow region, nor to draw final conclusions as to the proper correction for shape factor in Equations [1] or [2], as these items are being reserved for further study. It is sufficient at this time to state that the L/D_h parameter curves, in Fig. 4 of reference (4), are conservative for liquids in the range of $R_h = 150$ to 2100, for the test unit described in Figs. 1 and 6 of this paper.

In considering the economic aspects of normal heat-exchanger design for liquids in the laminar-flow region, it will be found that for, say, steam heaters, the Reynolds number spread of 1 to 2100 covers a number of liquids as shown in Table 2.

TABLE 2 DATA SHOWING REYNOLDS NUMBERS VERSUS TYPES OF OILS NORMALLY ENCOUNTERED IN STEAM HEATERS

Type of oil	Reynolds number range
Gasoline, kerosene	>2300
Light burning oils (1, 3, and 4)	200 to 8000
Medium fuel oils (No. 5)	80 to 300
Heavy fuel oils and asphalts	<100

NOTE: Limiting range—temperature 80 to 350 F; linear velocity 0.3 to 8 fps.

To indicate this condition from test results and to show the shift in transition range, Fig. 3 has been included, which plots average values for Fig. 2 (pr. still resid. and asphalt) and test results for Nos. 4 and 5 fuel oils. The pr. still resid. and asphalt tests (Fig. 2) were run at average values, $\left(\frac{\mu}{\mu_w}\right)^{0.14} = 1.5$ to 1.9, $\frac{c\mu}{k} = 2000$ to 5000. The Nos. 4 and 5 fuel-oil average test values were $\left(\frac{\mu}{\mu_w}\right)^{0.14} = 1.1$ and 1.26; $\frac{c\mu}{k} = 61$ and 333, respectively. Linear velocities ranged from 0.3 to 5 fps, in all cases.

In addition, Fig. 3 shows a plot of Norris and Spofford's (3) actual test results for sample N-7. It will be noted that the J_A values are above the $L/D_h = 11$ parameter line. The tests in this paper do not cover an L/D_h value as low as 11, although extrapolation from the values between $L/D_h = 313$ and 37.6, to $L/D_h = 11$, indicates agreement within 10 per cent.

Colburn (2) suggested the use of the Grashof number as a correction to the equation of the empirical line for viscous flow as follows:

$$\psi = 1.5\left(\frac{\mu}{\mu_f}\right)^{1/3}(1 + 0.015\, Gr^{1/3}) \qquad [3]$$

(where μ_f is viscosity at film temperature).

Sieder and Tate (1) suggest the correction of h_f by a modified form of Equation [3] when dealing with gases or light liquids. (Here μ in the Grashof number is taken at average stream temperature):

$$(0.8 + 0.012\, Gr^{1/3})\, h_f \qquad [4]$$

A brief check using Equations [3] and [4] with air at 70 F and $R_h = 700$ shows that the test unit for sample N-7 should give approximately a 10 per cent higher J_A value than the test unit in this paper, assuming L/D_h values are equal. This point is more or less academic since neither unit was tested on both liquids and air.

The equation for J_A in the laminar-flow region, as indicated in Fig. 3, where L/D_h parameters are controlling, is

$$J_A = 1.85\,(L/D_h)^{-1/3}\,(R_h)^{-2/3} \qquad [5]$$

This equation is conservative in the range $R_h > 100$ and may be as much as 40 per cent low at $R_h = 2000$ with $L/D_h = 313$ for the test unit herein described. As stated earlier in this paper, the final solution of the foregoing variation must await further study of the data accumulated.

In view of the preceding points, it is obvious that the thermal engineer must be careful, in selecting h_f, to give critical consideration to such factors as $\left(\frac{\mu}{\mu_w}\right)$; the shape and alignment of fins; the geometry of fin passages; etc. These factors may tend toward cumulative effects which would radically modify theoretical analysis or extrapolations of test results. Fortunately, the use of Fig. 4, reference (4), is on the conservative side for liquids and can be used with safety in ordinary cases.

Practical Applications

The data herein presented give an indication of the improvement that can be expected in the laminar-flow region for liquids by taking tubes with long continuous fins and altering the latter to relatively short noncontinuous sections. This procedure still maintains the economic advantage of long heat-exchanger shell construction with increases in over-all rates up to 100 per cent; it also preserves the desirable feature of ease of cleaning.

Fouling Rates

General Considerations. Published data on fouling rates for fin tubes are negligible at present. The data in this paper cover the theoretical aspects, together with actual results of semi-plant-scale operations.

As it happens, most longitudinally finned tube services cover the use of a relatively clean fluid (such as steam or water) on the inside of the tube, or the use of a dirtier fluid at linear velocities near or above the scouring range.

Therefore, in comparing longitudinal fin tubes with bare tubes, the main concern is with the fouling rate and its effects on the fin side, or in the case of bare tubes, on the outside surface.

Theoretical Considerations. Sieder (7) gives a very good résumé and proposed method for calculating fouling rates for bare tubes, which has been used in this paper.

The generalized equation for flow of heat from one fluid to another for bare tubes, with tube-wall and fouling resistance ignored is

$$\frac{1}{U_c} = \frac{1}{h_f} + \frac{1}{h_t} \qquad [6]$$

In commercial practice, a fouling factor is applied and the equation becomes

$$\frac{1}{U_d} = \frac{1}{h_f} + \frac{1}{h_t} + \frac{1}{h_d} \qquad [7]$$

However, in the case of fin tubes, the additional factor of fin effectiveness must be considered. Further, because of the high ratio of $\frac{A}{A_i}$, the tube-wall resistance to the flow of heat is appreciable and cannot be ignored. The equation then becomes

$$\frac{1}{U_d} = \frac{1}{h_{id}} + \frac{1}{h_{td}} \qquad [8]$$

where

$$h_{id} = \frac{h_{fd}\,\eta'\,\frac{A}{A_i}\cdot h_w}{h_{fd}\,\eta'\,\frac{A}{A_i} + h_w}$$

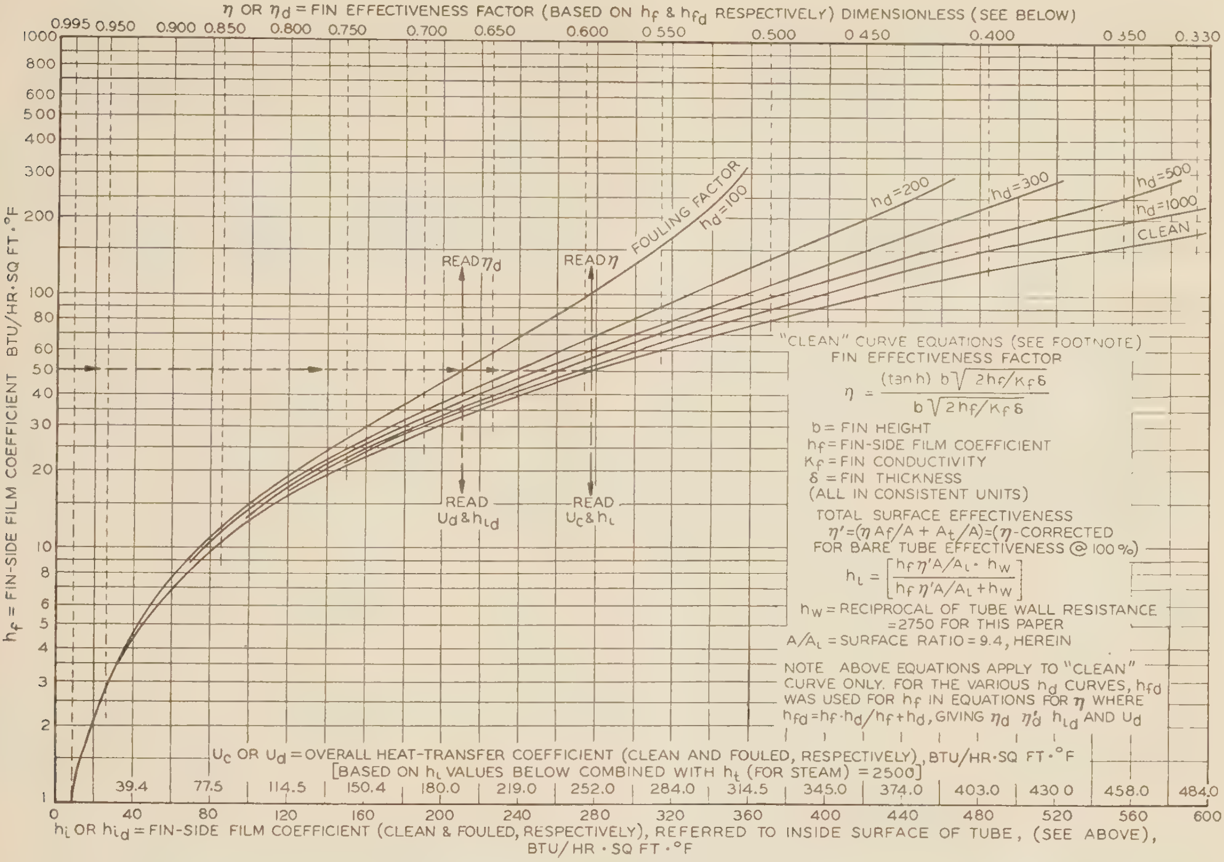

Fig. 4 Theoretical Effects of Fouling Rates on Longitudinal Fin Tube
(1 In. OD, 12 BWG steel with 20 steel fins, 1/2 in. high by 0.035 in. thick attached.)

The fin effectiveness factor η of reference (5) and total surface effectiveness factor η' are described in Fig. 4.

Fig. 4 has been prepared for the tube in Fig. 1, based on the equations noted therein, and plots h_f versus h_i versus U versus η with various fouling factors applied. From a study of Fig. 4, it is immediately evident that fouling affects the fin effectiveness factor η appreciably, always increasing the effectiveness. This gives the fin tube a decided advantage over bare tubes when fouling is considered.

As an example, a point $h_f = 50$ with $h_d = 100$ is indicated in Fig. 4, in heavy black lines. This gives $U_c = 250$ and $U_d = 192$, or the decrease due to fouling effect on U was 23 per cent. The fin effectiveness factor η was 0.598 at $h_f = 50$ and 0.67 fouled, or a 12 per cent increase. For a bare tube at the same h_f and h_d, using Equations[6] and [7], it is found that $U_c = 49$ and $U_d = 33$, or the decrease due to fouling was 33 per cent. Thus, it is seen that fouling has less effect on fin tubes, as compared to bare tubes, when considering outside surface. In addition, it is obvious that the increase in the fin effectiveness factor η when fouling occurs, is the factor responsible for the advantage.

The increase in η due to fouling is less at lower values of h_f and varies as the hyperbolic tangent with variations in h_f or h_d.

Another inherent advantage in fin tubes is that, in heating liquids which have a tendency to coke or form heavy polymers, the fin-surface temperatures are lower than with bare tubes due to η, with consequent less fouling. Conversely, in cooling, the fin surfaces are at higher temperatures with less tendency to deposit tars, etc.

Test Results. Fig. 5 is a plot of actual test results from intermittent semi-plant-scale test runs reported in this paper (see Appendix, "Test Procedure"). The test shown for the commercial fin-tube tank-suction heater was on a 24-in-diam unit, in bunker "C" fuel-oil service at a major oil company's plant.

It is well known that intermittent operation increases fouling rates above continuous operation, because of oxidation, stagnant-fluid conditions, etc. For this reason, the data, shown in Fig. 5, should be considered as on the high side. However, it does indicate that, for most fuel-oil heaters with steam temperatures not greater than 350 F, an applied fouling rate of h_d = 200 to h_f, should result in at least 1 year of operation without cleaning.

In Fig. 5, a semi-Navy-type fouling test is indicated (Δ), which consisted of leaving the unit full of pr. still resid. for 18 hr, with 80-psi steam inside the tube. Test runs before and after the fouling period gave the fouling factor noted. A dotted line over to the average plot curve shows this test approximating a 1-year operating period for fuel-oil service without cleaning.

It should be pointed out that the tendency for fuel oils to break down with time and elevated temperatures varies considerably. The fuel oil used for the semi-Navy-type test was a 6° API pr. still resid. from cracking operations at 900 F, which should be comparable to most bunker "C" fuel oils on the market.

On the lighter oils, very little fouling was encountered beyond that expected for intermittent operations.

Standard Fouling Factors. The Tubular Exchanger Manufacturers Association (T.E.M.A.) (8) has set up standard fouling factors, based on actual plant experience, over a period of many

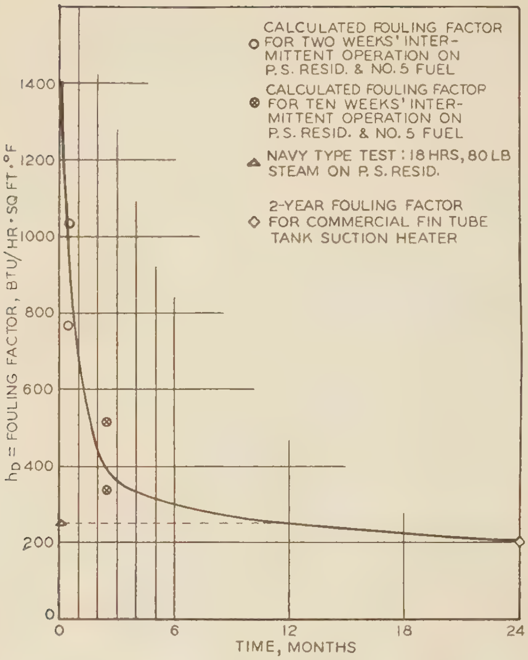

FIG. 5 TEST DATA ON FOULING RATES

years. The fouling factors which are applicable to data reported in this paper have been excerpted from reference (8) and are shown in Table 3. It will be noted that the test data check well in line with the T.E.M.A. Standards.

TABLE 3 EXCERPT OF FOULING COEFFICIENTS FROM STANDARDS OF T.E.M.A. FOR VARIOUS FLUIDS USED IN THIS PAPER

Fluid	Fouling coefficient, h_d
Industrial fuel oil	200
Residual bottoms, less than 25° API	200
Distillate bottoms, 25° API or above	500
Side stream cuts (Nos. 1, 2, 3, and 4, fuel oils) atmospheric dist. units	770
Steam (non-oil-bearing)	0
Steam, exhaust (oil-bearing, from reciprocating engines)	1000

Correlation of Pressure-Drop Data

All the original pressure-drop test data covered in this paper were evaluated by use of the modified form of the general Fanning equation, as outlined by Sieder and Tate (1), who introduced the function $\left(\frac{\mu}{\mu_w}\right)^{0.25}$ to make it applicable to all fluids.

For purposes of correlation with data presented by Norris and Spofford (3), the generalized Fanning equation was used with $\left(\frac{\mu}{\mu_w}\right)^{0.25}$ function added

$$f = \frac{gD_p\Delta P}{2\rho V^2 L}\left(\frac{\mu}{\mu_w}\right)^{0.25} \quad [9]$$

The pressure-drop results are shown in Fig. 2, based on both f and $J_A/(f/2)$.

It will be noted that, for any given fluid, the efficiency factor $J_A/(f/2)$ is substantially a constant when $L > 1$ ft and < 10 ft. This means that a long continuous longitudinal fin can be divided into relatively short sections without increasing the total pressure drop beyond that to be expected with the increased heat transfer.

The f value, for sample N-7 in Fig. 2, is a theoretical value based on Equation [9] and modified for $L = 0.5$ ft in ratio to tests in this paper for short lengths. This procedure was necessary since no test data were available at this point.

Under "Correlation of Heat-Transfer Data," reference was made to Davies and White's report (6) on friction factors covering isothermal flow for pipes of various shapes. They found that noncircular shapes caused disturbances to flow in the laminar-flow region and, in some cases, the transition range might begin at a value as low as $R_p = 200$.

To correlate friction factors for the test unit samples A-1, A-9, and N-7 with the Hagen-Poiseuille friction-factor curve for circular shape, and Davies and White's (6) findings, Table 4 is presented.

[a] Authors' tests include end losses.
[b] Davies and White maximum test values, from reference (6), Fig. 2, p. 70.
[c] Average test results.

Sieder and Tate (1) found that circular-tube friction factors for liquids in nonisothermal flow, in the laminar-flow region, would fall on the isothermal f curve when multiplied by 1.1 $\left(\frac{\mu}{\mu_w}\right)^{0.25}$. The evaluations of test data shown in Table 4 have not been corrected by the factor 1.1, as suggested by Sieder and Tate (1).

The Davies and White (6) f values, shown in columns 4 and 5 of Table 4, are based on rectangular shapes for ratio of depth to width. (The ratios were: A-1 = 0.41; N-7 = 0.156.) It will be noted that sample N-7 correlates better with Davies' (6) maximum limits for shape effects, or with parallel plates, rather than with rectangular shapes. Sample A-1 gave values well above the theoretical rectangular shape effect expected, and more nearly in line with an annular ring or parallel plates. It was originally believed that A-1 would correlate as a rectangle, since its flow area consisted of twenty small trapezoids.

Test data for pressure drop not shown in this paper indicate that the transition range begins somewhere near $R = 200$, which is in agreement with Davies and White's (6) conclusions.

Sample A-9, f values cannot be compared with samples A-1 or N-7, as it has twisted fins which offer additional resistance to flow.

General Conclusions

Heat Transfer.

1 The use of noncontinuous fin sections instead of long continuous fins increases h_f in the ratio of 2 to 1, where $L = 1.2$ to 10 ft.

2 Correlation of test data for liquids in this paper, where L/D_h is controlling, indicates the curves shown in Norris and Streid's (4) Fig. 4, are conservative above $R_h = 200$, because

present test results show the transition range beginning at about this point.

3 The dimensionless function $\left(\frac{\mu}{\mu_w}\right)^{0.14}$ should be included in the J_A value when correlating viscous liquids.

Pressure Drop.

1 The pressure-drop efficiency factor for noncontinuous fins is comparable to that on long continuous fins where L = 1 to 10 ft.

2 Correlation of test data on pressure drop in this paper with Norris and Spofford (3) gives fair agreement in the range of R_p = 700 to 2000 for sample N-7.

Fouling Rates.

1 From a theoretical viewpoint, fouling has less effect on fin tubes than on bare tubes, for as fouling increases, the fin effectiveness increases, tending to offset the fouling effect.

2 A fouling factor of 200 for longitudinal fin tubes in heavy-fuel-oil service, with steam temperatures not above 350 F, will normally assure at least 1 year of service without cleaning. Intermittent operations or operations at less than design throughputs may shorten this period.

Appendix

Test Equipment and Procedure

The essential items of the test setup for the work reported in this paper (and their general arrangement) are shown schematically in Fig. 6, as they were installed in the oil refinery where the tests were run.

Fin-Side Fluid Circuit. As previously mentioned, the fin-tube exchanger on which the test runs herein reported were made was of the "double-pipe" design (pipe-within-pipe type, see Fig. 1). The various fin-side fluids were drawn from refinery tankage (5 to 10,000-bbl capacity) and pumped through the annular space between the outside of the fin tube and the inside of the confining outer sleeve. Leaving the unit, the fluid then passed through a mixing chamber, which insured thorough commingling of the fluid particles for accurate outlet-temperature readings. Thermowells were provided as shown to give double checks on both entering and leaving fluid temperatures. Standard industrial-type glass thermometers were immersed in oil in these wells for the readings. These thermometers were check-calibrated against known standard ones in the refinery laboratory to establish their accuracy. Also, they were interchanged from time to time during the tests as a further check.

From the mixer, the fluid next went through a strainer and displacement meter (of the nutating-piston type), where the rates of flow were measured in conjunction with a standard laboratory timer clock, which was check-calibrated occasionally during the progress of the tests. Two sizes of meters were used in the tests to cover the wide range of flow rates run, and these instruments were check-calibrated from time to time during the course of the work to insure their accuracy. Upon leaving the metering device, the fluid then passed into the return piping system to refinery tankage.

Pressure drops across the test unit were measured by a differential-pressure recorder (of the mercury-manometer type). The location of the pressure taps in the inlet and outlet nozzles of the test unit, Fig. 6, meant that end losses were included in the pressure drops recorded. It should be pointed out, however, that, since the net free area of the end chambers below the nozzles was essentially equal to that of the nozzle pipes, these end losses therefore were kept to a nominal figure. Further, it must be noted that no calming section was provided to minimize inlet turbulence, since it was desired to approximate an actual commercial installation as closely as possible.

Fluids of various inlet temperatures were used in the work, and the manifold rates of flow which were run resulted in a considerable range of outlet temperatures. To insure further the accuracy of the temperature readings, the essential thermal apparatus was thoroughly insulated as shown. Standard pipe insulation (1-in-thick magnesia-asbestos) was used for the purpose, since this type readily suited dimensional and test-condition requirements. Tests for the magnitude of heat leakage through this material were not made, since, for the relatively low temperatures of the test operations, it was known that the possible error from this source would not be greater than 2 or 3 per cent.

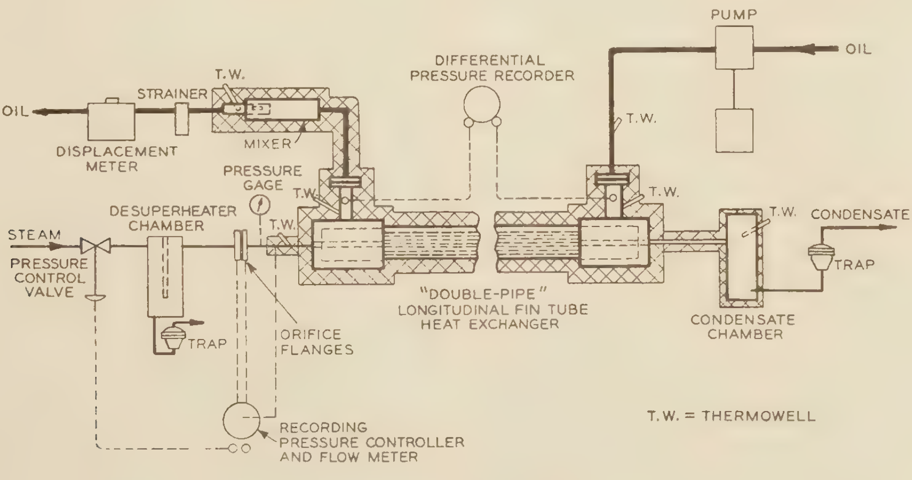

Fig. 6 Test-Unit Arrangement

Steam Circuit. Steam, at various pressures, was used as the heating medium inside of the fin tube. Live steam at refinery boiler-room conditions was taken from the mains and brought to the desired test-pressure requirements by means of the automatic air-actuated diaphragm control valve. The latter was connected to the recording pressure controller and flow-meter instrument, where manual setting of the desired test conditions was effected. A pair of orifice flanges, in conjunction with several interchangeable plates of different orifice sizes, were installed in the meter

system to cover the required test range. Suitable piping lengths, as required by the meter-installation manual, were strictly adhered to for correct and accurate operation of the meter system. An internally baffled desuperheater chamber was provided as shown, to insure the delivery of substantially dry, saturated steam to the test unit. A Bourdon-type pressure gage also was installed as shown, to give a double check on steam-meter-pressure readings. A trap at the bottom of the desuperheater chamber discharged the water removed from the steam, and this feature, together with observation of the pressure and temperature readings, assured that the desired steam conditions (freedom from superheat and wetness) were reasonably maintained.

At the steam outlet of the unit, it was found necessary to provide the condensate chamber shown, to guard against the possibility of flooding, by backing up condensate within the fin tube. An industrial-type steam trap was installed at the bottom of this compartment to discharge the condensate collected. Occasional blowdowns were made between tests to ascertain that the trap was operating correctly. Standard industrial-type glass thermometers (previously check-calibrated) in suitable thermowells were used for the temperature readings on the steam side.

Test Procedure. On any particular oil, tests were run at 3, 6, 12, 18, 24, and 30 gpm rate, with check tests going back down the scale 30, 24, 18, etc. Each test consisted of four consecutive sets of readings during a 10-min period after stable conditions were attained. The lower limit of oil throughput was set at 3 gpm, since it was found that any rates of flow below this value gave erratic readings which could not be measured accurately with the existing equipment.

For determining fouling rates, the first set of tests run, when the fin tube was new, were repeated at intervals. The difference between the original and repeat values of h_f were then recorded as fouling rates. The tubes used were of the bright annealed type and very little fouling occurred on the inside surface.

Average samples of the oil flowing through the unit were taken and tested in the plant laboratories for gravity and viscosity.

Calculation of Results. Since steam was used inside the tube, for which consistent results are available, the fin side coefficient h_f could be easily calculated, utilizing fin effectiveness curves based on (5), and shown in Fig. 4. The over-all heat-transfer coefficient used was obtained by dividing the total heat transfer by the total surface of the inside of the tube, using the log *MTD* between the fin-side fluid and the steam.

Since the data from these tests were to be set up for rating purposes, it was decided to use h_t of 5000 instead of 2500, to provide a factor of safety in the rating curves and yet not affect the consistency of the plot. Fig. 3 shows a plot of the No. 4 fuel-oil test results as calculated, using h_t = 5000 (o) and h_t = 2500 (x). The discrepancy introduced in the plot of these data relative to the other results shown is thus graphically illustrated. As stated previously, this introduced the desired factor of safety in the company standard rating curves. The foregoing assumption for the steam-side coefficient h_t, is in line with the film concept of condensation, as presented by Jakob (9). Verification of this point was established as well as could be accomplished with the existing setup, by passing steam through the unit at a linear velocity considerably in excess of 50 fps, and noting no apparent change in the outlet temperature of the oil.

Fluid characteristics were taken from the following sources:

c = specific heat; Standards of T.E.M.A., Fig. 20, ref. (8)

k = thermal conductivity; Bureau of Standards Miscellaneous Publications, No. 97

μ = absolute viscosity conversions; A.S.T.M. Tentative Standard D-341-32T viscosity-temperature chart.

Accuracy. Approximately 5 per cent of the plotted results did not give satisfactory agreement and consequently were discarded as being erroneous. The remaining 95 per cent were in substantial agreement, the variation being approximately ±6 per cent from the average. Further, heat balances made during the earlier part of the work (until oil-temperature results were verified satisfactorily) showed variations from 1 to 10 per cent, the oil-side duty always showing lower than the tube-side duty.

ACKNOWLEDGMENT

The authors wish to take this opportunity to express appreciation for the contribution to this work made by Mr. A. S. Denton in carrying out part of the tests and subsequent calculation of results. Credit is also due Messrs. S. Kopp and T. F. Fitzgerald for their many helpful suggestions during the test program. Appreciation of the co-operation of Mr. R. H. Norris in making available certain additional data not published in his reference papers and his valuable criticism and comments during the preparation of the present paper, is also hereby expressed. Further, the courtesy of the Tubular Exchanger Manufacturers Association, Inc. in giving permission to quote from its "Standards" is also gratefully acknowledged.

Discussion

T. R. Heyck.[4] One of the specified objectives of this paper is to indicate the advantages of noncontinuous longitudinal fins over long continuous fins for liquids. In Fig. 2 of the paper, for example, the fin sample designated as A-9, consisting of short noncontinuous sections 1.2 ft in length separated $^3/_4$ in. by turbulence promoters, showed a heat-transfer factor of 0.056, with

[4] The Griscom-Russell Company, Houston, Texas.

a pressure-drop efficiency factor of 0.113. This suggests the conclusion that fin sample A-9 should be used instead of, say, fin sample A-1 which shows a heat-transfer factor of 0.028, with a pressure-drop efficiency factor of 0.085.

In considering other aspects of this subject, however, the writer is inclined to doubt the advantages of noncontinuous longitudinal fins. It is likely that structure A-9 would foul more rapidly, and serious difficulty might be encountered in attempting to clean it. A simpler structure, more readily accessible for cleaning, might give better over-all results than a more complicated structure, which will show improved transfer rates initially, but which will drop off rapidly in performance on fouling service and be difficult to clean.

Referring again to fin samples A-1 and A-9, the latter indicates a friction-factor increase of 50 per cent. If a unit were provided with continuous fins, indicated as fin sample A-1 and arranged so that the total over-all average pressure drop between reasonable cleaning periods would be the same as the total over-all average pressure drop for a unit provided with fins similar to sample A-9 for the same period of operation, it is believed that the increased fluid velocity which could be used through the first unit would compensate to a considerable extent for the artificial turbulence created by the noncontinuous structure. The higher velocity in a straight passage is much less liable to foul. The authors' comments on this point would be greatly appreciated.

B. E. Short.[5] Referring to Fig. 5 of the paper, would it not be better to show the resistance to heat flow, caused by fouling, rather than a heat-transfer factor similar to the convection transfer coefficients? This is merely a matter of personal opinion, but each time the writer has examined Fig. 5, he has gained the impression that it shows the decrease in the film coefficient on the finned side of the tubes with time rather than the separate coefficient for the fouling substance. It is not known why the standards of T.E.M.A. have been changed in this respect, as indicated by Table 3, from the original form of fouling resistances issued by the Heat Transfer Institute, but it seems that the resistance factors are much easier to apply.

Why would it not be better to follow the aeronautical scheme for Reynolds number in the case of these finned surfaces and consider a dimension in the direction of flow? This would tend to make the lines, as shown in Fig. 3, for different L/D_h values fall within a single field rather than spread apart.

In regard to the use of the J_A factor in Fig. 3, for the correlation of the data, it seems that some caution should be used. As a means of correlating the heat-transfer data it appears to the writer to be equally as useful as the other combinations using the Nusselt number. According to Osborne Reynolds, however, a direct relation between heat transfer and pressure drop is true only for similar passages, and Taylor, Prandtl, and von Kármán have not shown reasons in their analyses, since Osborne Reynolds' papers, to disagree with his statements. Consequently, it seems that the use of the J_A factor to establish an apparent relationship between the friction factor and the heat-transfer factor should be applied with care for flow outside of tubes with such dissimilar-shaped passages.

E. N. Sieder.[6] The effect of discontinuous longitudinal fins on heat transfer and pressure drop is most interesting and should prove of commercial value in saving scarce and strategic materials.

It is unfortunate that the authors did not show more detailed plots of the original data, particularly in the transitional region between laminar and turbulent flow. The writer was somewhat surprised at the authors' statement that this transitional region starts at a Reynolds number as low as 200.

The writer has conducted a number of pressure-drop and heat-transfer tests on longitudinal-fin tubes of the same type as used by the authors and has found no indication of a definite break in the nature of flow for Reynolds numbers as low as 200. As a matter of fact, heat-transfer and pressure-drop tests, taken on a tube of the same size as that used by the authors but having only 12 fins instead of 20, indicated that the break in heat transfer and pressure drop occurred at or close to a Reynolds number of 2000.

However, it might be pointed out that the shape of the trapezoidal duct, comprising the elemental-flow area, more nearly approached the shape of a square for the tube having 12 fins when compared with the one having 20 fins, as used by the authors. We also found that heat-transfer and pressure-drop values could be accurately predicted by the use of the curves recommended by Tate and the writer in an earlier paper.[7]

Tests taken with a greater number of longer fins, giving elemental-flow areas nearly approaching the effect of parallel plates, indicate that the transitional point may be lower than 2000 but certainly not lower than 1000.

Authors' Closure

Mr. Heyck's conclusion that fin sample A-9 is to be recommended over A-1 is partly correct. However, it has been found more economical to produce sample A-7 with $L = 1.2$ ft and still achieve the results obtained with sample A-9. While it may be noted that these results compare favorably with those of sample A-5 from a heat-transfer standpoint, it must be pointed out that sample A-7 ($L = 1.2$ ft) represents the simpler construction from the production angle; and in addition, has the desirable advantage of not sacrificing any of the extended surface as is the case with sample A-5.

As to the matter of cleaning, it can only be stated that from actual experience on heavy pr. still resid. service, it has been found that this problem is of no greater consequence with noncontinuous than with continuous longitudinal fins. It should be realized that the arrangement sketches of Fig. 2 of the paper are, of necessity, not drawn to scale, and in the particular instance of sample A-9, this fact may tend to mislead the reader into visualizing a rather complicated structure. Actually, the straight sections of fin are over 1 ft in length, interrupted by relatively short oblique segments. The turbulence and intermixing produced at these points, it is found, tend to scour these fin segments and to minimize the cleaning problem here.

The suggestion that continuous fins can be made as efficient as noncontinuous fins by increasing the fluid velocity with the former fin arrangement within allowable over-all pressure-drop limitations warrants detailed consideration.

From Equation [9] of the paper, it will be seen that pressure drop (ΔP) normally varies as the square of the linear velocity V. Further, the slope of the (L/D_h) lines in Fig. 3 is $-^2/_3$, whence it can be said that h_f varies as $V^{-2/3}$ (since $V = G/\rho$ in the abscissa; $R_h = GD_h/\mu = V\rho D_h/\mu$), referring to Equation [5].

Taking $R_h = 30$ (in Fig. 3), for example, we find $J_A = 0.028$ for a 10-ft length of continuous fins (sample A-1), as against $J_A = 0.056$ for a similar length on a noncontinuous basis (sample A-9); also, $\Delta P_{A-9} = 1.5\,\Delta P_{A-1}$, from Fig. 2. The foregoing, then, for a given condition, represents a 100 per cent increase in h_f with only a 50 per cent increase in ΔP, for noncontinuous (A-9) versus continuous (A-1) longitudinal fins.

Since $\Delta P_{A-9} = 1.5\,\Delta P_{A-1}$ from Fig. 2, V for A — 1 can be increased only 23 per cent to stay within equivalent pressure-drop limitations. The increase in h_f from this would be less than 10

per cent and the effect on fouling rate from, say 5 up to 5.5 fps would not be appreciable.

Professor Short's comments are of interest. The confusion with respect to the use of fouling factors in Fig. 5 as reciprocals of fouling resistances is natural if one is accustomed to the use of the resistance forms. However, from practical everyday rating experience in the heat-transfer engineering industry, the authors have found the coefficient form of fouling factors a more convenient system with which to work.

The suggested use of Reynolds numbers incorporating a dimension in the direction of flow was considered when preparation of the paper was begun. However, since the preliminary work had been carried well along on the conventional basis before any thought of publication existed, dead-line limitations did not permit of a transposition to the suggested form of presentation, and this work was necessarily left for study at some more opportune time.

The authors are in complete agreement with Professor Short's precautionary remarks on the free use of data from tests with odd-shaped flow passages. As pointed out in the paper, various factors exist to which careful consideration must be given in applying test data to actual use outside the range of the original work. It must be stated that $J_A/(f/_2)$ relationships were included in the present paper reservedly, merely to indicate the comparison of the results of this investigation with previously published data.

Mr. Sieder's discussion is most timely. The savings in scarce and strategic materials through the use of noncontinuous fins is well worth while, since increases in over-all rate up to 100 per cent, after applying nominal fouling factors of $h_D = 200$, are achieved. The value of these factors is readily obvious on new installations. On continuous-fin double-pipe equipment already in service, noncontinuous-fin tubes could be installed and, depending upon service conditions, up to one half of the units in the original battery could be released for other work.

It is regretted that certain restrictions prohibited a more detailed presentation of the original test results. However, it was felt that sufficient data were included to indicate generally the conclusions arrived at through this investigation.

The apparent shift in the start of the transition region, as indicated by this work and suggested by the earlier data of Davies and White (6), was revealed primarily for the record and not as a final conclusive fact. As noted in the paper, the tests were made to simulate plant-scale conditions, with no calming sections and greater temperature rises in most cases than the usual 2-4 F used in normal laboratory work.

These factors no doubt are partly responsible for the shifting of the transition zone, as observed. However, since this work was undertaken for the essential purpose of producing practical rating curves, and since the aforementioned factors are normally present in actual operations of plant-scale equipment, the use of the data established by these tests as against the more theoretical values from laboratory-scale experiments should result in ratings which more nearly approach the desired plant-equipment performance.

Protecting Buried Metals Against Corrosion

By STARR THAYER,[1] HOUSTON, TEXAS

The author mentions briefly the various types of corrosion from the standpoint of methods used to combat it. His main concern, however, is with underground structures, such as pipe lines, which suffer a corrosion loss of upward of $100,000,000 yearly. Protective coatings have been developed which constitute a long step toward elimination of pipe-line corrosion, when applied to new pipe. Older lines can be protected by a cathodic process, based on correcting the galvanic differences in potential between small sections of the pipe wall, or changes in soil conditions. The process of making the pipe cathodic to the surrounding soil is described, illustrations of the practical effects of the method being given.

Introduction

PROBABLY there is no way of knowing actually how much we as a nation pay annually as tribute to corrosion. It has been estimated by some that one half of all of the iron mined is used to replace that lost through corrosion. One reliable estimate places this loss for the pipe-line industry alone in excess of $100,000,000 per year. This much is certain; we know that it is a very great national loss, larger than our losses from either floods or fires. There is nothing spectacular about a piece of rusty iron so it has received practically no national prominence. Perhaps an "anticorrosion week" would be as appropriate as our "fire-prevention week."

The elimination of these losses is an important undertaking at any time. During this time of national emergency, when all metals are so vitally needed in industry, it should be apparent that this work is of utmost importance.

Types of Corrosion

For convenience, we may separate the different kinds of corrosion into classes having to do with methods of prevention rather than with causes. Thus, we would have loss of metal from aboveground structures, or atmospheric corrosion, corrosion of industrial equipment, and corrosion of buried or submerged structures. The first two classes are approached from an entirely different angle from the third. Atmospheric corrosion is almost always combated with paints or a selection of materials such as copper for roofing material, and galvanizing for sheet iron and pipes. Industrial corrosion is generally combated to some extent with paints, but more often with a selection of materials. There are so many examples of this type of corrosion that only a few can be discussed here. Heat exchangers have come in for considerable attention. To date, the only practical method of reducing corrosion in such equipment is by the selection of special metals for the tubes. Losses in brine lines may be mitigated by confining the construction to only one kind of metal. If the line is constructed of steel, then all valves and fittings should be of the same material. Galvanic couples will be created if this is not done and one metal will suffer.

The elimination of corrosion in the case of buried or submerged structures, which is the principal topic of this paper, will be discussed more fully.

Underground Corrosion

The one single type of construction most exposed to underground corrosion is the pipe line. Probably more effort has been made to eliminate corrosion on these lines than in any other industry. With more than 130,000 miles of lines well scattered throughout most of the country, it is only natural that corrosion has become a serious problem. In most instances, the methods used in combating this corrosion can be applied to other underground or submerged structures, such as steel piping for other purposes, sheet piling, underground tanks, etc. This problem may be attacked by one or more of the following methods.

Selection of Materials. Some success has been had with the use of materials other than steel in eliminating underground losses. Copper pipe has been used with success in small sizes. Lead has been used as a covering for cables, with a minimum of trouble. Ceramic materials have lately been used for water lines and apparently will be satisfactory. However, pressures are limited with all of these. It is still necessary to use iron or steel when large volumes or high pressures are involved. At this time, there is nothing to indicate that a corrosion-resisting ferrous material will soon be available. Therefore the problem is reduced to making the iron or steel last as long as possible.

Selection of Right of Way. In laying pipe lines, it is sometimes possible to avoid known corrosive areas by selecting a more favorable location for the line. Swampy areas are sometimes avoided by going around them. Often, lines are built on trestle work to avoid laying them in a bad soil. It is the author's opinion, however, that these measures are not justified if any extra expense is incurred, and if it is done merely to avoid corrosive soils.

Protective Coatings. When corrosion is even suspected, it is common practice now, with most pipe-line companies, to apply a protective coating to the pipe. A few companies make it a practice to coat all lines. In the early days of pipe-line construction not much was known about coatings; for that reason, almost every conceivable material that was suspected of having protective qualities was used.

Within the last few years, worth-while progress has been made in the manufacture and application of coatings. The American Petroleum Institute, co-operating with the pipe-line industry and several coating manufacturers, began a study of this subject about 12 years ago. At about that time, Dr. Gordon Scott was employed to work on this subject, as well as on other phases of pipe-line corrosion. At the same time, the American Gas Association employed Dr. Scott Ewing for this purpose. Both of these experts in the field collaborated with the National Bureau of Standards.

One of the first undertakings of this group was to commence the study of the different types of coating materials and shields. Through the co-operation of coating manufacturers and pipe-line companies, sections of pipe were coated with the several materials in many widely scattered areas. These pipes were examined at intervals and detailed reports were made of their condition. The last and final inspection was made in 1940. At that time, the tests were 10 years old.

Space does not permit elaboration on the methods of making these examinations. It may be said, however, that a study of these reports will very clearly indicate the merits of the different

[1] Consulting Engineer.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

classes of materials. In summing up the data from these reports, we may draw the following conclusions:

1 The material must adhere to the pipe.
2 It must be of high dielectric strength.
3 It must be impervious to moisture.
4 It must resist soil stress. This may be accomplished with the addition of a shield.
5 It must retain these qualities over a long period.
6 It must be practical to apply.
7 Its cost must be reasonable.

It is evident that the best of coatings would be of little value if improperly applied. For some time, it has been possible to have pipe coated in stationary plants, with the assurance that an almost perfect application will result. In these plants, pipes are coated up to very large diameters, and are lined with a coating if necessary.

Often, lines are built and then coated. Sometimes the pipe is coated in stationary plants and then hauled to the line. The joints are coated by hand methods. However, a large part of the lines constructed now are completely coated after the welding has been done. Not so long ago, this was done by hand methods, which procedure resulted in an excessive waste of material, a good application being almost impossible. During recent years, machines have been developed which travel on the pipe and apply the coating and shield very satisfactorily. These machines waste very little material and will coat several miles per day if it is necessary.

It is now common practice to test lines electrically for possible faults in the coating before laying them in the ditch. With the use of detectors and all other available equipment it is possible to apply protective coatings economically, with the assurance that practically a perfect application is being secured.

Nearly all of the foregoing has reference to prevention and precautions to be taken in the design of new lines or structures. However, it is on the older lines, built some years ago, that the effects of corrosion are most serious. It is on these lines that the engineer has been able to accomplish the most good.

Cathodic Protection

Theory of Cathodic Protection. The theory of cathodic protection is rather simple. It is assumed that corrosion is electrolytic in action. Because of galvanic differences in potential between small sections of the pipe wall, or due to changes in soil conditions, or both, small batteries are created. Sometimes, these soil changes may be some distance apart and still cause trouble. Now, if the pipe lies in contact with a soil that is a conductor of electricity, small currents will be generated. Loss of metal will occur at the points of discharge from the pipe. This is illustrated

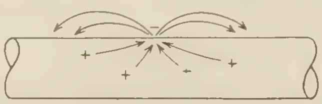

Fig. 1 Electrolytic Action on Pipe in Contact With Soil Which Acts as an Electrical Conductor

in Fig. 1. If the pipe is made cathodic to the surrounding soil, these currents can be prevented from leaving the pipe and there will be no loss of metal.

Application of Cathodic Protection. The application of this protection to a line or other structure is best illustrated by a rather simple electrical circuit, as shown in Fig. 2. As seen, the negative terminal of a source of direct current is connected to the pipe line or structure to be protected. The positive terminal is connected to a mass of scrap metal which is buried in the soil some distance from the line. In practice, we refer to the power supply as the "unit," the scrap metal as the "ground bed," and the connecting wire as the "ground-bed line." When the unit is turned on, current is forced from the ground bed, through the soil, and onto the pipe wall which carries it back to the unit.

Power Units. Naturally, the first and most important problem which arises in applying the protection is to secure a source of direct current. If commercial power lines are available, rectifiers can be used. Such units are now manufactured by several companies. They are available in almost any required size and come

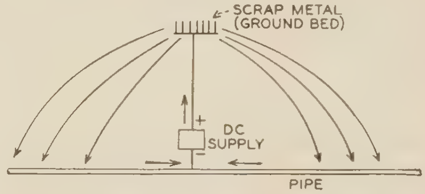

Fig. 2 Diagram Showing Application of Cathodic Protection to Pipe Line

complete, ready to put in use. Where power lines are not available, wind-driven units have been used with considerable success in some localities. Gas companies have used engine-driven units. In this case, fuel is taken from the pipe line. Some attempts have been made to use zinc anodes as the source of power. In this case, the driving force is the difference in potential between zinc and steel. This may be practical where the current requirements are comparatively small.

Ground Beds. The construction of the ground bed often becomes rather difficult. The purpose of this bed is to provide a path of low resistance for the current to enter the soil. It is necessary, therefore, to select the most favorable location. This is determined by securing the lowest soil resistance possible. The amount of metal to be buried, its distance from the pipe line, and the material to be used for the bed are factors which require consideration. Not only must the bed provide a low-resistance path, but it also must contain sufficient material to last for some time. Graphite or carbon anodes are available for this purpose and have been used to a considerable extent, especially when the bed is to be submerged in sea water.

Practical Application. In designing protection for a line or other structure, many factors must be considered. If engines are used, extensive protection will be secured from one unit. These units are not practical in small sizes. Wind units are limited in size and must be spaced on the line according to current requirements. Rectifiers may be large or small according to current requirements and location of power lines.

The amount of current necessary to protect a pipe line varies over a wide range. The factors that control this element are the size of the pipe, the condition of the soil surrounding the pipe, and the condition of the coating on the pipe, if any has been used. The last item is by far the most important factor. As an example of this, not long ago the author applied such protection to a line that had been coated by the most modern method. It took but 3 amperes to protect 20 miles of this line. Another line in the same type of soil and of the same size required 60 amperes per mile. This line is practically bare of any coating. The comparison is given as an example merely to show the variables encountered in the work.

Testing. As stated previously, the purpose of this system is to make the pipe cathodic to the soil. However, it must be more than just negative to stop the corrosion. By laboratory methods and by actual experience, we have found that the pipe must be at least 0.3 v negative to the soil to arrest the corrosion completely.

After a unit has been installed, the engineer measures the potential between the pipe and soil to determine its effectiveness. In

making these measurements, special equipment is used. First, it is necessary to have a contactor with the soil that will remain constant. A copper-sulphate plug is most commonly used for this purpose. The potential between this plug and the pipe is measured either with a high-resistance voltmeter or with a potentiometer.

If additional proof of the effectiveness is needed, coupons may be attached to the line. However, care must be exercised in doing this. Pilot coupons should also be placed unconnected in the same locality. In this instance, some time is required to get the information needed.

When the line is tested by means of the potential method, the readings may be plotted. When soil and coating conditions are uniform, a curve somewhat similar to the one shown in Fig. 3

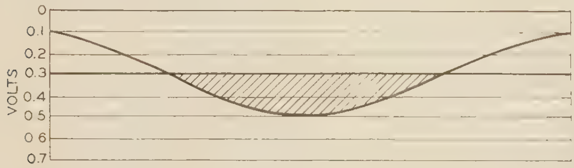

Fig. 3 Typical Curve Derived by Potential Method When Soil and Pipe-Coating Conditions Are Uniform

(The horizontal distance covered in this graph, as well as in Fig. 4, might be almost any distance. In some cases, it is as much as 16 miles and in other cases as little as 0.5 mile.)

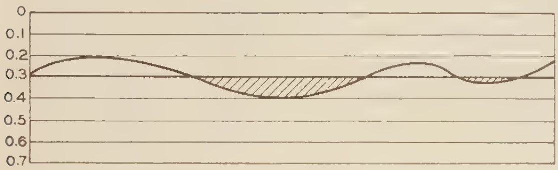

Fig. 4 Variations in Soil or Pipe-Coating Conditions Produce a Nonuniform Curve

would result. That part of the curve which shows a potential below the 0.3-v line would be protected. That part above this line but below the zero line would be protected but to a lesser extent. Any negative potential will prolong the life of the pipe.

It seldom occurs that a uniform curve, as shown in Fig. 3, is obtained. More often it will look something like the one shown in Fig. 4. These variations are due to changes in soil or coating condition.

Effectiveness of Cathodic Protection. Naturally, the question arises as to how effective this protection is. A few illustrations will demonstrate the value of this method. As far back as 10 years ago, the author applied this protection to two different lines that were in such bad condition and leak repairs were so frequent that their replacement was being considered. Cathodic protection was applied, with the result that both of these lines are still in service, no replacements having been necessary, and no further leaks have developed. Others have had similar experiences. On one section of the pipe line of an important company, a record of leak repairs was kept and plotted, as shown in Fig. 5. In 1936, cathodic protection was applied. The effectiveness of the method is shown by the curve obtained thereafter, as compared to what would have occurred had the protection not been applied. The prospective user may be assured that his corrosion losses will cease if this protection is properly applied.

Application to Structures Other Than Pipe Lines. Life can be prolonged on almost all underground or submerged metallic structures. Examples for treatment would be casings for water and oil wells, steel piling, underground cables, the inside walls of tanks, etc. Many large tank farms have applied this protection to the tank bottoms and connecting lines. Some work has been done in

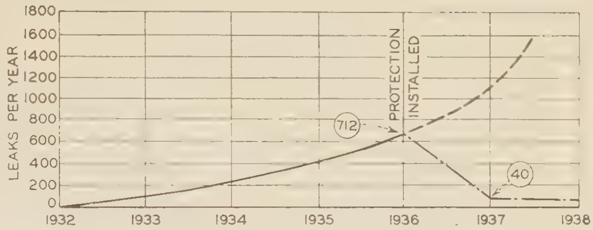

Fig. 5 Curve Showing Leak Repairs Before and After Cathodic Protection Was Applied

the protection of heat exchangers and condensers from corrosion. In at least one instance, the water jackets of an internal-combustion engine have been so protected.

Often, these structures are quite difficult to protect. As an example, one engineer applied this method of protection to a line consisting of 24 parallel pipes. In this case, large units were spaced but a few hundred feet apart, as against some miles apart on a pipe line.

Conclusion

It can no longer be said that the use of cathodic protection is an experiment. There are many hundreds of miles of lines now so protected and more are being added each year. Very few companies now replace corroded pipe, especially if any quantity is involved.

It is not likely that all corrosion can be eliminated. However, it is entirely incorrect to admit that corrosion is a necessary evil and must be tolerated. Probably most corrosion troubles can at least be mitigated.

Discussion

J. J. King.[2] The subject of protection of buried metals, particularly pipe lines, is one of vital interest to those connected with the oil-and-gas industry. The same may be said for many other industries, though perhaps to a lesser degree because of the lesser amounts of buried lines involved. As operating pressures on oil, gas, and gasoline pipe lines are such that only steel pipe can be safely used in most cases, the problem of protecting such lines properly is becoming more important as additional miles of pipe are put underground.

Many different methods of coating pipe lines are employed in the oil-and-gas industry with such factors as the nature of the soil through which the line will pass, the degree of protection desired, and funds available for coating determining the type to be used. As brought out by the author, the use of cathodic protection for buried metals does not remove the necessity for coatings. As a matter of fact, it can safely be said that the more nearly perfect the coating, the more satisfactory the results from cathodic protection.

In the early days of the application of cathodic protection to pipe lines, scrap steel was almost universally used for ground beds, but in recent years carbon rods have been used as a substitute for scrap metal in some instances, with complete success. As scrap steel is not so available now as in previous years, it would have been timely for the author to mention the relative merits of metal and carbon rods for ground beds.

Recently, experimental work has been carried out in connection with the use of magnesium rods for the protection of pipe lines by burying cylindrical sections of this metal alongside of the pipe. In so far as the writer knows, very little has been published on

[2] Engineer, Producing Department, The Texas Company, Houston, Texas. Mem. A.S.M.E.

this work. If the author would care to comment upon the matter in the closure to his paper, his readers would be grateful.

Author's Closure

Fig. 2 of the paper illustrates the circuit that is used in cathodic protection. As shown, a mass of scrap metal is buried some distance from the pipe line to be protected. In the past it has been almost the universal custom to use scrap pipe for this ground bed. The exception has been when carbon, or graphite anodes were used.

The advantages of the scrap metal are (1) it generally has been readily available in the past; (2) its cost has been very small; (3) it is easily installed. The disadvantage of using this metal is that it has a very much shorter life than the carbon would have. Also, at this time, scrap metal may be more vital to our country than carbon.

As explained in the paper, one of the requirements of this ground bed is to provide a low-resistance path for the current to pass off into the soil. Often this is possible only by having a large anode surface in con tact with the soil. In that case the cost of the carbon anode could possibly make its use prohibitive.

When the ground bed can be installed in sea water or in a soil of extremely low resistance, the use of carbon anodes would be preferable. Under such conditions, a small area would be required and a much longer life would result than with the use of metal.

It has been estimated that with the same current density on the discharge surface the graphite anode will last about 20 times as long as iron.

It is not probable that any set rule may be established as to which material should be used. There are so many factors involved that each installation should be engineered.

Some efforts have been made in the past to use a ground bed of such a material that an anodic condition would be created on the ground bed with the pipe line cathodic. This can be accomplished to a limited extent by the use of aluminum, zinc, or magnesium. In using this method, the circuit is the same as that shown in Fig. 2, with the exception that no generating unit is used.

It is easily seen that the driving force or difference in potential between the anode and the pipe line is very small. For that reason it is not possible to obtain any appreciable flow of current. Generally this current is measured in fractions of an ampere.

However, there is a place for this type of installation. Often it is necessary to protect a very limited area of small pipe or a larger but well-coated pipe. In such cases it is frequently not possible to install a power unit economically.

The advantage of the magnesium over zinc or aluminum for this purpose is that the difference in potential between this metal and the pipe is higher and the current flow is greater. Also, it is possible to protect a line completely with the magnesium, while the others only slow down the corrosion.

The disadvantage of this metal is that it is so unstable. It loses weight when buried in a soil and at a rapid rate whether connected in a circuit or not.

It is not probable that any of these metals will find a wide application since, at present, they are all on the critical list. It may be that other methods may be devised whereby the galvanic difference in potentials can be utilized.

The Application of Cathodic Protection for Corrosion Prevention

By R. J. SULLIVAN,[1] HOUSTON, TEXAS

The application of cathodic protection for the prevention of corrosion, either as the primary protective agent or in conjunction with external coatings, has been successfully and economically utilized on a variety of types of buried or submerged metal structures. This paper presents a short review of the subject of corrosion in general. However, it is devoted principally to the practical application of cathodic protection to numerous metallic structures. Sections are included covering the various types of equipment, the method of testing and keeping records in checking the operation of cathodic-protection installations, ground beds, preliminary survey methods, and illustrated descriptions of certain installations, such as pipe lines and oil-storage-tank farms.

A REVIEW of the published literature on corrosion will show that the result of a great amount of research, laboratory, and field work has been published on corrosion in general; that the effectiveness of pipe coatings has been tested in the field; and that cathodic protection has been found both practical and economical, either as a supplement to the coating, or as the primary protection for the submerged structures. Much has yet to be learned, however, about the proper application of cathodic protection.

The need for further research arises from the fact that the requirements for complete protection have not been agreed upon by all workers in this field, that better methods of predetermining the power requirements are needed, as well as further studies into the economics of the various types and combination of types of corrosion control. At the present time, the American Petroleum Institute (A.P.I.) is conducting an investigation on the effectiveness of resistance bonds.

Since we do not have the results of any research to report, this paper will be devoted to a short review of corrosion in general and methods of control. Principally, the discussion will deal with the equipment involved, various tests conducted, and records necessary to check the operation of cathodic protection units. Details of several electrolysis protection systems which are in service will also be included.

General Corrosion

Corrosion can be described as the disintegration or wearing away of metals by certain external agencies. This action can then be reclassified as caused by chemical or electrochemical attack or mechanical erosion. Often, corrosion and erosion operate together, promoting each other, and in practice may be difficult to distinguish. Evans (1)[2] of King's College, England, very aptly describes corrosion of a metal as "essentially the reverse process to the production of that metal from its ore. Metals occur in nature as oxide or sulphides; sometimes as normal or basic sulphates, chlorides, or carbonates which are reduced to the elementary condition by the smelting process; but when exposed in service, the metals sometimes return to the state of oxide sulphide, normal or basic sulphate, chloride or carbonate." Evans further states the interesting contrast "the study of metallurgy—the making of metals, appeals directly to a comparatively limited number of persons, but the study of corrosion—the unmaking of metals, has an interest for all who use metals, a far larger class."

Literature pertaining to corrosion indicates that, in general, there are two methods by which the disintegration of metals can take place. The first of these may be called direct chemical action and is typified by what happens when the metallic iron is exposed to the atmosphere at elevated temperatures. Under these circumstances, the iron reacts with and combines directly with the oxygen in the atmosphere to form the product which is commonly known as "mill scale," and which has essentially the same chemical composition as the naturally occuring iron ore called "magnetite." Other metals, when exposed to the same environment, behave in a similar manner to form a whole series of metallic oxides.

The second method by which disintegration of metal proceeds is called galvanic or electrochemical corrosion. This method differs from the first in that it is the result of the displacement of one element in one phase (usually in an aqueous solution) by another element originally present in another phase (in the solid form as a metal or alloy). Since this displacement of one element by another is invariably accompanied by a flow of electric current, this form of corrosion is broadly termed electrochemical. An excellent treatise on the accepted electrochemical theory of corrosion is presented by Speller (2).

Methods for Lessening and Preventing Corrosion

Various methods which have been successfully utilized in the protection of metals against corrosion, under a great variety of circumstances, are briefly as follows:

(*a*) Judicious selection of materials, which are immune to the corroding environment, is probably the most important means of preventing corrosion if the equipment involved is not too large. Various metals and alloys exhibit definite well-known properties when subjected to corrosive agents under certain conditions. Usually, the formation of a protective continuous film by interaction of the metallic substance with the corroding agent is the factor governing the suitability of the metal for the service. Because of this effect, lead is commonly used for exposure to sulphuric acid, the protective effect of the insoluble lead-sulphate coating keeping the attack low. Where the reaction of a considered material and a corroding agent is unknown, or questionable, corrosion tests can be made to judge their behavior, but these tests must be interpreted with caution, as aeration, temperature, movement of solution, etc., sometimes overbalance other factors. Kay and Worthington (3) offer a thorough discussion of the foregoing factors, and various alloy manufacturers (4) present tables listing materials and their suitability for different corroding agents. This method of preventing corrosion is widely used in condenser tubes, pipe, and the like. Special material is not usually adaptable for pipe lines because of the large tonnage

[1] Chief Engineer, Natural Gas and Gasoline Department, Humble Oil & Refining Company.

[2] Numbers in parentheses refer to the Bibliography.

Contributed by the Petroleum Division and presented at the Spring Meeting, Houston, Texas, March 23–25, 1942, of The American Society of Mechanical Engineers.

of steel involved, since a 1-mile section of 10-in. pipe line is composed of approximately 100 tons of steel.

(*b*) The mechanical application of impervious protective coatings such as paint and bituminous combinations, concrete mortar, and others, is very widely utilized and is ably discussed by Ewing (5), Larson (6), and Evans (1). An exhaustive series of pipe-coating tests has been conducted by the American Petroleum Institute for a period of 10 years, and the final report by Logan (7) has recently been published.

(*c*) The mechanical elimination of certain corroding constituents, i.e., oxygen and, to a lesser degree, carbon dioxide, have a pronounced effect on the corrosion of metals exposed to water. In many instances, the removal of these gases has successfully solved water-corrosion problems.

It is a well-established fact that oxygen in solutions combines with the hydrogen liberated as iron passes into solution during corrosion, thereby permitting the reaction to continue until the oxygen is used up. Oxygen also combines with the freshly dissolved iron to form an entirely new compound, an oxide of iron, and, in this manner, accelerates a concentration-cell pit, once it has started. Free carbon dioxide causes a lowered alkalinity in solutions, which increases the tendency for iron to pass into solution. For certain installations, where it is practical to remove these gases, corrosion can often be completely arrested. Both mechanical and chemical methods and combinations have been successful. Hammerschmidt (8) corrects the corrosive action of an engine cooling-water system by deaerating the water by means of natural gas which is passed countercurrent to the water through a novel contacting tower, after which the gas is utilized as engine fuel.

A notable example of mechanical deaeration has been described by Powell and Burns (9). A pipe line, designed to carry 4,000,000 gal per day of Mississippi River water a distance of 9 miles, suffered a rapid loss of capacity due to oxygen corrosion. The economic solution of this corrosion problem was obtained by a combination of physical and chemical deaeration. Ninety-five per cent of the dissolved oxygen was removed by passing the water through a slat-packed vacuum tower, operated at an absolute pressure of 1.5 in. Hg. The residual 5 per cent oxygen was removed by the addition of sodium sulphite, which combines with oxygen to form sodium sulphate. This deaeration plant has operated successfully since 1935.

(*d*) The chemical treatment of aqueous solutions by the addition of protective-film-forming agents, or the addition of oxygen-scavenging chemicals.

This subject is very broad, since each method of treatment is in itself a topic for lengthy discussion. The various types of waters encountered are susceptible to only certain chemical treatments. A judicious selection of chemicals is necessary since certain compounds will inhibit corrosion, but accelerate scaling, etc. The inhibitors generally used are sodium dichromate, sodium silicate, sodium hexametaphosphate, other phosphate salts of sodium, soda ash, caustic soda, lime, and various organic combinations. An example of this method is the treatment of boiler feedwater and cooling water for condensing and cooling systems with chemical inhibitors.

(*e*) The application of a counter electromotive force to reverse the natural electrochemical action taking place during the process of corrosion. This method is termed cathodic protection and will be discussed in the remainder of this paper.

Cathodic Protection

Cathodic protection is known as the process by means of which an electromotive force is applied to a corroding metallic structure in a manner such as to nullify or reverse the electrochemical reactions which take place during the natural corrosion of the metal. This method consists of making the structural metal the electrode which receives current from the corroding solution in an electrochemical cell. The structural-metal electrode in this case is called the cathode in a protective system. The other electrode from which the current enters the solution is called the anode. The cathode and the anode are connected externally by a suitable metallic circuit. When the current is supplied by a generator or a battery in the external circuit, the arrangement is called one of impressed-voltage cathodic protection. If the current is supplied by the natural galvanic action of two dissimilar metals used for anode and cathode, the arrangement is called galvanic cathodic protection. In both cases, the protection of the cathode structure is at the expense of the anode metal which corrodes in proportion to the protective current produced.

Galvanic cathodic protection has been used in protecting pipe lines, as well as small structures. A few years ago, a group of engineers experimented with various anode materials. However, at present the scarcity of suitable metals prohibits the use of this type of cathodic protection, and consequently will not be discussed.

The use of cathodic protection of underground structures probably developed through the practice of bonding these structures to the return circuits of electric railways for the prevention of stray-current electrolysis. It was soon observed that, in addition to stopping the leaks, caused by stray currents, there was a lessening of natural corrosion in the vicinity of the bonds. This suggested the possibility of preventing corrosion by impressing a negative potential on the pipe.

The potential difference between metallic structures and the surrounding solution necessary for protection has been reported by several investigators (10, 11, 12, 13, 14), and has been found to vary from 0.8 to 1 v when measured with a copper-sulphate electrode.

The amount of current entering the surface of a bare-metal structure, or the current density necessary to produce a protective potential depends upon the nature of the solution in contact with the metal. Laboratory investigators (15, 16, 12) have indicated that the required current density varies from 1.2 to over 30 ma per sq ft for various solutions. For well-coated lines or structures, the current density will be very small, since it is only necessary to protect the "holidays" or small uncoated areas.

The question of the possible damage done by a cathodic-protection installation to an adjacent nonprotected metallic structure and the proper method of preventing any damage have never been agreed upon. However, at the present time, the A.P.I. is conducting a research on this problem. Since most of the pipe-line companies are participating in the investigation, a satisfactory solution is likely to be obtained.

Results Obtained With Cathodic Protection

Hough (17) reviewed the results obtained by ten pipe-line companies at a meeting of the American Gas Association in Houston, in 1940. Nealy (18) and Miller (19) presented papers at the 1941 mid-year meeting of the A.P.I. on the application of cathodic protection to refinery equipment. These papers could be summarized as follows: That positive beneficial results were obtained; that there was no serious difficulty in maintaining cathodic protection; that the cost of applying cathodic protection is less than reconditioning and/or repairing the equipment; and that there is yet much to be learned about the proper application to secure the necessary protection with a minimum investment and power consumption.

Equipment

The essential equipment for constructing a cathodic-protection installation, as mentioned, are the anode (or ground bed), a source

of direct current, and the necessary electrical connections between the ground bed, source of direct current, and the cathode or the structure being protected. The selection of proper material is a problem similar to that of other engineering projects. There is an economic medium between the first cost and operating cost which should govern the selection of the equipment. Some very helpful information on the equipment available has been published by Ewing (5) and others (20).

Fig. 1 illustrates a typical cathodic-protection installation.

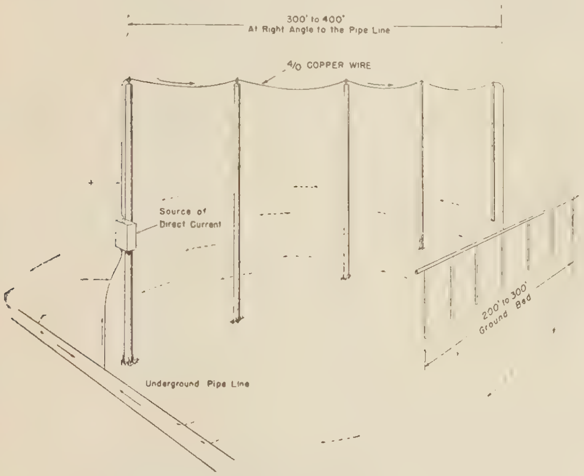

Fig. 1 Typical Cathodic-Protection Installation

Since the direct-current voltage is generally low (less than 15 v), it is obvious that large conductors must be used. Conductor lines of copper are generally used; however, in some instances, old steel cables have been utilized.

The anode (or ground bed) should preferably have low resistance, sufficient volume to last several years, and current spread.

To secure low resistance, it is necessary to locate the ground bed in a low-resistance soil, and also to provide a sufficiently large area of exposed anode surface. At times it is also necessary to add salt and sometimes water to the ground-bed soil to lower the resistance. The life of the bed can be estimated from the weight of metal installed, its electrochemical equivalent, the amount of current flowing, and an assumed efficiency. The efficiency of ground beds under different arrangements has been reported by Rogers (21) and McAnneny (22). For the best distribution of current over the entire structure, it is advisable to have ground beds distributed at several points along or around the structure, since it takes a definite amount of current to protect a unit area; if the current is concentrated more than is necessary, the excess is wasted. An exception would be in the case of a well-coated line or structure where it would probably be more economical to install a small number of large units, as the resistance offered by the protective coating prevents high current densities in the vicinity of the ground bed. The high metal-to-ground potential does not indicate a waste of power. It should be further stated that conditions, such as cheap power, size of the structure, and the like, might make it more economical to install large units even on bare structures.

The most commonly used material for ground beds is junk pipe, old castings, scrap iron or steel, and carbon or graphite rods. Some experimental chemical ground beds have been reported by McAnneny (22). While chemical ground beds have not been used to date, the present scarcity of junk pipe and other suitable materials will encourage their development.

The majority of ground-bed installations consist of junk pipe because it is reasonably cheap, easy to install, and provides a better current distribution per pound of metal than other forms of scrap iron. This pipe is installed either vertically or horizontally, depending upon such conditions as the space available, type of soil, and depth of low-resistance soil. The location of the ground bed will be influenced by the size and surface condition of the structure being protected.

The requirements of an apparatus for producing a suitable direct current are (*a*) reliability, so as to require little attention; (*b*) ability to produce large direct currents at low voltages; and (*c*) economy of operation. Four methods of producing direct current are in general use, i.e., the alternating-current rectifier, the motor generator, the gas-engine-driven generator, and wind-driven generator.

The alternating-current rectifier is the most widely used method for providing a source of direct current where the output is less than 3000 w. The advantages of the rectifier are simplicity of installation; low maintenance, since there are no moving parts (except the cooling fan in some models); over-all efficiency of between 55 and 65 per cent, depending upon the size and the source of alternating-current power available; and initial cost, which is comparable with the motor generator set.

Motor generator sets may be used if a source of alternating-current power is available as with the rectifier, and are generally used where the output is above 3000 w. The over-all efficiency is approximately 65 per cent. The current of a motor generator is constant and may be varied to any desired output. This set must have some attention because of the moving parts and is, therefore, more suited for tank-farm and station-protection installations than for use on pipe lines and isolated areas.

Gas-engine-driven generator sets of various sizes are being manufactured. Such units produce a constant source of direct current, but because of the inherent nature of the gas engine, they require frequent servicing and repair.

The windmill or wind-driven generator, while picturesque, is not a very dependable source of direct current, since the output of the generator depends upon power derived from the wind; thus, during a calm period, no current is generated. These units are available in sizes from 20 to 2000 w, and their principal use is in isolated locations where there is sufficient wind for their operation.

The majority of installations for pipe lines, tank farms, and station equipment utilize rectifiers, with the motor generator and gas-engine generator as second and third choice, respectively. The wind-driven generator is seldom used except in isolated places. In some cases, two wind-driven generator units are installed; one to protect the pipe line, and the other to charge a battery which will discharge to the electrolysis system during periods of no wind.

Ewing (5) and others (21) have presented analytical methods of determining the number of units and the size most suitable for protecting pipe lines and similar structures, by taking into consideration the condition of the coating and the soil resistivity, which is known or determined experimentally.

Another method for determining the current and number of units required for protecting well-coated lines has been to install a temporary unit for experimental purposes. The installation consists of a ground bed of four or five 4-in. carbon rods or four 10-ft pieces of 4-in. or 6-in. pipe in a shallow well-salted trench about 100 ft from the pipe line. For a source of power, either six or eight regular storage batteries are used. The pipe line, batteries, and ground bed are connected with No. 2 insulated copper wire. By the proper arrangement of the batteries in series and parallel, it is possible to obtain a suitable unit output.

After this equipment has been installed and adjusted, pipe-to-ground potentials are taken in each direction to determine how much pipe is being protected. At each end of the section where

the pipe-to-ground potential is 0.8 v (referred to a copper-sulphate electrode), the current flowing is determined. The sum of these readings deducted from the total drained from the line will indicate the amount of current required to protect that particular section. By measuring the length of line protected, the current per mile necessary for protection can be determined. From these data, the size and location of the units can be made.

The procedure for determining the current required for protecting poorly coated or bare lines is the same as that just outlined, except a larger ground bed is usually installed, and a welding-machine or similar direct-current generator is required in place of the storage batteries.

Cathodic-Protection Methods Employed by Author's Company

The natural-gas department of the author's company has applied cathodic protection on approximately 120 miles of 10-in. line, and on another 60 miles of line, ranging in size from 3 to 8 in. Some of these lines pass through developed suburban territory, and at places they cross and are parallel to other pipe lines, oil-field, and refinery equipment.

Cathodic protection was installed as a preventive measure, there having been no leaks to date. The oldest section of line was laid about 10 years ago and was provided with a protective coating of a cold asphalt application without a wrapper. The other lines are all 5 years old or less and were protected from external corrosion by the application of a primer, two coats of petroleum asphalt enamel, and an asbestos-felt wrapper. The exception to this procedure was river or swamp crossings, at which areas an additional coat of enamel and Osnaburg was also applied.

For cathodic protection on these lines, it was found most practical to locate the units at points within ready access to electric power and most suitable for ground beds.

The lines mentioned are protected with eight units, four of which supply some protection to the Humble Pipe Line Company. The lines of the Humble Pipe Line Company are new and have coatings equal to the natural gas department lines.

It has been assumed that the metal is protected when the pipe line is 0.8 v negative to the soil, the pipe-to-ground potentials being determined by means of a potentiometer and a copper-sulphate electrode. Some coupons were attached to the pipe and, to date, no pitting has been observed.

The following procedure has been adopted for routine tests. When the first cathodic-protection unit was installed, a few complete pipe-to-ground surveys of the protected area were made and were found to have the same trend each time. Then the practice of making a complete survey was dropped, and only a few readings are made at the present time at permanent test locations.

After a new unit is installed a pipe-to-ground-potential survey is made to determine the limits of protection from the unit or the point of lowest potential between the unit and adjacent units.

Permanent test stations are then made at convenient points. These are located at or near the end of the section protected and near the rectifier unit. At each of these locations, a permanent weatherproof insulated copper wire is soldered onto the pipe, after which the other end is made fast to a fencepost or the concrete pipe-line marker at the side of the road. Potential readings are made between this wire and a copper-sulphate electrode which is placed over the pipe line and 1 ft away from the lead-wire connection. Potentials are determined with a Rhodes potentiometer.

Routine checks over the whole system are made each month by measuring the pipe-to-ground potentials at the permanent test station, and by checking the rectified voltage and current. Field data are recorded in a civil-engineer's notebook as it is taken, after which the original sheets are removed and made into a permanent file. From these data, the system potential map and also the unit data sheets are kept up to date. The potential map is a map of the entire system which is provided with blank spaces near each test station and a unit for recording the measured potentials and unit output. The unit data sheets contain information on unit output in volts and the current drained from each line; the ground-bed resistance; the power bill for the month, and remarks. This potential map and the unit data sheets afford a quick check of the entire system with reference to potentials and condition of equipment. The system can be checked by one operator in less than 3 days.

Cathodic Protection of an Oil-Storage-Tank Farm

The Humble Pipe Line Company has applied cathodic protection on a large oil-storage-tank farm and pump station in the Gulf Coast area, where the soil is fairly corrosive.

This farm consists of 62 storage tanks, 115 ft diam, with the auxiliary connecting lines, pumps, and station equipment. About 28 miles of buried pipe are involved in sizes varying from 2-in. to 16-in., the majority being 8-, 10-, and 12-in-diam pipe. In addition, various large-diameter incoming and outgoing lines are involved. Some of the lines have been coated and others are bare.

A number of tank bottoms have required replacement due to a combination of internal and external corrosion. Pit-hole leaks caused by external corrosion were also occurring on the oil lines at such a rate that maintenance required the expenditure of several thousand dollars a year. A cathodic-protection system was, therefore, installed and placed in operation in May, 1941.

The equipment consisted of a total of nine copper-oxide recti-

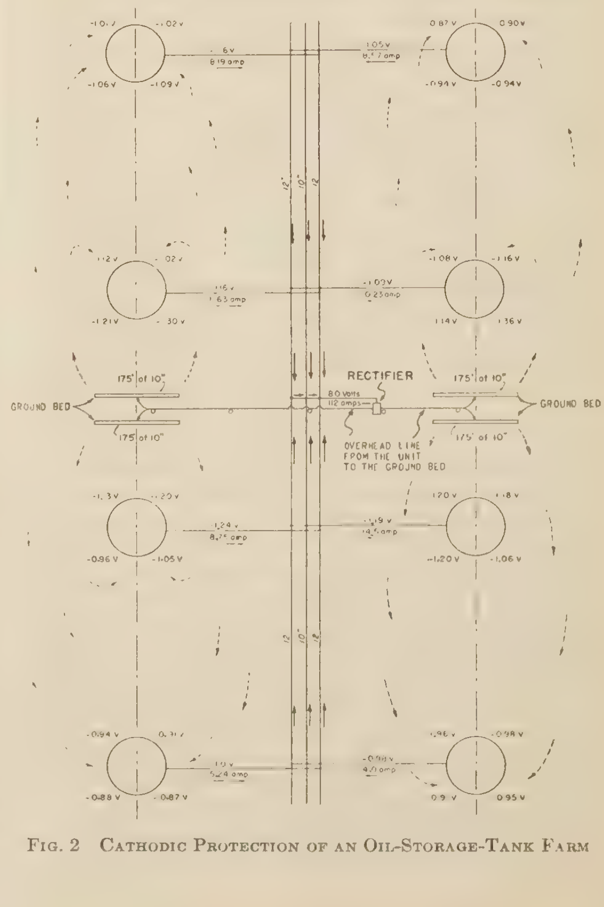

Fig. 2 Cathodic Protection of an Oil-Storage-Tank Farm

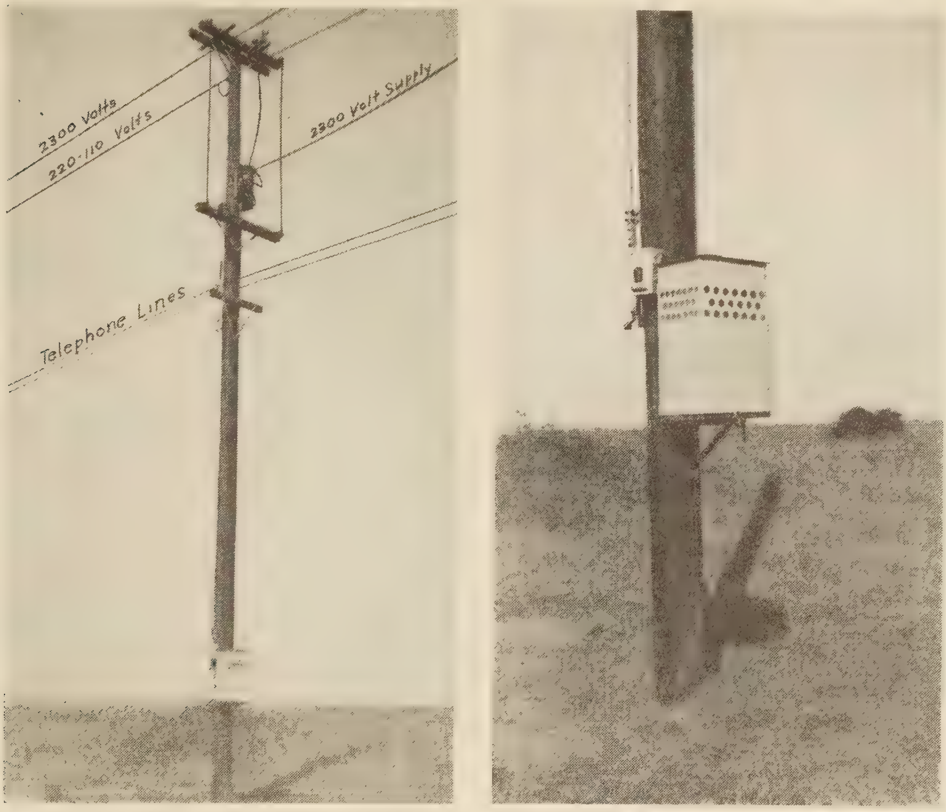

FIG. 3 CATHODIC-PROTECTION INSTALLATION USING SMALL CLOSELY SPACED UNITS WITH POWER AND TELEPHONE LINES ON SAME POLES

fiers with the necessary ground beds, alternating-current power lines and transformers, and direct-current drainage and feeder lines. Seven rectifiers were 10-v, 120-a units, manufactured by Westinghouse, and two units were $10^1/_2$ v, 130 a, manufactured by General Electric.

The arrangement of the rectifiers and ground beds for one of the units with respect to the tanks and lines is illustrated in Fig. 2; this unit is typical for the combined system. It was possible in most cases to achieve a symmetrical arrangement of the rectifiers and ground beds so that one unit was centrally located with respect to eight tanks and the pipe lines serving them.

The ground-bed arrangement, shown in Fig. 2, has been particularly effective and consists of approximately 20,000 lb of junk pipe of 8, 10, and 12 in. diam, which is expected to serve for about 10 years. The ground-bed pipe is buried horizontally about 5 ft deep. Four sections of pipe are used in each dual ground bed which is arranged as shown with parallel sections 20 ft apart. A 6-in. riser pipe is welded into the middle of each section to which are connected the positive terminals of the unit. The risers extend above the ground and are left open so that water can be poured in if necessary to lower the resistance. This represents an external resistance of $^1/_{18}$ ohm, and in no case was the resistance greater than $^1/_{10}$ ohm for a ground bed of this type. Additional metal is now being added to three less efficiently arranged ground beds to improve their configuration.

Results achieved in eliminating or reducing corrosion cannot be accurately estimated at present because of the short period of time the system has been in operation. A survey is being made, however, which will indicate the metal-to-earth potential of the various structures, and of the amount of current being collected by the various portions of the tank and pipe-line system which will theoretically indicate the degree of protection.

The metal-to-earth potential values are shown in Fig. 2 for four points around each of the tanks, as well as the potentials of the pipe lines leading to the tanks, and the current being drained from each tank. The lowest potential value was found to be 0.87 v which indicates that all structures in this portion of the tank farm are receiving adequate protection. It may be noted that both potential and current drainage are somewhat affected by proximity of the structures to the ground beds. In the case of one tank, satisfactory potentials are obtained with a drainage of 4 a. The drainage from another tank is $14^1/_2$ a, but the negative potentials of the metal to earth are unnecessarily high. This suggests that a more even distribution of potential at a lower power consumption might have been obtained with a yet wider distribution of the ground-bed anodes, or by a system of negative connections which would permit the introduction of resistances into the drainage connections to structures close to the ground beds. In this case, however, it is doubtful whether the saving in power from such changes would justify the cost of making them.

The best measure of the effectiveness of such a system of protection is the stoppage of failures due to corrosion. While the time the system has been in operation is too short for positive conclusions to be drawn, there has been an apparent reduction in the number of failures. From the beginning of 1938, through the third quarter of 1941, leaks occurred on the lines at this station at the average rate of six a month. During the last quarter of 1941, only three leaks occurred, or an average of one a month. A much longer time will naturally be required to observe any change in rate of failure of the tank bottoms.

It is believed that this system of protection, which cost the company about $13,000 to install, and which involves a yearly expenditure of about $3000 for power, maintenance, and depreciation, will prove to be much more economical than the previous maintenance methods, consisting of repairs and renewals.

Cathodic Protection on Large Bare or Poorly Coated Lines

A very practical and unique method of applying cathodic protection by one large pipe-line company in the Gulf Coast area on large and poorly coated lines is worthy of mention.

The telephone-line poles, which are located alongside the pipe line, were changed by replacing every third pole with a power pole on which was strung a 2300-v primary line and a 110-v secondary line. The pipe line is utilized as a common return for both primary and secondary circuits. The small rectifiers are located on these power poles and utilize the 110-v circuit. About ten rectifiers and ground beds are used per mile of pipe. By a judicious selection of material, it was possible to make a very flexible and economical installation.

The economy of the purchased power for such an installation is well illustrated by the following readings which were taken on a section of a coated line, part of which was protected with the small units just described, and part protected with a large unit. The large unit protected 2.6 miles of line with a direct-current output of 20 v and 40 a, or 800 w. On an equal and adjacent length of line, 26 small units had an average direct-current output of 30 v and 2.7 a, or 210 w. Views of this installation are shown in Fig. 3.

Conclusion

It is concluded that cathodic protection will prove the most economical means of preventing external corrosion for pipe lines and similar structures, and we are using it in addition to external protective coatings. At present, the author's company has protection on several hundred miles of pipe lines, part of which are in salt-water marshes and bays, as well as on oil-storage-tank farms. In closing, it should be restated that a great deal is yet to be learned about the proper application of this form of protection.

Acknowledgment

The writer wishes to thank the Humble Oil & Refining Company, for permission to publish the data contained in this paper, and Mr. E. O. Staffel and Mr. R. A. Brannon for their help in preparing it.

Discussion

R. W. Warner.[3] Corrosion is a relentless enemy and one that knows no quarter. It is possible that fundamentally all metals are subject to this process of reverting back to their original state unless prevented by some natural or man-applied means. Our most useful metal, iron, is particularly subject to the ravages of corrosion especially when combined with other metals or compounds for the purpose of improving its commercial characteristics.

The author has presented an exceedingly interesting paper on some of the methods used by his company in combating corrosion of pipe lines and storage tanks. General acceptance of the electrolytic theory of corrosion at once suggested the feasibility of an electrolytic preventative. As he points out this is relatively simple in theory but more difficult in application because of the tremendous variety of conditions in the field.

Electrolytic corrosion is accompanied by the flow of electrical current in response to natural potentials which become established between a metal and a surrounding electrolyte which may be soil, a salt-brine solution, plain water, or any other medium capable of conducting electric current. The arrangement becomes a natural electrolytic cell. An ordinary dry battery is a common example of such a cell in commercial form.

The amount of voltage developed in such a natural battery is not large, in fact usually well under one volt. It depends upon a wide variety of conditions, such as the kind of metal present, the purity of the metal, the presence of unrelieved strains in the metal, the temperature gradient between parts of the metal, and upon the electrolyte itself. In the case of pipe lines buried in the earth this voltage also depends upon the chemical characteristics of the soil. Even though only a small voltage is developed, the natural battery thus formed is short-circuited through the body of the metal itself so that an electric current flows constantly. The amount of this current also is small but the cumulative action over a period of months or years is enormous.

[3] Professor of Electrical Engineering, The University of Texas, Austin, Texas.

Decomposition occurs only at points where the current leaves the metal. Wherever it enters no harm is done. The metal or electrode from which current flows into an electrolyte is known as the anode while that by means of which the same current leaves the electrolyte is called the cathode. Corrosion does not take place at the cathode. In order, then, to prevent corrosion which takes place as a result of the natural potentials mentioned it is necessary only to prevent the flow of the electric current, or to be on the safe side, to force it to flow in the opposite direction. The metal it is desired to protect is thus forced to become a cathode. Some other piece of metal, the corrosion of which will be harmless, is placed in the electric circuit as the anode. All the corrosion is centered at the anode. This, in the case of a pipe line or storage tank to be protected, is the ground bed. The best method of application and the amount of protective current required depend entirely upon the local conditions; and the author has given the upper and lower limits of the current needed.

It has been observed in many cases that a film or coating is deposited on metals that are being protected as cathodes. This film of itself possesses a certain protective value against corrosion just as do paint, asphalt, and other coatings. Its composition depends upon the electrolyte and the material of the anode. With metals in a salt-brine solution a chunk of zinc may effectively be used as the anode. A protective film consisting of a complex compound of zinc, oxygen, and chlorine is formed on the surface of the cathode. Its presence is a visual indication that the protective scheme is functioning. The film is soluble but will furnish complete protection for some time after the protective current is removed. To form such a film on steel, a current density of approximately 5 ma per sq ft of surface to be protected is necessary. This value falls well within the limits of current density given by the author for the protection of pipe lines and storage tanks.

When cathodic protection is applied to metals buried in the earth a similar coating is formed on the metal. It consists of compounds taken from the soil and deposited electrolytically upon the metal; without doubt it possesses protective characteristics. It would be interesting to know how long this coating would furnish protection if the current were to be removed. This might materially affect the cost of protection.

It is believed that the nonrusting characteristic of stainless steel is due to the presence of a natural protective film perhaps only one molecule in thickness. It is possible that an exhaustive study of protective films in general would furnish valuable information about corrosion.

Pipe lines buried in the earth frequently lie in the path of natural stray earth currents. Not a great deal is known about these wandering currents—as to what causes them, where they originate, or where they end—other than that they circulate constantly through the surface of the earth in widely varying amounts, sometimes in one direction and then reversing and flowing in the opposite direction. They undoubtedly follow pipe lines and contribute to their decomposition. A study of these natural currents would no doubt yield valuable and interesting information.

The author mentions the economic phase of cathodic protection and while the economics are certainly in favor of protection it would be extremely interesting to know more about the amount of annual savings that can be expected. This would form excellent material for a subsequent paper. Also, it would be interesting to know about the effectiveness of this method of protection, after a period of perhaps ten years of operation.

Indexes to A.S.M.E. Papers and Publications

THIS and the following pages will serve as a guide to the current publications of the A.S.M.E. during the calendar year 1942 and also to publications developed by technical committees.

Regular Society Publications, 1942

Mechanical Engineering, monthly (see index on page RI-85)
A.S.M.E. Transactions, monthly (see index on page RI-95)

How to Find Papers Presented at 1942 A.S.M.E. Meetings

THE technical programs of the meetings of the Society and of its Professional Divisions have been published in *Mechanical Engineering* and may be located by consulting the index on pages RI-85–94. A majority of these papers were published, or will be published, in *Mechanical Engineering* or the Transactions (including the *Journal of Applied Mechanics*) and may be located by reference to the indexes of these publications. Several additional papers and reports included in these 1942 programs were not published during the year in Transactions or *Mechanical Engineering* but were issued in mimeographed or photo-offset form.

Complete sets of these are on file for reference purposes at the office of the Society and the Engineering Societies Library, under the title of "Miscellaneous Papers Presented at A.S.M.E. Meetings, 1942." Photostat copies of any of the papers may be secured from the Library at twenty-five cents a page to members, or thirty cents a page to nonmembers.

Publications Developed by the Technical Committees

THE Society's technical committees, the first of which was organized many years ago and all of which have been continuously at work on codes, standards, research, and other special reports, have developed a series of publications of permanent value to the membership. The following list is presented here for record and for ready reference. This list covers the entire group of publications of these committees completed to date which are now available.

To assist the members in securing copies of these publications the sale price is also given. A discount of 10 per cent is allowed to A.S.M.E. members on standards and a 20 per cent discount on all other publications except where otherwise noted.

A.S.M.E. AMERICAN STANDARDS

Bolt, Nut, and Rivet Proportions

Large Rivets (B18.4—1937), $0.65
Plow Bolts (B18f—1928), $0.35
Round Unslotted-Head Bolts (B18.5—1939), $0.50
Slotted-Head Proportions: Machine Screws, Cap Screws, and Wood Screws (B18c—1930), $0.45
Small Rivets (B18a—1927), $0.30
Socket Set Screws and Socket-Head Cap Screws (B18.3—1936), $0.40

Code for Design of Transmission Shafting (B17c—1927), $0.75
Shafting and Stock Keys (B17.1—1934), $0.45
Screw Threads for Bolts, Nuts, Machine Screws, and Threaded Parts (B1.1—1935), $0.60
Screw Thread Gages and Gaging (B1.2—1941), $0.60
Acme and Other Translating Threads (B1.3—1941), $0.45
Tolerances, Allowances, and Gages for Metal Fits (B4a—1925), $0.50
Woodruff Keys, Keyslots, and Cutters (B17f—1930), $0.35

BOILER CONSTRUCTION CODE

1942 Addenda to:
Locomotive Boiler Code, $0.50
Low-Pressure Heating Boilers, $0.50
Miniature Boiler Code, $0.15
Power Boiler Code, $0.45
Unfired Pressure Vessel Code, $0.50
Specifications for Materials, $0.85
Boiler Code Interpretation Service, $5.00 annually
API-ASME Code for Unfired Pressure Vessels
1942 Addenda, $0.40

POWER TEST CODES AND AUXILIARY SECTIONS

Test Codes for

Atmospheric Water-Cooling Equipment (1930), $0.45
Compressors and Exhausters (1935), $0.95
Displacement Compressors, Vacuum Pumps, and Blowers (1939), $0.75
Dust Separating Apparatus (1941), $0.90
Evaporating Apparatus (1941), $0.50
Feedwater Heaters (1927), $0.35
Gas Producers (1928), $0.55
Hydraulic Prime Movers (1938 with 1942 Addenda), $0.60
Internal-Combustion Engines (1930), $0.55
Liquid Fuels (1930), $0.35
Reciprocating Steam Engines (1935), $0.65
Reciprocating Steam-Driven Displacement Pumps (1927), $0.65
Refrigerating Systems (1927), $0.55
Solid Fuels (1931), $0.55
Speed-Responsive Governors (1927), $0.45
Stationary Steam-Generating Units (1936), $0.60
Steam Condensing Apparatus (1938), $0.65
Steam Locomotives (1941), $0.55
Steam Turbines (1941), $2.50

Auxiliary Sections

General Instructions (1929), $0.35
Definitions and Values (1931), $0.40
Part 1—General Considerations (1935), $0.35.
Part 2—Pressure Measurement
Chapter 1, Barometers; Chapter 6, Tables, Multipliers, and Standards (1941), $0.60
Chapter 2, Static and Total Pressure, Static Holes and Tubes, and Chapter 3, Pipes for Pressure Measurement (1936), $0.65
Chapter 4, Bourdon, Bellows, Diaphragm, and Deadweight Gages (1938), $0.65
Chapter 5, Liquid Column Gages (1942), $0.75
Part 3—Temperature Measurement
Chapter 1, General; Chapter 5, Pyrometric Cones; Chapter 6, Liquid-in-Glass Thermometers; and Chapter 7, Bourdon Tube Thermometers (1931), $0.75
Chapter 2, Radiation Pyrometers (1936), $0.55
Chapter 3, Thermocouple Thermometers or Pyrometers (1940), $0.65
Chapter 8, Optical Pyrometers (1940), $0.35
Part 4—Head Measuring Apparatus (1933), $0.35
Part 5, Chapter 4—Flow Measurement by Means of Standardized Nozzles and Orifice Plates (1940), $2.75
Part 6—Electrical Measurements (1934), $1.25
Part 8—Measurement of Indicated Horsepower (1941), $0.75
Part 9—Heat of Combustion (1932), $0.40
Part 10—Flue and Exhaust Gas Analyses (1936), $1.35
Part 11—Determination of Quality of Steam (1931), $0.45
Part 12—Measurement of Time (1942), $0.40
Part 13—Speed Measurements (1939), $0.45
Part 14—Linear Measurements (1936), $0.55
Part 15—Measurement of Surface Areas (1937), $0.75
Part 16—Density Determinations (1931), $0.30
Part 17—Determination of the Viscosity of Liquids (1931), $0.45
Part 18—Humidity Determinations (1932), $0.50
Part 20—Smoke-Density Determinations (1936), $0.65
Part 21—Leakage Measurements (1942), $0.60

RESEARCH

Fluid Meters:
Part 1—Theory and Application (1937), $3.00
Part 2—Description of Meters (1931), $1.75
Part 3—Selection and Installation (1933), $1.50
Report of the A.G.A.-A.S.M.E. Committee on Orifice Coefficients (1935), $2.75
Tests on Electrical Equipment for Drilling Rotary Drilled Oil Wells (1933), $0.85
Tests on Steam Equipment for Drilling Rotary Drilled Oil Wells (1932), $0.85
Bibliography on Cutting of Metals (1866–1930), $1.25
Bibliography on Deterioration of Condensing Equipment (1845–1930), $1.25
Bibliography on Effect of Temperature Upon Properties of Metals (1928–1931), $1.25
Bibliography on Management Literature and Supplement (1903–1935), $2.75
Bibliography on Mechanical Springs (1678–1927), $1.25
Bibliography on Woods of the World (1928), $1.25
Bibliography on Marketing Research (1935), $1.00
Bibliography on Machining of Wood (1939), $1.25

SAFETY CODES

Safety Code for Elevators (A17.1—1937 with 1942 Supplement) (10 per cent discount), $1.00
Elevator Inspectors' Manual (A17.2—1937) (10 per cent discount), $0.75

Safety Code for Mechanical Power-Transmission Apparatus (10 per cent discount) (B15—1927), $0.35
Compressed-Air Machinery and Equipment (B19—1938), $0.30

BIOGRAPHIES

BIOGRAPHIES issued under the sponsorship of the A.S.M.E. Biography Committee are as follows:

Autobiography of John A. Brashear (1924), $5.00
Autobiography of an Engineer, by W. LeR. Emmet (1940), $3.50
Autobiography of John Fritz (1940), $3.25
Biography of James Hartness, by Joseph W. Roe (1937), $4.00
Biography of Fred J. Miller (1941), $1.00
Biography of John Stevens, by Archibald Douglas Turnbull (1928), $5.00
Biography of John Edson Sweet, by A. W. Smith (1925), $4.50
Biography of Robert Henry Thurston, by William F. Durand (1929), $5.00
Life of Henry Laurence Gantt, by L. P. Alford (1934), $5.00

BOOKS ON SPECIAL SUBJECTS

Aeronautical Dictionary (1929), $1.65
Corrosion-Resistant Metals (1936), $1.25
Engineering's Part in the Development of Civilization (1939), $1.50
Flow of Water in Pipes and Pipe Fittings (1941), $8.00
General Discussion on Lubrication (1938) (no discount), $6.50
Hydraulic Laboratory Practice (1929), $10.00
Hydraulic Structures (1937), $18.00
I.S.A. Tolerance System (1942), $2.50
Manual on Cutting of Metals (1939), $5.00
1943 A.S.M.E. Mechanical Catalog and Directory, $3.00 (set gratis to members upon request)
1941 Oil Engine Power Cost Report (1942), $1.25
Sixty Year Index to A.S.M.E. Technical Papers (1941), $3.75
Surface Finish (1942) (no discount), $3.25
Theoretical Steam Rate Tables (1937), $1.25

PERIODICALS

*Mechanical Engineering**—Annual Subscription rate in United States $6; to Canada $6.75; elsewhere, $7.50
A.S.M.E. Transactions,* including *Journal of Applied Mechanics*, Annual subscription rate in United States, $12, elsewhere, $12.75

* Subscription price included in A.S.M.E. membership dues.

Index to Mechanical Engineering

Volume 64, January—December, 1942

(A) denotes Abstract; (BR)Book Review; (C) Correspondence; (D) Discussion; (Ed) Editorial; (P) Photograph

Issue	Page Numbers
January	1–92
February	93–170
March	171–254
April	255–332
May	333–430
June	431–512
July	513–578
August	579–642
September	643–692
October	693–766
November	767–842

Index to A.S.M.E. Transactions

Volume 64, 1942

The A.S.M.E. Transactions for 1942 was issued monthly. Four of the twelve issues are the *Journal of Applied Mechanics*, the page numbers of which are preceded by the letter A.

The Society Records for the year 1942 appeared as supplements, one in February, 1942, the Memorial Biographies in October, 1942, and the index section in January, 1943. The page numbers for these supplements are designated by the symbol RI, and the February supplement contains its own index.

(BR) denotes book review; (D) discussion of a paper.

Issue	Page Numbers
January	1– 64
February	65–160
April	161–256
May	257–392
July	393–528
August	529–624
October	625–720
November	721–816
Journal of Applied Mechanics	
March	A- 54
June	A- 55–A-102
September	A-103–A-150
December	A-151–A-198
